Title: Dental stem cells of the apical papilla increase TRPA1 responses in trigeminal neurons

Authors: *M. ESKANDER, N. RUPAREL, A. DIOGENES
Endodontics, UTHSCSA, San Antonio, TX

Abstract: Regenerative endodontic procedures are biologically based procedures designed to restore normal physiologic function in the pulp-dentin complex by the delivery of mesenchymal stem cells (MSCs). Stem cells of the apical papilla (SCAP) are recognized as a prominent population of MSCs in these procedures. Many regenerative endodontic patients regain sensitivity to cold stimulation as early as one year post-procedure, even with a coronal restoration in place. However, the mechanisms mediating neuronal sprouting and transduction of physiologic stimuli (eg. cold sensation) after regenerative endodontic procedures is not fully understood. We have hypothesized that SCAP modulate nociceptive function through a paracrine mechanism that involves the release of soluble trophic factors and upregulation of TRPA1 function. To test this hypothesis, we established a co-culture system with a previously characterized human SCAP cell-line and rat primary trigeminal sensory neurons in a dual-chamber culture environment. Nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and glial cell-derived neurotrophic factor (GDNF) gene expression levels and release from SCAP co-cultured with TG neurons was measured by qRT-PCR and specific ELISA assays, respectively. In addition, the effect of SCAP co-culture on TRPA1 activity was evaluated using whole cell patch-clamp electrophysiology. SCAP co-cultured with TG neurons displayed significant upregulation of BDNF ($p<0.001$) and GDNF ($p<0.001$) mRNA. In addition, the release of BDNF was significantly higher than GDNF or NGF release ($p<0.001$). Finally, TG neurons co-cultured with SCAP demonstrated increased TRPA1 mediated (mustard oil-evoked) inward currents at 24 hours ($p<0.001$) and 48 ($p<0.05$) hours in co-culture compared to inward currents in neurons cultured alone. Collectively, these data suggest that SCAP responded to the nearby presence of neurons by the release of supportive trophic factors that in turn increased TRPA1-mediated responses. Importantly, this novel dental stem cell-neuronal interaction may underlie the mechanism of cold detection in the regenerated dental pulp.

Title: Involvement of pro-survival pathways and epigenetic mechanisms in extremely low-frequency electromagnetic field induced enhancement of adult hippocampal neurogenesis

Authors: *L. LEONE[1], S. FUSCO[1], M. V. PODDA[1], S. A. BARBATI[1], A. MASTRODONATO[1], D. D. LI PUMA[1], R. PIACENTINI[1], S. ZAFFINA[2], C. GRASSI[1]

Abstract: In recent years, much effort has been focused to identifying strategies able to stimulate adult neurogenesis, a process that generates new neurons throughout life and that appears to be dysfunctional in the senescent brain and neurodegenerative diseases. We previously reported that *in vivo* exposure to extremely low-frequency electromagnetic fields (ELFEFs) promotes the proliferation and neuronal differentiation of hippocampal neural stem cells (NSCs) that functionally integrate in the dentate gyrus (DG). Here, we demonstrated that *in vivo* ELFEF stimulation also promotes the survival of neurons generated from NSCs residing in the hippocampal neurogenic niche. This effect is associated with down-regulation of the pro-apoptotic protein Bax and increased expression of the anti-apoptotic protein Bcl-2. As a result of increased survival of granule cells in the hippocampal DG, the ELFEF- exposed mice showed improved spatial learning and memory. To gain insights on the molecular mechanisms underlying ELFEFs' effects on the process of adult neurogenesis, we extended our studies to an *in vitro* model of NSCs isolated from the hippocampi of newborn mice. We found that ELFEFs enhanced proliferation and neuronal differentiation of hippocampal NSCs by regulation of epigenetic mechanisms leading to pro-neuronal gene expression. Upon ELFEF stimulation of NSCs, we observed a significant enhancement of expression of the pro-proliferative gene hairy enhancer of split 1 and the neuronal determination genes NeuroD1 and Neurogenin1. These events were preceded by increased acetylation of H3K9 and binding of the phosphorylated transcription factor cAMP response element-binding protein (CREB) on the regulatory sequence of these genes. Collectively, our results further underscore the potential for the use of ELFEFs in

ameliorating the neurogenesis alterations associated with normal aging or neuropsychiatric and neurodegenerative diseases. Moreover, our study identifies a novel molecular mechanism responsible for ELFEF-induced enhancement of hippocampal neurogenesis, that could be targeted in future stem cell-based therapeutic approaches.

Catolica de Chile, Santiago, Chile

Abstract: Wnts are secreted glycoproteins that have distinct roles during early development, and also they are key regulators of late embryonic and postnatal development of the central nervous system. In the adult brain, the Wnt signaling pathway regulates neurogenesis in the subgranular zone (SGZ) of the hippocampal dentate gyrus. In this region, Wnt ligands have shown to regulate both, proliferation and differentiation of neural progenitor cells. Here, we investigated the role of Wnt receptors Frizzled (FZD) in adult neurogenesis. In mammals, 10 FZD receptors have been identified and these may activate different signaling cascades in response to a specific Wnt

ligand. The presence of FZD receptors in the SGZ was studied by immunofluorescence staining in brain sections of 2-month-old wild-type mice and also in cultured adult hippocampal progenitors (AHPs) isolated from adult mouse brain. In the hippocampus, neural progenitor cells and newborn immature neurons were identified by immunodetection of protein markers. We determined that FZD3 is present in neural progenitor cells in the SGZ, and it was also observed in cultured AHPs. On the other hand, FZD1 was observed in progenitor cells but was mainly detected in immature neurons in the dentate gyrus, suggesting that the expression of this receptor is increased during differentiation. In AHPs, overexpression of FZD1 induced a decrease in the levels of the progenitor cell markers Nestin and SOX2, suggesting that differentiation was induced. Finally, retroviral shRNA-mediated knock-down of FZD1 in the dentate gyrus decreased neuronal differentiation of progenitor cells. Our findings suggest that there is a temporal expression of FZD receptors during adult hippocampal neurogenesis, and these receptors could mediate specific Wnt effects during the development of newborn neurons. Also, our results indicate that FZD1 regulates the differentiation of neural progenitors cells in the adult hippocampus.

Title: Neuroprotection with antioxidant anthocyanins against ethanol-induced oxidative stress and neurodegeneration via PI3K/Akt/GSK3β pathway

Authors: *G. YOON, S. SHAH, M. KIM
Life Sci., Gyeongsang Natl. Univ., Jinju, Korea, Republic of

Abstract: Oxidative stress has been implicated in the pathophysiology of several neurodegenerative disorders. Numerous studies have reported that ethanol exposure produces reactive oxygen species (ROS), one of the most noted molecular mechanisms of ethanol

neurotoxicity. We recently reported $GABA_{B1}$ receptor dependent protection of anthocyanins against ethanol-induced apoptosis in prenatal hippocampal neurons. Here, we sought to extend these findings by examining the effect of anthocyanins neuroprotection against ethanol in the hippocampus of postnatal day 7 rat brain. After four hours of ethanol alone and along with anthocyanins administration, the expression of glutamate receptors (AMPARs), intracellular signaling molecules, different synaptic, inflammatory and apoptotic markers were evaluated. The results indicate that anthocyanins significantly reversed ethanol-induced inhibition of glutamatergic neurotransmissions, synaptic dysfunction, $GABA_{B1}R$ activation and neuronal apoptosis by stimulating PI3K/Akt/GSK3β pathway in the hippocampus of postnatal age brain. Anthocyanins also inhibited ethanol activated phosphorylated c-Jun N terminal kinase p-JNK, phospho Nuclear Factor Kappa B (p-NF-kB), Cyclooxygenase 2 (COX 2) expressions, attenuated neurodegeneration and neuronal cell death in the hippocampal CA1 region of developing brain. Furthermore anthocyanins increased cell viability, attenuated ethanol-induced PI3K dependent ROS production, cytotoxicity and caspase-3/7 activation *in vitro*. In summary these results indicates that anthocyanins are beneficial against ethanol abuse in the developing stage.

Title: The requirement of Bcl-2 in neuronal stem and progenitor cell development in the adult brain

Authors: *M. CEIZAR, J. DHALIWAL, M. SMALLWOOD, Y. XI, D. LAGACE
Cell. and Mol. Med., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: A large proportion of neuronal stem and dividing progenitor cells (NSPCs) in the adult brain die due to apoptotic cell death. Elucidating at what stage during NSPCs development apoptosis occurs and the mechanisms that regulate apoptosis would aid in promoting the regenerative therapeutic potential of adult neurogenesis. Knockout mouse models suggest that the B-cell Lymphoma-2 (Bcl-2) family of pro-apoptotic (e.g. Bcl-2-associated X (BAX)) and anti-apoptotic (e.g. Bcl-2) proteins are regulators of NSPC death through activation of the intrinsic mitochondrial apoptotic pathway. To evaluate the role of Bcl-2 in NSPCs throughout their development, Bcl-2 was removed from NSPCs within the adult brain *in vivo*. Retroviral mediated gene transfer of Cre directly into the dentate gyrus of floxed Bcl-2 (fBcl-2) mice resulted in the complete ablation of neurogenesis by 30 days post infection supporting that Bcl-2 is essential for survival of the dividing progenitor cells. This was also confirmed through removal of Bcl-2 using a nestin-induced CreER^{T2} conditional mouse. Conditional ablation of Bcl-2 reduced the total number of recombined PCs and increased the number of activated caspase-3 (AC3) expressing cells by 12 days following induction of recombination. Additionally removal of Bcl-2 reduced the GFAP+/SOX2+ stem cell population in hippocampus, suggesting that Bcl-2 is necessary for stem cell maintenance. In agreement with the role of Bcl-2 acting upstream of BAX, the combined removal of Bcl-2 and BAX was able to rescue the Bcl-2 mediated ablation of neurogenesis. Together, these finding support the requirement of Bcl-2 and BAX in stem cells and the generation of newborn neurons in the adult brain.

Title: Differential oxygen tension in the SGZ niche determines the early survival of newborn hippocampal granule cells

Authors: *C. CHATZI[1], E. SCHNELL[2,3], G. WESTBROOK[1]
[1]OHSU, Vollum Institute, Westbrook Lab., Portland, OR; [2]Portland VA Med. Ctr., Portland, OR; [3]OHSU, Portland, OR

Abstract: The subgranular zone (SGZ) of the adult hippocampal dentate gyrus (DG) is one of the two neurogenic niches in the mammalian brain where new neurons are continuously generated from neural stem cells and progenitors. In the adult mouse as many as 4000 new granule cells are born daily, but only a small subset of those (~30%) survive the 4 weeks post-mitosis to differentiate into mature granule cells. To survive, adult-generated granule cells must pass through two critical periods: an early one during transition from intermediate progenitors to neuroblasts, and a later during integration of immature neurons into pre-existing hippocampal circuits. Although the integration phase is activity-dependent, little is known about the mechanisms responsible for early survival during the first week post-mitosis. Given the increasing evidence that differential oxygen tensions may be an important component of the neurogenic niche, and that oxygen-sensing may regulate the survival of neural stem cell precursors, we tested the role of oxygen tension on early granule cell survival. In order to characterize the oxygen tensions within the SGZ, we injected adult mice with the hypoxia marker pimonidazole hydrochloride. Several hypoxic niches were detected along the inner border of the SGZ with the hilus, consisting of adult neural stem cells and early intermediate progenitors. Interestingly, oxidative byproducts, marked by 8-hydroxyl-2′-deoxyguanosine, were highly localized in late intermediate progenitors and neuroblasts located adjacent to the hypoxic areas. Thus, we hypothesized that migration of a subset of intermediate progenitors along differential oxygen gradients might result in oxidative damage and thus trigger an early phase of apoptosis. In order to test this idea, we employed a hypoxia mimetic agent, DiMethylOxallyl Glycine (DMOG), that stabilizes Hypoxia Inducible Factor-1α (HIF-1α), the major regulator of oxygen homeostasis under normoxia. Mimicking hypoxia with DMOG specifically promoted the survival of the DG newborn cells during their transition from intermediate progenitors to neuroblasts (PND 3-7). However, DMOG had no effect on proliferation and differentiation both *in vivo* and *in vitro*. Using whole-cell recording of 3 day-old DG progenitors and immunohistochemical markers of neural activity, there was no detectable neural activity at this early stage, suggesting that the action of DMOG on survival was activity-independent. We propose that differential oxygen tensions within the SGZ contribute to the neurogenic microenvironment and determine the early survival of adult DG newborn cells.

Title: MicroRNA expression in the early postnatal hippocampus of the rat differs between the sexes and is regulated by estradiol and DNA methylation

Authors: *K. E. KIGHT[1], J. M. BOWERS[2], M. M. MCCARTHY[2,3]
[1]Program in Mol. Med., [2]Pharmacol., [3]Psychiatry, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Neurogenesis is regulated by numerous extrinsic and intrinsic factors, and varies among brain regions and across the lifespan. We have previously reported that early postnatal neurogenesis in the hippocampal formation of the Sprague Dawley rat differs between males and females, and is regulated by steroid hormones. Cell proliferation is greater in the dentate gyrus of males compared to females during the first week of life, but not the second, and this is modulated by estradiol signaling (Bowers et al., 2010). The downstream factors mediating the sex difference in cell genesis and the cell cycle response to estradiol in the early postnatal hippocampus are as yet unknown. In this study we examined the expression of several microRNAs known to be functionally involved in neuronal cell genesis, differentiation, and maturation. Female rat pups had higher baseline expression of several mature microRNAs in the dentate gyrus during the first postnatal week, including miR124, which is known to be involved in cell-cycle exit and neuronal differentiation. Exogenous administration of estradiol decreased expression of several microRNAs in the female dentate, while blocking estradiol signaling in males with tamoxifen increased microRNA expression. The effects of estradiol and tamoxifen on microRNA levels are inversely correlated with their effects on cell proliferation. In females, the increased cell proliferation in the early postnatal dentate in response to estradiol was blocked by inhibition of DNA methylation using zebularine, and zebularine also increased expression of miR124 and other microRNAs in the female dentate. Blocking DNA methylation with zebularine had little effect on expression of these microRNAs in the dentate of male pups. These results demonstrate a sex difference in microRNA expression during early postnatal development of the hippocampus, corresponding to a period in which a robust sex difference in cell genesis is seen. These results also suggest that microRNAs may be involved in mediating the effects of hormonal

signaling and epigenetic factors on cell proliferation and neurogenesis in the developing hippocampus. This work is supported by NINDS award 040726B1 to MMM.

Title: BMP signaling regulates the tempo of adult hippocampal progenitor maturation at multiple stages of the lineage

Authors: *A. M. BOND[1], C.-Y. PENG[1], E. A. MEYERS[1], T. MCGUIRE[1], O. EWALEIFOH[2], J. A. KESSLER[1]
[1]Neurol., [2]Microbiology-Immunology, Northwestern University's Feinberg Sch. of Med., Chicago, IL

Abstract: Novel environmental stimuli, such as running and learning, increase proliferation of adult hippocampal neural stem cells (NSCs) and enlarge the population of new neurons. However, it remains unclear how increased numbers of new neurons can be generated in a time frame far shorter than the time required for proliferating stem cells to generate these neurons. Here we investigated how bone morphogenetic protein (BMP) signaling regulates neural progenitor cell maturation in the adult hippocampus. BMPs are a class of morphogens within the transforming growth factor β superfamily, and are known to negatively regulate hippocampal neurogenesis. We show that BMP signaling in the SGZ regulates the tempo of neural progenitor cell (NPC) maturation by directing their transition between states of quiescence and activation at multiple stages along the lineage. Virally mediated overexpression of BMP4 caused NPC cell cycle exit and slowed the normal maturation of NPCs, resulting in a long-term reduction in neurogenesis. Conversely, overexpression of the BMP inhibitor noggin promoted NPC cell cycle entry and accelerated NPC maturation. Similarly, BMP receptor type 2 (BMPRII) ablation in Ascl1+ intermediate NPCs accelerated their maturation into neurons. This in turn resulted in a

period of increased neurogenesis that is associated with enhance cognition on a hippocampus dependent task. Thus inhibition of BMP signaling is a mechanism for rapidly expanding the pool of new neurons in the adult hippocampus by tipping the balance between quiescence/activation of NPCs and accelerating the rate at which they mature into neurons.

Title: Mitochondrial pro-apoptotic proteins are target of cooperative microRNA regulation in early stages of adult hippocampal neurogenesis induction after status epilepticus

Authors: *M. SCHOUTEN[1], S. A. FRATANTONI[2], C. J. Y. HUBENS[3], S. R. PIERSMA[2], T. V. PHAM[2], E. VREUGDENHIL[3], P. J. LUCASSEN[1], C. P. FITZSIMONS[1]
[1]SILS-CNS, Univ. of Amsterdam, Amsterdam, Netherlands; [2]VUmc-Cancer Ctr., Amsterdam, Netherlands; [3]LUMC, Leiden, Netherlands

Abstract: The total outcome of adult hippocampal neurogenesis (AHN) is tightly regulated both by cell proliferation and apoptosis. IP administration of KA at doses that induce status epilepticus (SE) induce AHN starting at three days after treatment remaining for as long as 15 days in mice (1). We hypothesize that during the early stages of AHN induction after KA-induced status epilepticus (SE) a dysbalance in apoptosis-related proteins stabilizes mitochondrial integrity, subsequently rescuing newborn neurons from apoptosis. By means of proteomics, transcriptomics and microRNAomics analyses we identified several apoptosis related targets and microRNAs that were differentially expressed in the dentate gyrus 3 days after KA treatment. Interestingly, while protein levels of some members of the BCL family of apoptosis-related proteins were decreased, mRNA levels remained unchanged, suggesting a possible role for microRNA regulation. This role was confirmed in hippocampal neural stem cell (NSC) cultures. Our data shows that specifically upregulated microRNAs bind to the 3'UTR of mRNA of members of the BCL family and inhibit protein expression. Furthermore,

overexpression of specific microRNAs and concomitant downregulation of their targets revealed a significant contribution to lowering KA-associated caspase3 activity in NSCs. As observed before, low amounts of caspase3 activity induced a differentiation phenotype (2). These data support our hypothesis that NSC apoptosis is hampered shortly after induction of SE and suggests microRNA upregulation as an intrinsic regulatory mechanism to favor differentiation over induction of apoptosis. Abstract: Adult neurogenesis occurs throughout life in the subgranular zone (SGZ) of the dentate gyrus of hippocampus and the subventricular zone (SVZ) lining the lateral ventricles in the adult mammalian brain. Newborn neurons in SGZ integrate into the neural circuit, thereby implicating in learning and memory. The adult neurogenesis is declined with age, however, it still remains unknown about the mechanisms of age-related decline in neurogenesis. Checkpoint kinase 2 (Chk2), a mediator of DNA damage response, is essential for p53-mediated apoptosis and cell cycle arrest in response to DNA damage. Here we show that Chk2 deficiency accelerates a decrease in the neural stem cells in SGZ, leading to a decline in hippocampal neurogenesis. The weight of the body and brain of 4.5-month-old Chk2 KO mice was indistinguishable from those of wild type mice. Quantitative analysis in SGZ reveals that the number of S100beta-,

Sox2+ neural stem cells and DCX+ immature newborn neurons is significantly reduced in the 4.5-month-old Chk2 KO mice compared to that of wild type mice. The ratio of differentiation from neural stem cells to immature neurons in Chk2 KO mice is comparable to that of wild type mice. These results suggest that Chk2 may be required for the maintenance for adult hippocampal neural stem cell pool and cognition during aging. Title: Neuroblasts without a neurogenic niche maintain adult neurogenesis on the second stage of the central olfactory pathway in the shore crab, Carcinus maenas

Authors: *M. SCHMIDT, C. D. DERBY
Neurosci. Inst., Georgia State Univ., ATLANTA, GA

Abstract: Adult neurogenesis persists in the central olfactory pathway of the decapod crustacean brain. The first stage in this pathway is the olfactory deutocerebrum (OD), which receives afferent input from olfactory receptor neurons. Adult neurogenesis in the OD is maintained by a few putative neural stem cells, identified as 'adult neuroblasts' (aNBs). Each aNB is associated with a small group of neuronal progenitor cells located in a proliferation zone (PZ) within the paired neuronal soma clusters of the OD: the lateral cluster (LC) containing the somata of ascending projection neurons (PNs) and the medial cluster containing the somata of local interneurons (LNs). In spiny lobsters Panulirus argus and crayfish Procambarus clarkii, each aNB of the OD is embedded in a distinct aggregate of small, bipolar cells likely representing a neurogenic niche (Schmidt, J Comp Neurol 503:64-84, 2007; Song et al., Arthrop Struct Dev 38:339-360, 2009; Schmidt & Derby, J Comp Neurol 519:2283-2319, 2011). The second stage of the central olfactory pathway is the lateral protocerebrum (LP), which is the target of ascending OD-PNs. The LP contains the hemiellipsoid body (HB), a neuropil corresponding to the mushroom body of insect brains (Wolff et al., J Comp Neurol 520:2824-2846, 2012). The somata of intrinsic HB-LNs form a large soma cluster attached to the HB, the HB cluster (HBC).

In anomuran and brachyuran crabs including Carcinus maenas, the HBC contains a circumscribed PZ (Schmidt, Brain Res 762:131-143, 1997). We examined if the PZs in the LC and HBC of the brain of adult C. maenas are associated with aNBs embedded in neurogenic niches by combining *in vivo* labeling using the S-phase marker BrdU with nuclear labeling. Three BrdU injections given in 8 h-intervals with a total survival time of 24 h resulted in the labeling of (1) neuronal progenitor cells in the PZs of LC and HBC, (2) cells associated with a neurogenic niche in the LC, and (3) one large cell at the edge of the PZ in the HBC (n = 6 crabs). Significantly, this cell, which we identify as a putative aNB based on being larger than the cells in the PZ of the HBC, was not associated with a cellular aggregate reminiscent of a neurogenic niche. We conclude that adult neurogenesis in the LC and HBC of shore crabs is based on aNBs, which in the LC are associated with a neurogenic niche whereas in the HBC they are not. The latter result tightly links adult neurogenesis in the HBC of shore crabs to adult neurogenesis in the mushroom bodies of insect brains, where Kenyon cells, the intrinsic mushroom body LNs, are generated by the activity of large aNBs not associated with a neurogenic niche (Dufour & Gadenne, J Comp Neurol 495:635-643, 2006)

Title: Lncrnas in granule cell progenitor differentiation

Authors: *C. PENAS[1], V. STATIAS[3], J. CLARKE[4], M. ZHANG[5], N. AYAD[2]
[1]John P. Hussman Inst. for Human Genomics, [2]Ctr. for Therapeutical Innovation, Univ. of Miami, Univ. of Miami, Miami, FL; [3]Ctr. for Therapeutical Innovation, University of Miami, Miami, FL; [4]Dept. of Food Sci. and Technol., University of Nebraska-Lincoln, NE; [5]Epidemiology, University of Georgia, GA

Abstract: We have performed a systems level analysis of cell cycle exit in the developing nervous system. We chose the granule cell progenitor (GCP) as a model to study cell cycle exit due to its abundance in the mammalian brain and importance to cerebellar development. We

performed RNA sequencing of GCPs at various times of differentiation and identified several long noncoding RNAs (lncRNAs), which are differentially expressed as GCPs exit the cell cycle. Considering the complexity of the "dark matter" RNA (produced by the 70% of the genome that does not encode proteins) and the relative high mass of that RNA in cells compared to the protein-coding RNA, it is logical to assume that lncRNAs harbor yet uncharacterized regulators of basic cellular processes, such as the cell cycle. Yet no systematic analysis of the contribution of long coding RNAs to cell cycle exit has been performed. We have performed functional studies, which demonstrate the contribution of long noncoding RNA to cell cycle exit of GCPs *in vitro*, *ex vivo*, and *in vivo*. Further, we have utilized long noncoding RNA- RNA interactions to generate a statistical model of cell cycle exit in the developing nervous system.

Title: The presenilins are not required for cell intrinsic regulation of adult hippocampal neurogenesis

Authors: *M. VACULIK[1], J. DHALIWAL[1], K. L. KUMAR[1], A. MAIONE[1], T. KANNANGARA[1], J.-C. BÉÏQUE[1], J. SHEN[2,3], D. C. LAGACE[1]
[1]Cell. and Mol. Med., Univ. of Ottawa, Ottawa, ON, Canada; [2]Neurol., Brigham and Women's Hosp., Boston, MA; [3]Neurosience, Harvard Med. Sch., Boston, MA

Abstract: Presenilins (PS1 and PS2) are components of the gamma-secretase complex and mutations in these genes are the major cause of familial Alzheimer's disease (AD). Cognitive decline in AD and the role of PSs in embryonic neurogenesis raised the possibility that reduced neurogenesis may contribute to AD-associated cognitive deficits. This was further supported by

conditional deletion of PSs in the adult cortex resulting in learning and memory impairments, synaptic deficits and age-dependent neurodegeneration. These findings prompted us to investigate whether PSs alter hippocampal neurogenesis in the adult brain. To birthmark and track the fate of dividing progenitor cells (PCs) in the dentate SGZ, we injected a mixture of retroviral GFP-Cre (*CAG-GFP-Cre)* and control RFP (*CAG-RFP)* into floxed *PS1* mice in the *PS2*-null background. The resulting *PS*-null GFP+ PCs developed normally and within 1 month the majority of PCs had a mature granule cell phenotype, measured by expression of NeuN, dendritic morphology and electrophysiological assessment including the AMPAR/NMDAR ratio. Exercise also induced an increase in the *PS*-null GFP+ and control RFP+ cells in animals that had 2 weeks of access to a running wheel compared to animals housed with a locked wheel, suggesting *PS* does not alter exercise induced increase in adult neurogenesis. To evaluate further whether *PSs* are required for adult neurogenesis, we generated a *PS* conditional KO (cKO) mouse carrying *NestinCre-ER*^{T2}, *RosaYFP*, homozygous floxed *PS1*, and *PS2*-null alleles. At five weeks of age, *PS* cKO mice and littermate controls received tamoxifen to induce recombination in the *Nestin* expressing stem/progenitor cells and their progeny. Compared to controls, the number of recombined (YFP+) cells co-expressing the stem cells markers (Sox2 and GFAP) or Ki67-expressing proliferating cells was unchanged in *PS* cKO mice. Additionally, up to 60 days following removal of PSs, the number of mature neurons expressing NeuN was also normal. Together these results indicate that loss of PSs does not affect proliferation, survival, and maturation of neurons generated within the adult hippocampus, suggesting a divergent role for PSs in the embryonic versus adult neurogenesis.

Title: Regulation of the process of adult neurogenesis in the adult hippocampal dentate gyrus by Parvalbumin-positive GABAergic neurons

Authors: *H. MIWA[1,2], N. TAMAMAKI[3], Y. YANAGAWA[1,2]
[1]Genet. & Behavioral Neurosci., Gunma Univ., Maebashi, Gunma, Japan; [2]Japan Sci. and

Abstract: Adult neurogenesis occurs throughout life in discrete regions of the mammalian brain. In the hippocampal dentate gyrus (DG), immature neurons, originating from adult neural progenitors at the subgranular zone, migrate into the granule cell layer to become new dentate gyrus granule cells. Adult neurogenesis is highly regulated by physiological and pathological stimuli, including exercise, environmental enrichment and seizures. One of the well-established mechanisms for regulation of the process of adult neurogenesis is activity to newborn neurons using the neurotransmitter γ-aminobutyric acid (GABA). Several recent studies have suggested that GABA has crucial roles in regulating different steps of adult neurogenesis, including proliferation of neural progenitors, migration and differentiation of neuroblasts, and synaptic integration of newborn neurons. GABAergic neurons in the DG are a diverse group that can be classified by a variety of morphological, neurochemical, and physiological characteristics. Parvalbumin (PV)-containing GABAergic neurons project axon terminals that synapse exclusively on the axon initial segments to control the output, synchronizing the action potential firing of large group of principal neurons. Furthermore, PV-positive GABAergic neuron activity regulates Type I stem cell quiescence via tonic GABA receptor signaling. To investigate the roles of PV-positive GABAergic neurons in postnatal neurogenesis, we generated PV-positive neuron-specific GAD67 knockout mice using the Cre-loxP system. PV-Cre; GAD67flox/flox mice showed reductions in expression of calbindin, a mature granule cell marker, but similar levels in expression of calretinin, a immature granule cell marker, compared to the control GAD67flox/flox mice. These data suggest that PV-positive GABAergic neurons have a critical role in the maturation of newborn neurons during postnatal dentate gyrus neurogenesis.

Title: Histone deacetylase 1 is required for doublecortin expression: implication for ethanol inhibition of neurogenesis

Authors: *J. Y. ZOU[1], F. T. CREWS[2]
[2]Bowles Ctr. for Alcohol Studies, [1]Univ. North Carolina, Chapel Hill, Chapel Hill, NC

Abstract: Histone deacetylases (HDACs) are nuclear enzymes capable of repressing gene expression by removing acetyl groups from histones and play important role in maintaining functional neurogenesis, but little is known about the functional specificity of different HDAC isoforms in regulation of ethanol-impaired hippocampal neurogenesis. The present study investigated the specific role of HDAC isoforms in regulation of hippocampal neurogenesis under control as well as during ethanol exposure in an organotypic hippocampal-entorhinal cortex (HEC) slice culture model. HEC slices were prepared from P7 neonates, maintained in culture for two weeks and then treated with pan-HDAC inhibitors including trichostatin A (TSA), sodium butyrate (SB) and valproic acid (VPA) and specific HDAC1 inhibitor MS-275. DCX immunoreactivity (IR) and BrdU+ neural progenitors were measured with immunohistochemistry. Treatments of HEC slices with pan-HDAC inhibitors SB (100uM) and VPA (100uM) for 4 days significantly increase DCX+IR and proliferation of BrdU+ progenitors. Treatment of HEC slices with specific HDAC1 inhibitor MS-275 (500nM) drastically inhibited DCX expression and progenitor cell proliferation. HDAC1 knockdown with specific siRNA had the same effects on DCX expression as MS-275. Combination of MS-275 with pan-HDAC inhibitors SB and VPA eliminates the increased effects of SB and VPA on DCX expression. However, combined treatments of MS-275 and HDAC1 activator such as acetyl-CoA reversed MS-275-induced reduction of DCX expression. These results strongly suggest that HDAC1 is required for maintaining hippocampal neurogenesis. Ethanol (100mM) treatment for 4 days significantly reduced DCX expression and proliferation of neural progenitors accompanying with reduction of HDAC1 mRNA expression. The presence of MS-275 during ethanol treatment further decreased DCX expression. Ethanol inhibition of DCX expression was also reversed by HDAC1 activator Acetyl-CoA. Western blot analysis further indicates that ethanol exposure results in mobilization of HDAC1 from nuclear to cytoplasmic compartments, suggesting reduced nuclear HDAC1 activity. Together, these novel findings suggest that HDAC1 is required for hippocampal neurogenesis and may be a therapeutic option for ethanol-impaired neurogenesis.(Supported by NIAAA)

Title: Transcription factors Coup-TFI and Coup-TFII regulate the migration and survival of Pax6-expressing granule cells of the olfactory bulb

Authors: *Z. XING, J. LI, Z. XU, Q. LIANG, Z. LIU, Z. YANG
Inst. of Brain Sci. and State Key Laborato, Shanghai, China

Abstract: In the adult brain, the main function of SVZ neural stem cells is generating interneurons for the olfactory bulb (OB) throughout life. In general, the slowly dividing B1 cells give rise to rapidly dividing transit amplifying C cells, which in turn generate large numbers of immature neurons (also known as neuroblasts, or A cells) that migrate forwards along the rostral migratory stream (RMS) to the OB, where they become olfactory mature interneurons. In the present study, we have examined the function of chicken ovalbumin upstream promoter transcription factors COUP-TFI and COUP-TFII in regulation of mouse OB interneuron migration and survival. We found that COUP-TFI, but not COUP-TFII, is expressed in the SVZ stem/progenitor cells, migrating neuroblasts and mature OB interneurons. Conditional inactivation of COUP-TFI resulted in upregulation of COUP-TFII expression in the SVZ-RMS-OB pathway. In COUP-TFI/COUP-TFII double conditional mutants, we found that Pax6-expressing mature interneurons in the granular cell layer were lost. We also found that NeuN-expressing cells accumulated in the double mutant SVZ. Accordingly, apoptotic cells were significantly increased in COUP-TFI/COUP-TFII double conditional mutant SVZ. These results suggest that Coup-TFI and Coup-TFII regulate the migration and survival of a subpopulation of OB granule cells. **Keywords**: Sp8; Dlx5/6; neural stem cells; neurogenesis; parvalbumin; interneurons; olfactory bulb

Title: Serotonin 1a receptor in sex-specific neonatal hippocampal development and later-life mood disorders: Possible cooperation with gpr30

Authors: *P. BANERJEE[1], S. SAMADDAR[2], A. MARSILLO[2], R. SCHRODER[1,2]
[1]Dept Chem & Neurosci Prog, City Univ. New York Staten Isla, STATEN ISLAND, NY;
[2]Doctoral Program in Biol., CUNY Grad. Ctr., New York, NY

Abstract: The neurotransmitter serotonin (5-HT) plays an important role in mood disorders and its synthetic rate is lower in the brain of women than men. Intriguingly, mood disorders are twice as common in women than men. It has been demonstrated that 5-HT signaling through 5-HT1A receptors (5-HT1A-R) is crucial for early postnatal hippocampal development and later-life behavior. Although 5-HT signaling through 5-HT1A receptors (5-HT1A-R) regulates early brain development, the mechanistic underpinnings have remained unclear. We have shown that suprabasal 5-HT1A-R signaling in postnatal day 6 (P6) mice through protein kinase Cε (PKCε) and extracellular receptor activated kinase 1/2 in the dentate gyrus (DG) boosts neonatal neuroblast proliferation in both sexes. However, the basal 5-HT1A-R signaling exerts a female-specific effect and neuroproliferation is severely impaired in P6 female but not male 5-HT1A-R(-/-) (KO) mice. Establishing the sex-specific developmental importance of early neuroproliferation, the KO female but not male mice showed significantly elevated anxiety-like behavior at P60. Intrahippocampal infusion of the selective PKCε stimulator DCP-LA at P6 partially rescued neuroblast proliferation in the KO females and repeated systemic treatment from P6 to P14 corrected the later-life anxiety-like behavior. To explore the possible mechanism of this sex-specific effect of 5-HT1A-R signaling, we studied the involvement of the estradiol receptor GPR30, which has been reported to associate with the 5-HT1A-R and also influence its signaling activity. 5-HT1A-R-mediated neuroproliferation in the P6 hippocampus was eliminated in the presence of the GPR30 antagonist G15 and the GPR30 agonist G1 elicited a dramatic increase in neuroproliferation. GPR30 has been believed to localize in the intracellular membranes. Our studies will investigate the possibility of its interaction with the 5-HT1A-R through both direct association as well as interaction with the signal transducers, such as G-proteins and effector molecules.

Title: Cross-talk between beta1-integrin and bone morphogenetic (BMP) signaling in the regulation of adult neurogenesis

Authors: *S. M. BROOKER, H. A. NORTH, C.-Y. PENG, T. L. MCGUIRE, J. A. KESSLER
Northwestern Univ. Feinberg Sch. of Med., Chicago, IL

Abstract: The continuous generation of new neurons occurs throughout life in two localized regions of the adult mammalian brain, the subventricular zone (SVZ) of the lateral ventricles and the subgranular zone (SGZ) of the dentate gyrus (DG) of the hippocampus. Behavioral studies in rodents have suggested that ongoing hippocampal neurogenesis may play a key role in cognition. Diverse signaling molecules present in the SGZ regulate multiple aspects of the neurogenic process, including neural stem cell (NSC) maintenance, proliferation, and differentiation. In particular, inhibition of BMP signaling promotes hippocampal neurogenesis and improves cognition. However, relatively little is known about how different signaling pathways may interact to regulate NSC behavior. We found that BMP signaling in NSCs is modified by β1-integrin, an extracellular matrix-interacting protein that has been implicated in maintenance of NSCs. Co-immunoprecipitation studies demonstrated that β1-integrin physically interacts with both type I BMP receptors (BMPR1a and BMPR1b) in both the wild type adult hippocampus and in cultured NSCs. We used the Cre/LoxP system to genetically ablate β1-integrin in cultured NSCs derived from the SVZ of β1-integrin floxed mice. Ablation of β1-integrin in NSCs resulted in increased partitioning of BMPR1b into lipid rafts, increased pSMAD1/5/8 and p38 signaling, and increased expression of BMP target genes including GFAP and inhibitor of differentiation (ID) proteins. Disruption of lipid rafts resulted in a marked reduction in BMP signaling, indicating that lipid rafts are critical for BMP signaling in NSCs. We conclude that β1-integrin modulates BMP signaling in neural stem cells *in vitro* by regulating the localization of BMP receptors within the cell membrane.

Title: Differential expression of hyperpolarization-activated and cyclic nucleotide-gated (HCN) channel isoforms during hippocampal development in the mouse

Authors: ***H. SEO**[1,2], M.-J. SEOL[1], K. LEE[1]
[1]Dept. of anatomy, Kyungbook Natl. Univ. of Med., Daegu, Korea, Republic of; [2]Dept. of Biomed. Science, Kyungpook Natl. Univ., BK21 Plus KNU Biomed. Convergence Program, Daegu, Korea, Republic of

Abstract: Hyperpolarization-activated cyclic nucleotide-gated (HCN) channels are intermembrane proteins that serve as nonselective ligand-gated cation channels in the plasma membranes of heart and brain cells. Among HCN channels isoforms 1, 2, 3, and 4, HCN1, 2, and 4 are widely expressed throughout the brain and help to control the rhythmic activation of pacemaker oscillatory neurons during brain development as well as to control neural synaptic plasticity in the adult brain. In the mouse, the hippocampus has been studied extensively as a part of brain responsible for learning and spatial memory related to synaptic plasticity. Therefore, we examined the expression profile of brain-enriched HCN1, HCN2, and HCN4 in the hippocampus of mouse by ontogenic study with the tissue obtained from postnatal day (PND) 0, 7, 21, and 56. All of HCN1, HCN2, and HCN4 are expressed abundantly through the whole hippocampal area at PND 0 and PND 7 and each HCN channel showed the specific expression according to the hippocampal layer after PND 7. Especially, HCN4 expressions are collocalized with GFAP-positive immunoreactivity in stratum lacunosum moleculare layer at only PND 7. In PND 21 and PND 56, all of HCN1, 2 and 4 were outstandingly expressed at the pyramidal cells of all CA fields and parvalbumin-positive interneuron primarily at CA3. In the dentate gyrus, the immunoreactivity for HCN1, 2, and 4 are exhibited at hilus and granular cells near molecular layer, but not at double-cortin (DCX)-positive cells of subgranular zone in both PND 21 and PND 56. Taken together, the mapping process we performed to discovery the hippoocampal

expression pattern of HCN isoforms in mouse suggest the specific expression and distinct potential role of hippocampal HCN1, HCN2, and HCN4 during neural development.

Title: Atypical PKC-CBP pathway regulates murine adult neurogenesis

Authors: ***J. WANG**[1], K. HSU[1], L. HE[2], F. WONDISFORD[2], F. MILLER[3]
[1]Sprott Ctr. For Stem Cell Research, OHRI, Ottawa, ON, Canada; [2]Dept. of Pediatrics and Med., Johns Hopkins Med. Sch., Baltimore, MD; [3]Developmental and Stem Cell Biol., Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Our previous studies showed that CBP phosphorylation at serine 436 (S436) by atypical PKC (aPKC) is important for CBP to promote embryonic neural precursor differentiation in culture (Dev Cell, 2010). Recently, intriguing findings that CBP levels and/or activity are also required to regulate adult neurogenesis led us to ask whether aPKC-mediated phosphorylation of CBP at S436 is also a key modulator of adult neurogenesis. To do this, we used two knock-in mouse models to target the aPKC-CBP pathway, CBPS436A and p300G422S, where an aPKC phosphorylation site was modified in CBP and p300 alleles in order to generate phosphorylation-defective (CBPS436A) and phosphorylation-competent (p300G422S) mouse models. By using BrdU *in vivo* labeling technique, we showed that the total number of hippocampal newborn neurons (BrdU/NeuN+ cells) was significantly decreased in the CBPS436A mutants, while the total number of hippocampal newborn neurons (BrdU/NeuN+ cells) was significantly increased in the p300G422S mutants at the age of 3 months. More interestingly, we observed that the proportion of double labeled BrdU/NeuN + neurons over total BrdU + cells was only reduced in the hippocampi of CBPS436A mutants at the age of 6-month, associated with an increased proportion of double labeled BrdU/Sox2 + neural stem cells (NSCs)

in the same hippocampi. However, the total number of immature doublecortin (DCX) + neurons was not changed in the CBPS436A mutants at the age of 6 months. These data suggest that aPKC-mediated CBP phosphorylation is important for adult neurogenesis, and that it modulates differentiation of NSCs and maturation of newly-born neurons in an age-dependent fashion. In addition, our co-immunoprecipitation experiments showed that the association of CBP with CREB in the CBPS436A hippocampal tissues was abolished at the age of 6 months, but not at the age of 3-month, suggesting that CREB might be a downstream signaling of the aPKC-CBP pathway to regulate adult hippocampal neurogenesis in an age-dependent manner. To probe the upstream kinase that regulates the aPKC-CBP pathway to promote adult neurogenesis, we cultured subventricular zone (SVZ) adult neurospheres and showed that AMPK activators (metformin and AICAR) promoted adult neurogenesis in culture and that the increased neurogenesis caused by AMPK activators was abolished in cultures derived from CBPS436A mice, but potentiated in cultures derived from p300G422S mice. In summary, the aPKC-CBP pathway regulates adult hippocampal neurogenesis in an age-dependent manner and the aPKC-CBP pathway is essential to mediate AMPK-induced adult neurogenesis in culture.

Title: Neuroligin-1 knockdown reduces survival of adult-generated newborn hippocampal neurons *in vivo*

Authors: *E. SCHNELL[1], T. H. LONG[2], A. L. BENSEN[3], E. K. WASHBURN[3], G. L. WESTBROOK[3]
[1]Portland VA Med. Ctr., Portland, OR; [2]Sch. of Med., [3]Vollum Inst., OHSU, Portland, OR

Abstract: Adult-born hippocampal granule cells mature *in situ* over several weeks through the elaboration of dendrites and the formation of synaptic contacts. Survival of these adult-born neurons is modulated by neural activity, and thought to be enhanced by excitatory synaptic signaling. Using retrovirus-mediated gene knockdown in young adult mice *in vivo*, we confirmed that a reduction in expression of the synaptogenic protein neuroligin-1 decreases dendritic spine formation by immature newborn neurons in the dentate gyrus. At an early post-mitotic stage (21 days post-mitosis), the decrease in spines preferentially resulted from a decrease in filopodial-like spines without a change in excitatory synaptic transmission, suggesting that these filopodial-like structures were non-synaptic. Although primarily associated with synaptogenesis, neuroligin-1 knockdown during early granule cell maturation also delayed dendritic outgrowth, resulting in a decrease in dendritic branch number and length at 2 weeks post-mitosis. Neuroligin-1 knockdown was also associated with a reduction in long-term survival of newborn granule cells. Thus, our results indicate that neuroligin-1 not only has a role in dendritic spine formation during adult neurogenesis, but also has broader roles - in dendritic growth and the survival of newborn cells. We hypothesize that proper morphologic development of newborn cells is a prerequisite survival signal for newborn granule cells.

Title: Self-regulation of adult hippocampal stem cells via secreted VEGF

Authors: *E. D. KIRBY, A. KUWAHARA, T. WYSS-CORAY
Stanford Univ., Palo Alto, CA

Abstract: Vascular endothelial growth factor (VEGF) supports a number of potentially beneficial processes in the adult brain, including angiogenesis, synaptic plasticity cell proliferation, and neuronal survival. Though mature astrocytes were previously believed to be the primary source of VEGF within the brain, we have recently shown that adult neural stem/progenitor cells (NPCs) in the adult hippocampus secrete substantial amounts of VEGF, potentially helping to shape their own neurogenic niche. A number of cancer cell types similarly secrete VEGF and it has been hypothesized that this self-derived VEGF is an essential stem cell factor that supports the multipotent self-renewal of tumor cells. We therefore investigated whether self-secreted VEGF in adult hippocampal NPCs may similarly be stem cell essential. We found that mouse adult hippocampal NPCs express several isoforms of secreted VEGF as well as VEGFR2 (aka Flk1/KDR). Expression of both VEGF protein and its receptor were tightly regulated by growth factors and decreased dramatically with differentiation. Inhibition of VEGF via shRNA severely limited the long-term renewability of NPCs. In addition, transiently blocking VEGF signaling with either of two VEGFR2-specific kinase inhibitors reduced the number of recoverable large spheres in a sphere assay. Combined, our findings suggest that self-secreted VEGF in adult hippocampal NPCs is essential for maintaining stem cell identity and loss of VEGF may play a role in inducing differentiation. Current research is investigating the consequences of this stem cell self-regulation via VEGF *in vivo*, as well as the effects of NPC-derived VEGF on other cells in the neurogenic niche.

Title: GABA bidirectionally controls AP firing in newborn hippocampal granule cells

Authors: *S. HEIGELE, J. BISCHOFBERGER
Inst. of Physiol., Univ. of Basel, Basel, Switzerland

Abstract: Newly generated young hippocampal granule cells in the adult brain receive depolarizing GABAergic synaptic inputs, which were shown to be important for their development and functional maturation. Whether activation of GABAergic synapses can evoke action potential (AP) firing in newly generated granule cells is yet unknown. To identify the young neurons in the adult brain, we used transgenic mice expressing the red fluorescent protein DsRed under the control of the doublecortin (DCX)-promoter. Perforated-patch recordings (gramicidin) revealed that the reversal potential of GABAergic synaptic currents is substantially more positive in DCX-expressing young neurons (-34.2±2.1mV) as compared to mature granule cells (-71.9±2.9mV). Coincidentally activated with depolarizing current injections or glutamatergic synaptic transmission, GABAergic synapses generated a biphasic response pattern. GABAergic synaptic currents were indeed able to excite AP firing in young granule cells within a conductance window between ~0.5 and 6nS. Larger GABAergic inputs, however, effectively blocked AP firing via shunting inhibition, which might be important to protect the young cells from over excitation. Synaptic GABAergic transmission was fully blocked by 10µM gabazine, whereas a half maximal concentration (0.2µM) increased AP firing at high stimulation intensities, showing that both AP boosting and shunting inhibition are mediated by a GABA-A receptor mediated chloride conductance. Taken together, we show that GABAergic synaptic inputs in newly generated young granule cells can dynamically support either AP generation or shunting inhibition dependent on hippocampal network activity. Abstract: Autophagy is an evolutionarily conserved lysosomal degradation pathway that contributes to the maintenance of cellular homeostasis. In stem cells, autophagy has cell type specific roles in cell maintenance, expansion and differentiation. The function of autophagy throughout the development of adult-generated neurons formed from neural stem and progenitor cells (NSPCs) remains unknown. Here we demonstrate autophagic flux in the NSPCs in the subgranular zone of the dentate gyrus and investigate the role of autophagy in adult neurogenesis through removal of the autophagy-related gene 5 (*Atg5),* which is required for the formation of autophagosomes. Using a tandem DsRed-LC3-GFP retrovirus we show autolysosomes are present in NSPCs throughout their development. Inducible removal of Atg5 in the adult brain using Glast-CreER^{T2} mice (6 weeks old) reduced the number of stem cells (GFP+Sox2+GFAP+) with a subsequent reduction in the number of dividing (GFP+Ki67+) as well as a decrease in the number of new neurons formed (GFP+DCX+NeuN+). These results suggest that Atg5 reduces the stem cell population and subsequently reduces neurogenesis in the absence of altering the fate of the NSPCs. To examine if Atg5 has a role in the survival of neural progenitor cells independent of its role in stem cells, we performed retroviral mediated ablation of Atg5 in the dividing progenitor cells in the dentate. At 7, 30 and 60 days post retroviral injection there was a significant reduction in the number of Atg5-null progenitor cells suggesting Atg5 is required for progenitor cell survival. The reduced survival of *Atg5*-deficient progenitor cells was rescued in mice that lacked the essential pro-apoptotic protein *Bax* (Bcl-2–associated X *protein)* supporting that *Atg-5* deficient cells die through a *Bax*-dependent mechanism. Additionally, removal of *Atg5* prevented running-induced increases in neurogenesis, supporting that autophagy contributes to the beneficial neurogenic effects of exercise. These findings highlight *Atg5* as an intrinsic regulator of NSPCs and regulator of adult neurogenesis.

Title: The role of epigenetic repression in a developmental sex difference in hippocampal neurogenesis

Authors: *S. L. STOCKMAN[1,2], M. M. MCCARTHY[1,2,3]
[1]Pharmacol., [2]Program in Neurosci., [3]Physiol., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Sexual differentiation of the brain is an important process in normal development and has vast implications on later behavior. Our laboratory has identified a sex difference in neonatal hippocampal proliferation. Newborn male rats exhibit an increased rate of cellular proliferation in the dentate gyrus, CA1 and CA3 of the hippocampus compared to females and most of these become neurons. Administration of exogenous estradiol to newborn females increases cell genesis to levels consistent with males, whereas inhibition of estradiol signaling in males eliminates the sex difference (Bowers et al., Biol. Sex Diff., 2010). Sex differences are traditionally accomplished through elevation of testosterone in neonatal males that is locally aromatized to estradiol in the brain. However, throughout the period of increased male neurogenesis, there is no sex difference in hippocampal estradiol content implicating an alternative source of the difference (Konkle et. al, Endocrinology, 2011). Therefore, we hypothesized that suppression of estradiol mediated neurogenesis in females may be responsible for the observed sex difference in neonatal hippocampal proliferation. Epigenetic modifications translate environmental variables into enduring, but malleable, changes in gene expression making them appealing targets to mediate the sex differences seen in proliferation. Canonical modes of epigenetic regulation include direct modification of the DNA, primarily through methylation, as well as alteration to histone tails that modify the state of chromatin. The purpose of this study was to assess contributions of variations in histone acetylation in epigenetic repression of neurogenesis in females. On PN1 and PN2, male and female Sprague-Dawley rat pups were injected i.p. with the histone deacetylase (HDAC) inhibitor Trichostatin A (0.25mg/kg in 5% DMSO in saline) or comparative control and injected s.c. with either estradiol benzoate (100 ug/0.1 mL in sesame oil) or vehicle. Three hours after drug and hormone injection animals were injected with 5-bromo-2'-deoxyuridine (BrdU, 100mg/kg in saline). On PN3 animals were transcardially perfused, and brains sectioned coronally for BrdU immunohistochemistry. BrdU cell counts were conducted stereologically using StereoImager. Our results indicate that treatment of newborn females with HDAC inhibitors mirror the increase in proliferation seen following administration of exogenous estradiol (ANOVA, $p<0.05$). These findings suggest that

exogenous estradiol may act to increase total histone acetylation to overcome suppression of estradiol mediated neurogenesis in females. Supported by NIH grant R01NS 050525 to MMM

Title: Brain-specific expression of lysosomal-associated membrane protein 5 (LAMP5) gene

Authors: *M. KOEBIS[1], Y. SAITO[1], Y. SHINODA[1], T. FURUICHI[1,2]
[1]Tokyo Univ. of Sci., Noda, Japan; [2]Lab. for Developmental Gene Regulation, RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: In the mammalian central nervous system (CNS) more than a half of the genes in the genome are expressed in a spatiotemporally regulated manner. Although they are thought to be involved in brain developments and functions, most of them remain to be studied for the subcellular localizations and molecular functions of their encoded proteins in the CNS. When they are expressed in a specific stage of the brain development or in a specific cell type or brain region, the genes should be involved in the neural development and function, such as differentiation of neurons, neural network formation, and synaptic plasticity. Recently, we have developed Cerebellar Development Transcriptome Database (CDT-DB) (Sato et al., Neural Netw, 2008), and identified several brain-specific genes whose encoded proteins have not yet been characterized for their functional significance in the CNS including the gene encoding lysosomal-associated membrane protein 5 (LAMP5, also known as BAD-LAMP). We found that Lamp5 is highly expressed in embryonic mouse cerebellum and is down-regulated in later developmental stages while its expression at the whole brain level increases along with the development. The nematode orthologous gene of Lamp5, unc-46, encodes a type III transmembrane protein with several glycosylation sites. UNC-46 has been shown to locate in the synaptic terminal of GABAergic neurons and regulate the release of GABA, an inhibitory neurotransmitter that plays an important role in brain development. A previous study also showed that LAMP5 protein was expressed in the II/III and V layers of mouse postnatal cerebral cortex. However, its expression over other brain regions during developmental stages is still unknown. In the present study, we have performed immunohistochemistry of murine brain

sections at various developmental stages with a polyclonal antibody against LAMP5 and found its expression in cerebellum and a certain cell population, which is presumably located near the locus coeruleus. We are now generating a Lamp5 knockout mouse to investigate the physiological function of LAMP5 in the CNS.

Title: Effects of TRPV1 deficiency on the adult hippocampal neurogenesis

Authors: ***S.-E. WANG**[1], S. KO[1], H. JO[1], H. SON[1,2]
[1]Grad. school of biomedical science and engineering, Hanyang Univ., Seoul, Korea, Republic of; [2]Biochem. and molecular biology, Hanyang University, Sch. of medicine, Seoul, Korea, Republic of

Abstract: Transient Receptor Potential family Vanilloid 1 (TRPV1) is well known for stress response protein in the central nervous system. Activation of TRPV1 polymodal cation channels permits the Ca^{2+} influx through it. Ca^{2+} influx through TRPV1 can induce endocytosis of AMPAR that results in long-term depression (LTD) and neurodegeneration. Since intracelluar increase of Ca^{2+} regulates synaptic plasticity and signal transduction in neurons, we first hypothesized that TRPV1 deficiency may affect neuronal plasticity including adult hippocampal neurogenesis. We show that the number of 5-bromo-2'-deoxyuridine (BrdU)(+) cells is increased in the hippocampal dentate gyrus (DG) of TRPV1 KO mice compared to wild type C57B/L6. Furthermore, expression of double cortin (DCX) and polysialylated-neural cell adhesion molecule (PSA-NCAM), which are markers of early neuronal differentiation, are enhanced in hippocampal DG of KO mice compared to wild type mice. Loss of TRPV1 also increases synaptic molecules, such as postsynaptic density-95 (PSD95), glutamate receptor 1 (GluR1) and synapsin1. These results suggest that TRPV1 deficiency may positively regulate neuronal plasticity including adult hippocampal neurogenesis. *Keywords ; TRPV1, neurogenesis*

Title: Delayed cerebellar development in transgenic mouse expressing a mutant thyroid hormone receptorβ-1 in Purkinje cells

Authors: L. YU, T. IWASAKI, N. SHIMOKAWA, *N. KOIBUCHI
Dept. of Integrative Physiol., Gunma Univ. Grad. Sch. of Med., Maebashi/Gunma, Japan

Abstract: Thyroid hormone (TH) is essential for growth and development of cerebellum. TH exerts its major roles by binding to TH receptors (TRs). Deficiency of TH during perinatal period causes abnormal brain development. To study the role of TH on cerebellar development, we have generated a transgenic mouse expressing a dominant-negative TR specifically in the cerebellar Purkinje cell. A mutant human TRβ1 (G345R), which binds to TH-response element but cannot bind to T3, was subcloned into exon 4 of the full length L7/ Pcp-2 gene, which is specifically expressed in the Purkinje and the retinal rod bipolar cells. The transgene was specifically expressed in the Purkinje cell in the postnatal cerebellum. Postnatal Purkinje cell dendritic arborization was significantly delayed in the transgenic mice. To our surprise, granule cell migration was also significantly delayed. In the primary cerebellar culture, TH-induced Purkinje cell dendrite arborization was also suppressed. Using semi-quantitative PCR, we have examined the change in TH-responsive gene mRNA levels. Levels of IP3 receptor type1 and RORα mRNA, which are mainly expressed in the Purkinje cell, and BDNF mRNA, which is expressed in both Purkinje and granule cells were significantly decreased. Furthermore, levels of NT-3 mRNA, which is mainly expressed in the granule cell was also decreased. Levels of myelin basic protein mRNA, which is mainly expressed in the oligodendrocyte was not altered. Motor coordination of transgenic mice was significantly disrupted. These results indicate that the development of Purkinje cell is directly regulated by TH through binding to TR, whereas TH action through TR in the Purkinje cell is also important for development of other subset of cerebellar cells such as granule cells.

Title: Novel osmotin attenuates glutamate-induced synaptic dysfunction and neurodegeneration via the JNK/PI3K/Akt pathway in postnatal rat brain

Authors: G. YOON, S. SHAH, *M.-O. KIM
., Dept. of Biol., Gyeongsang Natl. Univ., GAZA 900, Jinju, Korea, Republic of

Abstract: Overactivation of the glutamatergic-induced excitotoxicity pathway has been reported in several neurodegenerative diseases. Molecules that inhibit the release of glutamate or the over-activation of glutamate receptors can minimize neuronal cell death in these diseases. Osmotin, a homologue of mammalian adiponectin, is a plant protein has been examined in the present study for the first time to determine how it may protect against glutamate-induced synaptic dysfunction and neurodegeneration in the postnatal day seven rat brain. The results indicate that glutamate treatment induced excitotoxicity by over activating glutamate receptors, synaptic dysfunction and neuronal apoptosis after four hours in the cortex and hippocampus of the postnatal brain. On the other hand, post administration of osmotin, significantly reversed glutamate receptors activation, synaptic deficit and neuronal apoptosis by stimulating the JNK/PI3K/Akt intracellular signaling pathway. Moreover, osmotin treatment also abrogated glutamate-induced DNA damage, apoptotic cell death and attenuated the localization and distribution of p53 and p-Akt and caspase-3 in the hippocampus of postnatal brain. Taken together all these results suggest that osmotin might be a novel neuroprotective agent in the excitotoxic diseases.

Title: Corticogenesis of the cerebellar cortex in lysosomal acid phosphatase (Acp2) mutant mice

Authors: *H. MARZBAN[1], K. BAILEY[1], M. RAHIMI BALAEI[1], A. U.MANNAN[3], S. GHAVAMI[2]
[1]Dept. of Human Anat. and Cell Sci., [2]Univ. of Manitoba, Winnipeg, MB, Canada; [3]Inst. of Human Genetics, Univ. Med. Ctr. Goettingen, Goettingen, Germany

Abstract: Introduction: The cerebellum is a highly organized centre of motor coordination and cognition. Structurally it consists of a three-layered cortex with distinct neuronal subtypes, such as granule cells (gcs) and Purkinje cells (Pcs). It is suggested that Pcs utilize reelin dependent pathways to form a monolayer in the cerebellar cortex. Reelin expressed by gcs, is required for Pcs distribution from the clusteric stage to establish a monolayer of Pcs between the molecular and granular layers of the cerebellar cortex. Proliferation of the gcs is influenced by Shh (Sonic hedgehog) expressed in Pcs. A mouse mutant called nax (naked-ataxia), resulting from a spontaneous mutation in lysosomal acid phosphatase (Acp2), presents multi-layered Pcs that ectopically invade the molecular layer. We hypothesize that the establishment of this mono layered Pcs is not dependent on the reelin pathway. Materials and Methods; Acp2 mutant mice were used for this study. Molecular expression and distribution were assessed by immunohistochemistry and Western blotting. Results; The cerebellar cortex of the Acp2 mutant mice which was characterized by the absence of the vermis, reveals the presence of Pcs in a randomized, dispersed manner spanning the entire molecular layer rather than a monolayer in the cerebellar cortex. The amount of gcs is severely reduced in the cerebellum which is more prominent rostrally as compared to their numbers in the caudal cerebellum. It is also observed that Pax6 expression follows the pattern of gcs proliferation and migration during postnatal development. The pattern of reelin expression is down-regulated in the Acp2 mutant cerebellum at around P12 and accompanies the down-regulation of Shh. Conclusion; The down-regulation of Shh that followed the declined reelin expression may be secondary to Pcs degeneration. However, the presence of reelin is comparable with wild type during early postnatal development, indicative of reelin effect during clustric stages however failed to form mono layered Pcs. Pcs differentiation is severely delayed inthe Acp2 mutant cerebellar cortex and it can be concluded that multilayer Pcs may be due to the failure of appropriate cross-talk between Shh and the reelin signalling pathway during postnatal cerebellar development.

Abstract: There is growing evidence that untreated pain experienced in the neonatal period could lead to changes in the neuronal circuitry, which may be associated to an adverse neurodevelopmental outcome. Moreover, pain treatment with opioid is not free of deleterious effects on the central nervous system. In this study we examined the effect of the neonatal inflammatory pain, initiated in the postnatal day 1 of life (PN1), followed or not by analgesia, over the hippocampal neurogenesis in a rat model. Female and male Wistar rats were randomly assigned to four groups: control (without any stimulus); pain, whereas the nociceptive inflammatory stimulus was performed by the injection of the complete freund´s adjuvant (CFA) into the plantar surface of the paw on postnatal day 1; fentanyl (daily injections from PN1-PN8); and analgesia, fentanyl injection 30 minutes before the CFA injection on PN1, followed by daily fentanyl injection from PN2 to PN8. On PN9, 5-bromo-20-deoxyuridine (BrdU) was given, and 24h later the animals were perfused. BrdU+ cells were counted in the subgranular zone of the dentate gyrus of the hippocampus. Kruskal-Wallis was applied, being significant $p<0.05$. We found that the male analgesia group showed greater number of BrdU+ cells compared with the male fentanyl group (p .0005). The female analgesia group also presented with more BrdU+ cells in the dentate gyrus compared to the fentanyl group. Our findings suggested differences at the hippocampal neurogenesis among the male and female rats, following an inflammatory painful stimulus and the fentanyl administration, represented by an increase of the neurogenesis with

CFA and fentanyl administrations. We are still working on more data looking for the explanation for these results.

Number of BrdU+ cells in the dentate gyrus of the hippocampus		
Group	Mean	N
Female Control	8.1	4
Male Control	13.1	4
Female Pain	9.3	4
Male Pain	12.3	4
Female Analgesia	54.6	4
Male Analgesia	52.1	4
Female Fentanyl	20.1	4
Male Fentanyl	7.1	4
BrdU+ cells are expressed by total number of BrdU+ cells/the length of dentate gyrus (μm) multiplied

Title: High aerobic capacity is necessary and sufficient for the beneficial effects of exercise on hippocampal neurogenesis and cognition

Authors: *C. M. TOGNONI[1], J. M. SAIKIA[1], J. DU[1], K. M. ANDREJKO[1], E. A. BABB[2], R. M. PEACE[3], L. G. KOCH[4], S. L. BRITTON[4], L. W. JONES[5], C. L. WILLIAMS[1]
[1]Psychology & Neurosci., Duke Univ., Durham, NC; [2]Sch. of Med., Univ. of North Carolina at Chapel Hill, Chapel Hill, NC; [3]Pathology, Duke Univ. Med. Ctr., Durham, NC; [4]Anesthesiol., Univ. of Michigan, Ann Arbor, MI; [5]Med., Mem. Sloan-Kettering Cancer Ctr., New York, NY

Abstract: It is commonly accepted that exercise (e.g., wheel running or treadmill training) increases hippocampal neurogenesis and cognitive function. However, exercise exerts myriad effects on body and brain, and it is unclear what the contribution of aerobic capacity, the body's ability to consume oxygen, is to these effects. To isolate the role of aerobic capacity in hippocampal plasticity, we exploited selectively-bred rat models of acquired (high/low responders to training: HRT/LRT rats) and inherent (high/low capacity runners: HCR/LCR rats) aerobic capacity. HRT and LRT rats have the same aerobic capacity at baseline, yet after 8 wks of comparable treadmill training, HRT but not LRT rats significantly increase their aerobic capacity. While sedentary LRT and HRT rats had equivalent levels of hippocampal neurogenesis, only HRT rats had increased DCX+ young neurons following training. These data were positively correlated with their performance on pattern separation tasks, which have been shown to be neurogenesis-dependent. Increased aerobic capacity appears to be necessary for exercise to increase in hippocampal neurogenesis and cognitive function. To determine whether high aerobic capacity is sufficient for enhanced hippocampal function, we examined HCR and LCR rats, which have an inherent 2- to 3-fold difference in aerobic capacity. We found that HCR rats also had 2- to 3-fold more DCX+ young neurons in the hippocampus than LCR rats and rats from the heterogeneous founder population. HCR rats also had 4- to 5- fold more newborn BrdU+ cells that had matured into NeuN+ adult neurons compared to LCR rats, but no differences in the number of BrdU+ cells 24 hr after injection, indicating that aerobic capacity has a specific effect on neuronal survival in the hippocampus. In contrast, when neurogenesis in the subventricular zone was examined, HCR rats had more proliferation in this region than LCR rats but did not appear to have more surviving neurons in the olfactory bulb. We asked whether HCR's enhanced neurogenesis translated to enhanced hippocampal cognition, as is typically seen in exercise-trained animals. Compared to LCR rats, HCR rats performed with higher accuracy on pattern separation tasks, and their performance was positively correlated with their levels of hippocampal neurogenesis. Together, these findings demonstrate that aerobic capacity, not exercise *per se*, is critical for enhanced hippocampal plasticity and function. Because human populations are widely variable in inherent and acquired aerobic fitness, these findings have important implications for the recommendation of physical exercise as a cognitive therapy.

Title: Patterns of olfactory bulb cell genesis are altered with long-term, partial deafferentation in adult zebrafish

Authors: D. M. TRIMPE, *C. A. BYRD
Dept Biolog Sci., Western Michigan Univ., KALAMAZOO, MI

Abstract: Our lab has shown that repeated intranasal irrigation with Triton X-100 in adult zebrafish severely alters the olfactory organ and diminishes innervation to the olfactory bulb, resulting in a decrease in bulb volume. Cessation of the treatment allows for reinnervation and recovery of bulb volume. We predicted that patterns of cell genesis could account for deafferentation-induced bulb volume reduction and reafferentation-induced bulb volume recovery. The hypothesis of this study was that the decrease in bulb size, seen after reduced afferent input with repeated detergent ablation of the olfactory epithelium, is due to decreased cell genesis or migration of newly formed cells into the bulb and that cessation of the detergent treatment will result in a reversal of the deafferentation-induced reduction in bulb size through increased cell genesis or migration into the olfactory bulb. First, potential effects on proliferation in the ventricular zone were examined in 3-week chronically Triton X-100-treated fish and in fish allowed to recover for 3 weeks using anti-bromodeoxyuridine, anti-proliferating cell nuclear antigen, and anti-SOX2. Fish were exposed to bromodeoxyuridine via intraperitoneal injection. Cell proliferation in the olfactory bulb was not affected by this deafferentation or by recovery. Additionally, preliminary data showed no observable differences in proliferation in the ventricular zone. Next, migration of newly formed cells into the olfactory bulb was examined by exposing fish to bromodeoxyuridine at the time of the initiation of Triton X-100 treatment, followed by chronic detergent treatment every three days for three weeks. Contrary to our hypothesis, we observed a bilateral increase in anti-bromodeoxyuridine labeled profiles in the olfactory bulb ($P<0.05$ for the treated bulb and $P<0.05$ for the internal control bulb). Allowing the bulb to recover from detergent treatment for three weeks did not reduce this bilateral increase. These findings suggest that recovery of bulb volume after chronic detergent treatment may be due, at least in part, to increased migration of cells into the olfactory bulb internal cell

layer. These studies permit investigation into the adult brain's potential for recovery from physical or functional deafferentation due to injury or disease.

Title: Gluten and casein-derived opiate peptides alter redox status and produce epigenetic-based differences in gene expression

Authors: *N. HODGSON[1], M. TRIVEDI[1], R. DETH[1], A. CLARKE[2]
[1]Pharmaceut. Sci., Northeastern Univ., Boston, MA; [2]A2 Corp. Ltd, Auckland, New Zealand

Abstract: Intolerance to wheat and milk causes symptoms of gastrointestinal (GI) inflammation in sensitive individuals and the prevalence of this intolerance is increasing. GI inflammation can adversely affect the absorption of critical nutrients and can also affect immune cells, which are resident in the intestine. Gluten and casein are prominent proteins from wheat and milk, respectively, and their intestinal hydrolysis gives rise to homologous seven amino acid peptides with opiate activity. A gluten-free/casein-free (GF/CF) diet can relieve symptoms of GI inflammation and is also reported to improve neurological conditions including autism and schizophrenia, as well as reducing autoimmunity. Since oxidative stress and impaired methylation have been implicated in autism and schizophrenia, we examined the influence of gluten- (GM7) and both human and bovine and casein-derived opiate peptides (hBCM7 and bBCM7), on redox and methylation status in cultured SH-SY5Y neuroblastoma cells. All three peptides caused time-dependent changes in cysteine uptake, and levels of cellular metabolites in glutathione synthesis (antioxidant) and methionine cycle (methylation) pathways, similar to, but less extensive than, the effects of morphine. After a 4 hr treatment with hBCM7, bBCM7 or morphine we observed changes in the global pattern of DNA methylation, using MBD-SEQ to identify site-specific changes in CpG methylation. Differential effects of hBCM7 vs. bBCM7 on promoter methylation status could be discerned. Microarray studies revealed differential gene transcription associated with the changes in global DNA methylation. Morphine, hBCM and

bBCM treatment showed both overlapping changes in transcription as well as changes which were distinct for each agent. The changes induced by bovine form of BCM7 were similar to morphine and much different to the human form. This study is the first study to link casein/gluten derived peptides to epigenetic changes in neurological disorders, and provides a novel mechanistic explanation for the benefit of GF/CF dietary intervention for the treatment of autism and other inflammatory disorders. It is noteworthy to mention that, BCM7 is released only from the A1 type of casein and not the A2-beta casein.

Abstract: Neural activity is tightly coupled to energy consumption, particularly sugars such as glucose. Yet we find that, unlike mature neurons and astrocytes, neural stem/progenitor cells (NSPCs) do not require glucose to sustain aerobic respiration. NSPCs within the adult subventricular zone express enzymes required for fatty acid oxidation and show sustained increases in oxygen consumption upon treatment with a polyunsaturated fatty acid. NSPCs also demonstrate sustained decreases in oxygen consumption upon treatment with etomoxir, an inhibitor of fatty acid oxidation. In addition, etomoxir decreases the proliferation of subventricular zone NSPCs without affecting cellular survival. Finally, higher levels of neurogenesis can be achieved in aged mice by ectopically expressing PGC1a, a factor that increases cellular aerobic capacity by promoting mitochondrial biogenesis and metabolic gene transcription. Endogenous neural stem cells are excellent therapeutic targets, retaining the capacity to rebuild and repair tissue in the adult brain by producing new neurons and astrocytes. Since catabolic activity is a fundamental characteristic of a cell, exquisitely optimized to meet energetic needs and constraints, the identification of metabolic substrates required by the adult neural stem cell is imperative to understanding the process of regeneration. Regulation of metabolic fuel availability could prove a powerful tool in promoting cellular proliferation in the central nervous system. Boosting the regenerative potential of the aging brain by providing additional aerobic respiratory capacity may alleviate cognitive deficits associated with normal aging, such as impairments in working memory and olfaction.

Title: Effects of intranasal epidermal growth factor treatment on the subventricular zone after chronic perinatal hypoxia

Authors: *J. SCAFIDI[1], J. EDWARDS[2], J. KURZ[3], V. GALLO[2]
[1]Dept of Neurol. and Ctr. for Neurosci. Res., Children's Natl. Med. Ctr., WASHINGTON, DC; [2]Ctr. for Neurosci. Res., [3]Dept of Neurol., Children's Natl. Med. Ctr., Washington, DC

Abstract: There are no effective treatments available that improve function in the growing population of very preterm infants (<32 weeks gestation) with neonatal brain injury. Diffuse white matter injury (DWMI) is a common finding in these children that contributes to their chronic neurodevelopmental impairment. As we recently published (Scafidi et al., Nature, 2014), using chronic perinatal hypoxia (postnatal day P3-11) as a clinically relevant mouse model of very preterm brain injury, the administration of intranasal epidermal growth factor (HB-EGF; P11-14) stimulates the endogenous response of EGF receptor (EGFR)-expressing progenitor cells in the white matter and promotes cellular, biochemical and functional recovery. It is established that injury results in a significant expansion of the neural stem cells (NSCs) and progenitor cells that reside in the subventricular zone (SVZ). However, it is unknown whether administration of intranasal HB-EGF in the developing brain provides an additive stimulatory effect on newly generated NSCs and progenitor cells after chronic perinatal hypoxia and the specific phenotype of the cells that results from HB-EGF treatment *in vivo*. In this study, we demonstrate the following results in the SVZ after chronic hypoxia: i) a significant increase in phosphorylated-EGFR and EGFR ligand expression immediately after hypoxia but not at later time points; ii) a significant increase in the number of proliferating cells (anti-Ki67+); iii) a significant increase in number of Ascl1-expressing bipotential progenitor cells; and iv) a significant increase in the number of NG2-expressing oligodendrocyte progenitor cells (OPCs). Interestingly, there was a significantly additive, but transient (P15, but not P18) effect on all cell types in the chronic hypoxia group treated with intranasal HB-EGF, while inhibition of EGFR using an antagonist prevented any hypoxia-induced increases in these cell populations. Finally, we also used fate-mapping techniques with tamoxifen-inducible Cre-transgenic mice to demonstrate the effects of chronic hypoxia and HB-EGF on SVZ GFAP-expressing stem cells and PDGFalphaR-expressing progenitor cells. Our results indicate that hypoxia promotes expansion of SVZ progenitor cells and HB-EGF potentiates the effects of the injury. Therefore, understanding the effects of intranasal HB-EGF treatment on the SVZ is crucial in order to develop this treatment as a potential therapeutic strategy for neonatal brain injury arising from very premature birth.

Title: Physical exercise prevents suppression of hippocampal neurogenesis and mitigates cognitive impairment in chemotherapy-treated rats

Authors: *J. HUANG[1], G. WINOCUR[2], J. M. WOJTOWICZ[1]
[1]Physiol., Univ. of Toronto, Toronto, ON, Canada; [2]Baycrest Inst., Toronto, ON, Canada

Abstract: Increasing evidence shows chemotherapy-induced cognitive impairments in humans and rodents. These deficits include confusion, memory loss, decreased attention span, and inability to focus or concentrate. Physical exercise is known to enhance hippocampal neurogenesis and improve cognitive function. In this study we examined the effect of physical exercise on rats that were treated with chemotherapeutic agents. 3-month-old Long-Evans rats (n=37), housed in either standard cages or cages that allowed unlimited access to a running wheel, received intra-peritoneal injections of 5-fluorouracil and methotrexate, or equal volumes of saline. They subsequently underwent a series of cognitive tasks - including spatial memory (SM), non-matching-to-sample rule learning (NMTS), and delayed NMTS (DNMTS) tests. Expression levels of Ki67, doublecortin (DCX) were examined in the dentate gyrus. Analysis of variance (ANOVA) was used to test differences between groups on behavioral measures and cell counts. First, chemotherapy significantly reduced the number of DCX+ cells in the dentate gyrus by approximately 25% ($P=0.02$), while running markedly increased DCX+ cells ($P<0.01$). In addition, rats exposed to running showed evident increases in both Ki67+ ($P<0.05$) and BrdU+/DCX ($P<0.05$) cells. No significant difference in average running distance was observed between saline- and chemotherapy-treated rats ($P>0.25$). Behaviorally, ANOVAs showed significant main effects of chemotherapy on performance in SM, NMTS and DNMTS. Running improved the performance on all these tasks. In summary, we report promising results where the adverse effects of chemotherapy on both hippocampal neurogenesis and behavioral performance were rescued by running, indicating physical exercise as a highly feasible and safe therapeutic intervention against chemotherapy-induced cognitive deficits.

Title: Why social interaction can facilitate adult neurogenesis

Authors: A. M. DIOS, *M.-F. CHENG
Rutgers Univ., NEWARK, NJ

Abstract: We have previously shown that adult neurogenesis in the ventral medial nucleus of the hypothalamus (VMN) can be facilitated by social factors. When a male ring dove is housed with a female mate in comparison to being housed in isolation or with a male, there is a significantly higher level of mature new neurons in the VMN lesion area and an increase in courtship function. In this study, we seek to determine whether an increase in the production of new neurons in males can be explained by properties of the female stimulus or is a result of the male's own activity that engages the circuitry involved in neurogenesis. In study one, male doves were housed with females that they were bonded to versus those that they were not bonded to, namely, two similar stimuli that provoke varying levels of male behavior. The VMN was lesioned and the number of double labeled NeuN+/BrdU+ cells at the lesion site were analyzed using a confocal laser microscope immediately after lesion and at weeks 2,4, and 8 post lesion. Recovery of courtship behavior was measured during these time points. Behavior of all males and the females they were housed with were recorded every three days during the 8 week recovery period. Brain derived neurotrophic factor (BDNF) is closely associated with the neurogenesis process. In study two, we determine whether activity dependent BDNF level is associated with levels of neurogenesis by comparing BDNF levels in bonded versus non-bonded males (ie: males engaged in low versus high courtship activity).

Title: Long-term effects of early exercise on adult hippocampal neurogenesis in aging rats

Authors: *C. M. MERKLEY, C. JIAN, A. MOSA, Y.-F. TAN, J. WOJTOWICZ
Dept. of Physiol., Univ. of Toronto, Toronto, ON, Canada

Abstract: It is well established that early life experience is associated with cognitive ability in old age and the development of neurological disease. The Neurogenic Reserve hypothesis has emerged as a mechanism for cognitive reserve, based on evidence that enrichment maintains neurogenesis at a higher level and results in improved learning and memory. The majority of studies to date have examined short-term consequences of enhancing or blocking neurogenesis but long-term changes with age resulting from early intervention remain less well understood. The goal of this study was to address the hypothesis that early life experience, such as a period of voluntary running in juvenile rats, can alter properties of adult neurogenesis for the remainder of the animal's life. Briefly, male Long Evans rats were grouped into Runners (running wheel access) and Controls (sedentary). After a 30 day running period, cohorts of animals were sacrificed 1 week, 5 weeks, 6 months and 9 months post-running. All animals were injected with thymidine analogues, 5-iodo-2'-deoxyuridine (IdU) and 5-chloro-2'-deoxyuridine (CldU), 1 week and 4 weeks prior to perfusion, respectively. Single and dual-label immunohistochemistry for IdU and CldU was conducted along with other immunohistological markers to assess cellular proliferation (Ki67), neuronal differentiation (Doublecortin (DCX)), survival and maturation (Calbindin (CaBP)) of the labeled adult-born cells. Our results indicate that the number of differentiating neuronal precursors is increased in Runners early on, but within 5 weeks post-running has returned to Control levels. However, the rate of neuronal maturation and survival during a four week period after cell division was enhanced in rats up to 11 months of age (9 months post-running).These results suggest that short term enhancement of neuronal differentiation is under homeostatic regulation, whereas neuronal maturation and survival show long-term alterations with age that do not appear to be regulated in a homeostatic manner. This study is the first to show that a transient period of physical activity at a young age promotes changes in neurogenesis that persist over the long-term, which is important for our understanding of the modulation of neurogenesis by exercise with age. Functional integration of adult-born neurons within the hippocampus that resist homeostatic regulation with aging may be an essential feature of adult neurogenesis that promotes the maintenance of neural plasticity in old age.

Title: Reduction of adult hippocampal neurogenesis via cranial irradiation enhances morphine self-administration and morphine-induced locomotor sensitization

Authors: ***S. E. BULIN**[1], D. R. RICHARDSON[1], K. H. SONG[2], T. D. SOLBERG[2], A. J. EISCH[1]
[1]Dept. of Psychiatry, [2]Radiation Oncology, Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Drugs of abuse dynamically regulate adult hippocampal neurogenesis, a process important for hippocampal-dependent functions such as context learning and memory, context discrimination, and regulation of the stress response. To test the hypothesis that hippocampal neurogenesis is involved in the vulnerability to morphine addiction, we assessed whether ablation of neurogenesis enhances vulnerability to addiction during morphine self-administration (MSA) and morphine locomotor sensitization (MLS). Male Sprague-Dawley rats (~6 weeks old) were exposed to either sham treatment (Sham) or image-guided cranial x-ray irradiation (IRR) to eliminate new hippocampal neurons. Ablation was confirmed via absence of doublecortin+ immature neurons. Six weeks post-IRR when inflammation subsided, rats began either MSA (Sham=16, IRR=15) or MLS (Sham=12, IRR=12). For MSA, IRR rats self-administered more morphine vs. Sham rats ($p<0.019$). This was not a general enhancement of learning, motivation, or locomotion, as operant learning and locomotor activity were unchanged. After 28 days of withdrawal, IRR rats exhibited higher context-induced reinstatement than Sham rats ($p<0.038$). In a separate group of rats used for MLS, IRR rats exhibited a dose-dependent enhancement of

morphine locomotor sensitization, with a greater increase in beam breaks vs. Sham rats when sensitized at 5 mg/kg ($p<0.018$), but similar increases at 10 mg/kg, suggesting a ceiling effect. Irradiated rats also showed increased activity during a dose-response experiment at 1 mg/kg. Along with previous studies, these data indicate that reduced hippocampal neurogenesis confers vulnerability for multiple classes of drugs of abuse. While other irradiation-induced changes (e.g. gliosis) are being considered for their involvement in these behaviors, it is intriguing to consider whether therapeutics that increase or stabilize neurogenesis prevent addiction and/or relapse. Mechanistic studies are also ongoing to explore the involvement of neurogenesis in the neural circuitry underlying the morphine-induced activation of the hippocampus and downstream brain areas, and how this circuitry is altered when adult neurogenesis is ablated.

Title: Fructose impairs neuronal differentiation of adult neural stem cells *in vitro*

Authors: J. A. LEONARD[1], A. L. RAMIREZ GARCIA[1], *N. SPITZER[2]
[1]Biol. Sci., Marshall Univ., Huntington, WV; [2]Dept of Biol. Sci., Marshall Univ., HUNTINGTON, WV

Abstract: In recent decades the consumption of fructose, as high fructose corn syrup in processed foods, has increased dramatically and has now been recognized as a significant health concern. In hepatocytes and adipocytes, high levels of fructose generate uric acid, leading to generation of reactive oxygen species (ROS) that cause cellular damage. Fructose penetrates the blood brain barrier through the Glut5 transporter, but its effects on the mechanisms operating in neurons is not well understood. In animals exposed to a high-fructose diet, cognitive deficits similar to those associated with aging are observed. Reduced neurogenesis is thought to contribute to the cognitive decline in aging, indeed, a high-fructose diet also reduces adult neurogenesis, although the cellular mechanisms by which this occurs is unclear. In mammals,

defined populations of adult neural stem cells (NSCs) are located in the hippocampus and the subventricular zone (SVZ). Here, they continue to proliferate, giving rise to progenitor cells that migrate, differentiate and integrate into existing circuitry where they are involved in plasticity with roles in memory formation, learning, behavioral responses, and reward systems. In addition, NSCs are thought to migrate to damaged brain tissues and contribute to repair. *In vivo* and *in vitro*, NSCs can differentiate into oligodendrocyte, astrocyte, or neuronal phenotypes in response to appropriate chemical signals. Adult NSCs from the SVZ can be maintained as progenitors in culture and plated in conditions that encourage differentiation, allowing investigation of the cellular mechanisms underlying this process at the level of individual cells. This accessible model system has been used to identify many of the exogenous signals that drive differentiation, and the intracellular mechanisms involved. We tested the effects of fructose exposure on the mechanisms underlying differentiation in NSCs cultured from the SVZ of young adult rats. Using immunocytochemistry, we found that the proportion of cells expressing β-tubulin III, an early neuron marker, was reduced in cells cultured in media containing fructose. This indicates that fewer NSCs differentiate towards a neuronal lineage after fructose exposure. Time lapse microscopy revealed that the neurites extended by NSCs cultured in the presence of fructose are less complex, with fewer branch points than those differentiating in control conditions. These results suggest that fructose inhibits the maturation of NSCs towards a neuronal fate. These cellular effects on differentiating NSCs could contribute to the cognitive decline observed in animals subjected to a high-fructose diet.

Sci., Kyushu Univ., Fukuoka, Japan

Abstract: New neurons generated by the neural stem cells (NSCs) in the adult hippocampus play an important role in emotional regulation and respond to the action of antidepressants. Depression is a common and serious side effect of interferon-α (IFN-α), which limits its use as an antiviral and anti-tumor drug. However, the mechanism(s) underlying IFN-induced depression are largely unknown. We characterized the behavior of mice subjected to chronic IFN-α treatment using a comprehensive battery of behavioral tests, and found that the animals exhibited a depression-like behavioral phenotype including learned helplessness and decreased social interactions. Using these mice and a neuronal cell culture system, we found that IFN-α directly suppressed NSC proliferation, resulting in the reduced generation of new neurons. Both systemic and brain-specific mouse knockouts of the IFN-α receptor prevented IFN-α-induced depressive behaviors and the inhibition of neurogenesis, suggesting that IFN-α suppresses hippocampal neurogenesis via its receptor in the brain, to induce depression. These findings provide new insight for understanding the neuropathology underlying IFN-α-induced depression and for developing new strategies for the prevention and treatment of IFN-α-induced depressive effects.

Title: Exercise modifies the neuronal network of newborn dentate granule cells

Authors: *C. VIVAR, B. D. PETERSON, H. VAN PRAAG
Lab. Neurosci., NIH/ Natl. Inst. On Aging, Baltimore, MD

Abstract: The adult mammalian brain continuously generates new neurons in the hippocampus. The integration of newborn neurons into the existing hippocampal neuronal network is considered physiologically important for learning and memory. Enhancement of neurogenesis has been suggested to improve cognition. A simple intervention like exercise increases activity-dependent synaptic plasticity and memory function, and correlates with enhanced adult hippocampal neurogenesis. We previously described that newborn hippocampal neurons are sequentially innervated by structures important for memory function forming a unique neuronal circuit. To understand how exercise enhances learning and memory, it is essential to determine whether physical activity can modify the unique neuronal circuits of the newborn hippocampal neurons. Using a combination of retrovirus to label dividing cells and rabies virus as a retrograde tracer we identified the monosynaptic inputs to the newborn hippocampal neurons in young male C57Bl/6 mice (5-6 weeks old) in sedentary control or exercise conditions. Stereotaxic surgeries were performed to deliver the retrovirus into the right dentate gyrus (DG) of the hippocampus, and several weeks thereafter rabies virus was injected into the same DG location. Preliminary histological analysis shows that both subcortical and cortical afferents to the DG were transsynaptically labeled, and that these projections were modified by voluntary wheel running. In particular, exercise increased cortical input to the newborn granule cells, which may contribute to improved pattern separation and memory storage.

Title: The influence of acetylcholine within the neurogenic niche of the spinal cord

Authors: *S. A. DEUCHARS, L. F. CORNS, L. ATKINSON, J. DANIEL, I. J. EDWARDS, J. DEUCHARS
Univ. of Leeds, Leeds, United Kingdom

Abstract: The area surrounding the central canal of the spinal cord is a highly plastic area that is a postnatal neurogenic niche. Within this region are ependymal cells which may be the source of new astrocytes and oligodendrocytes following injury (Barnabe-Heider et al. (2010), Cell Stem Cell 7: 470-482) and cerebrospinal contacting cells (CSFcCs), the function of which is poorly understood. Acetylcholine in other CNS neurogenic regions has profound effects on proliferation and differentiation (Berg et al. (2013), Development 140: 2548-61); these are mediated through specific nicotinic receptors. To test whether acetylcholine may have similar effects in the spinal cord, we examined the effects of application of cholinergic drugs in acute spinal cord slices and in spinal cord slice cultures. Spinal cord slices were obtained from Urethane (2g/kg i.p.) anaesthetised Wistar rats (9-12 days old) that were transcardially perfused with sucrose aCSF and either maintained for acute whole cell patch clamp electrophysiology or prepared for organotypic culture (Hilton et al. (2006), J. Neurochem 98:690-9). All CSFcCs (n = 82) and ependymal cells (n = 36) responded to focally applied acetylcholine with a robust depolarisation; the responses in CSFcCs (15.7 ± 0.8 mV) were significantly larger than those elicited in ependymal cells (3.0 ± 0.3 mV); lack of effect of tetrodotoxin indicated that the response was direct. The non-α7-containing nicotinic cholinergic receptors (α7*nAChR) antagonist dihydro-β-erythroidinne decreased the cholinergic response in both ependymal cells (3.7 ± 0.7 mV to 1.9 ± 0.4 mV; n = 9) and CSFcCs (16.1 ± 1.8 mV to 3.0 ± 0.5 mV; n = 20, while the α7*nAChR modulator PNU 120596 significantly potentiated the remaining depolarisation in ependymal cells (1.5 ± 0.2 mV to 7.3 ± 1.9 mV; n = 4; $p < 0.05$) and all CSFcCs (3.6 ± 0.7 mV to 27.6 ± 4.0 mV; n = 10; $p < 0.001$); this revealed that both α7*nAChRs and non-α7*nAChRs were mediating the cholinergic responses. Application of α7*nAChR modulators in spinal cord cultures induced proliferation, revealed by increased EdU uptake, in ependymal cells but not CSFcCs. Our study provides evidence that acetylcholine may play a role in modulating the activity of cells within the neurogenic niche of the spinal cord.

Title: Environmental enrichment effects on adult hippocampal neurogenesis in mice: Dorsal vs. ventral dentate gyrus

Authors: *F. GUALTIERI[1], T. BOSWELL[2], T. V. SMULDERS[1]
[1]Inst. of Neurosci., [2]Sch. of Biol., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: The hippocampus is a well-defined anatomical structure belonging to the brain's limbic system that may not act as a unitary structure, with the dorsal (Septal pole) and ventral (Temporal pole) portions of it being involved in different roles. Functionally, it has always been associated with long-term memory and spatial navigation, but it also modulates corticosteroid feedback through the type I & II glucocorticoid receptors and one of its sub regions, the dentate gyrus (DG), is a source for neurogenesis. Our aim is to compare the difference in neurogenesis within dorsal and ventral DG in both standard condition and in an environmental enrichment paradigm to identify which subdivision is more sensitive. In our experiment we used 96 eleven-week-old CD-1 female mice, running four replicate experiments in each of which 24 animals were randomly divided into 4 ENRICHED and 4 CONTROL cages. Enrichment consisted of: i) running wheels, ii) increased space for social activity and iii) murine urinary proteins (MUPs) present in dirty bedding obtained from C57BL6 male mice. The control condition consisted of the standard group housing with minimal enrichment accordingly to UK 3Rs guidelines. Each replicate was conducted for 8 days and their brains were collected as follows: on third were post fixed in 4% PFA-PBS and used for morphological analyses, two thirds were processed for DG dissection. Subsequently, each dissected DG was divided in ventral and dorsal parts and rapidly frozen in dry ice for molecular biology analyses. Immunohistochemistry for Doublecortin (DCX) was carried out in 40 μm slices using the ABC indirect technique with 3,3'-Diaminobenzidine as the chromogen. Images were taken with a 20X objective on a Leica DM-LB microscope and processed with ImageJ to quantify changes in DCX positive surface area within the DG. Molecular biology analysis (quantitative PCR and protein quantification) was carried out on the dissected dorsal and ventral DG of each animal to quantify neurogenesis markers such as DCX. This study helps to clarify the functional differentiation between dorsal and ventral hippocampus and their respective sensitivity to environmental enrichment. Furthermore, using real-time PCR or ELISA assay to measure gene/protein expression allows for a quicker way to quantify hippocampal neurogenesis. This could be used to monitor the welfare condition (e.g. in terms of environmental enrichment in the home cages) of laboratory rodents, as well as in animal models aiming to investigate pathologies in which neurogenesis plays a crucial role (e.g. depression, Alzheimer's disease, etc.).

Abstract: The extracellular matrix (ECM) glycoprotein tenascin-C (TnC) plays an important role during cell proliferation, migration, neurite outgrowth and guidance early in embrional and postnatal development when it is abundantly expressed in neuronal and non-neuronal tissue. Its expression is downregulated in adult CNS with the exception of areas of plasticity and active neurogenesis. Since it is known that exposure of animals to enriched environment (EE) leads to a variety of molecular, cellular and behavioral changes, this study was designed to examine the role of TnC in: 1) structural plasticity of the hippocampus after EE by following the redistribution of perineuronal nets (PNNs) - dynamic structures involved in regulation of neuronal plasticity by immunostaining with Wisteria floribunda agglutinin (WFA), and 2) adult neurogenesis in the subgranular zone of the dentate gyrus by following markers of cell proliferation (BrdU, Ki67 and Dcx). In addition, we investigated the involvement of two ECM degrading enzymes, matrix metalloproteinases 2 and 9 (MMP-2 and MMP-9), in these prossesess by gel and *in situ* zymography. Wild-type (TnC+/+) and TnC deficient mice (TnC-/-) were housed in standard conditions (SC) and EE for 4 and 8 weeks starting from postnatal day 21. Quantitative analysis of WFA signal intensity revealed that TnC +/+ mice reared in SC have higher PNN intensity as compared to TnC -/- mice. On the other hand, we found significant reduction of WFA signal in TnC +/+ mice reared in EE, indicating strong degradation of PNNs

and enhanced structural plasticity induced by EE, while in TnC -/- mice the effect was opposite with slight increase in PNN intensity after EE, thus implying that TnC is necessary for PNN decomposition. Furthermore, we found a significant rise in the number of BrdU, Ki67 and Dcx stained cells in TnC +/+ after EE that also occurred in TnC -/- mice, however, with higher values in both SC and EE as compared to respective groups in TnC +/+, suggesting an inhibitory effect of TnC in adult neurogenesis. Concerning MMP activity, gel zymography revealed increased MMP-9 activity after 4 weeks of EE in the hippocampus of both genotypes, while MMP-2 activity remained unchanged. However, *in situ* zymography showed significantly reduced activity of both MMPs after 8 weeks of EE in TnC +/+ and generally weak activity in TnC-/- animals. These results together emphasize a significant role of TnC in neuronal plasticity and adult neurogenesis, and also imply that interaction between TnC and MMP-9 might be critical in these processes.

Title: Silver nanoparticles interfere with differentiation of adult neural stem cells in culture

Authors: ***R. J. COOPER**, N. SPITZER
Biol. Sci., Marshall Univ., Huntington, WV

Abstract: Silver nanoparticles (SNPs) have unique chemical and physical properties due to their small size and high surface area. They are widely used for their antimicrobial properties in commercial and consumer products, leading to exposure by inhalation or ingestion. At the cellular level, SNPs bypass membranes, disrupt cytoskeletal dynamics, induce oxidative stress, damage DNA, and cause apoptosis or necrosis. Recent studies indicate that SNPs breach the blood-brain barrier and accumulate in the brain. Notably, most work on SNPs examines their effects at concentrations exceeding the levels found in physiological systems, and their effects on

endogenous adult neural stem cells (NSCs) in the brain are not known. NSCs reside primarily within the subventricular zone (SVZ) of the lateral ventricles and in the hippocampus. In a healthy adult brain, these NSCs proliferate, migrate, and differentiate to integrate into existing circuits. The differentiation process results in development of mature cellular properties typical of neurons, astrocytes or oligodendroyctes *in vivo* and *in vitro*. This process of neurogenesis is a normal brain function; it is involved in learning and memory and has been implicated in endogenous repair systems. To investigate the effects of SNPs on the cellular differentiation programs of NSCs, we used an accessible model system of cultured NSCs isolated from the SVZ of young adult rats. These progenitor cells are maintained as neurospheres, and then induced to differentiate by appropriate media conditions. We observed a significant increase in the formation of f-actin inclusions when differentiating NSCs were exposed to sub-lethal levels of SNPs. Chemical enhancement of the SNPs to allow their visualization confirmed that SNPs do not co-localize with the actin inclusions. This implies that the inclusions, which are similar to those observed in response to an actin-stabilizing toxin, are formed due to an SNP-induced disruption of cytoskeletal actin dynamics, instead of being associated with sequestered SNPs. In order to further investigate cytoskeletal effects of sub-lethal SNP exposure, we used B35 neuroblastoma cells, a model for neurite extension, and time-lapse microscopy. We found that exposure to SNPs resulted in a significant decrease in maximum neurite extension. As neurite extension and dynamics are a vital part of NSC differentiation, disruption of cytoskeletal function could lead to a corresponding dysfunction of adult neurogenesis. Therefore, exposure to SNPs released from a wide variety of products may produce a deviation from healthy brain function, and a decreased capacity for learning, memory and endogenous repair.

Title: Doublecortin in the cerebrospinal fluid after hypoxic-ischemic brain injury in the rat neonate is a biomarker of neurogenesis

Authors: C. BREGERE[1], U. FISCH[1], S. LIEB[1], L. CHICHA[1], P. BUSTOS[1], F. GOEPFERT[2], T. KREMER[2], *R. GUZMAN[1]
[1]Dept. Neurosurg., Univ. of Basel, Basel, Switzerland; [2]Pharma Res. & Early development, DTA Neurosci., F. Hoffman-La Roche AG, Basel, Switzerland

Abstract: Study's objectives There is an unmet clinical need to monitor endogenous neurogenesis *in vivo* in developmental brain disorders. Biomarkers of neurogenesis may prove valuable for diagnostic, prognostic and therapeutic purposes. Doublecortin (DCX) is considered as a marker for neurogenesis, because it is highly expressed in migrating neuroblasts. Using a rat model of neonatal hypoxia-ischemia (HI), the study's objectives were to (i) quantify DCX in the cerebrospinal fluid (CSF) of neonates prior to and after an HI brain injury, and to (ii) examine whether DCX measured in the CSF reflects neurogenesis in the brain after HI. **Methods** Right-sided HI was elicited at postnatal day (P) 7 in Sprague-Dawley rats via ligation of the right common carotid artery and 40 minutes exposure to 8% O_2. Control animals received a sham surgery without hypoxic exposure at P7. CSF was collected before (P5) and after (P10) surgery, and DCX was quantified using a specific and highly sensitive immunoassay. BrdU (100 mg/kg) was injected intraperitoneally from P7 to P9. Animals were sacrificed at P10 and their brains were processed for immunohistochemical analysis. **Results** In sham-treated neonates, the concentration of DCX in the CSF (DCX-CSF) decreased by 85% between P5 and P10 (n=11, $p<0.0001$, paired t-test). In contrast, DCX-CSF increased by 123% in HI-injured animals (n=11) during the same time interval. Interaction between postnatal day and treatment was significant (two-way ANOVA $p=0.0197$). In the HI group, a positive correlation between DCX-CSF and stroke severity was observed. DCX immunointensity was increased in the ipsilateral subventricular zone (SVZ) and dentate gyrus from HI-injured animals in comparison to sham animals. The number of BrdU-positive cells was higher in the right SVZ from HI animals versus sham animals ($p<0.01$). **Conclusion** The decline in DCX-CSF in sham neonates between P5 and P10 is in accordance with the well-documented postnatal downregulation of DCX in the brain, and confirms that DCX is a highly developmentally regulated protein. The results after HI suggest that DCX-CSF reflects the neurogenic and proliferative responses in the brain 3 days after the insult. Overall, DCX in the CSF appears to be a valid *in vivo* biomarker of neurogenesis in the rat model of neonatal HI.

Title: *In utero* lead (Pb) exposure and neuron-specific DNA methylation changes in mice

Authors: *Z. FAROOQUI[1], K. M. BAKULSKI[2], C. FAULK[1], A. BARKS[3], D. C. DOLINOY[1]
[1]Univ. of Michigan, Ann Arbor, MI; [2]Johns Hopkins Univ., Baltimore, MD; [3]Univ. of Minnesota, Minneapolis, MN

Abstract: Abstract: Recent human post-mortem evidence indicates that frontal cortex neuronal cells have distinct DNA methylation signatures compared to non-neurons. In addition, the methylation landscape of neuronal cells varies depending on neuronal activity, based on *in vivo* research in adult mice. This evidence suggests that the methylome may be plastic, and particularly sensitive to environmental conditions such as lead (Pb) exposure. Studies in rodents and monkeys exposed to Pb in the first few weeks and first year of life, respectively, suggest that gene expression in the adult brain is associated with early life exposures. Epigenetic epidemiology research in the brain usually examines whole tissue samples comprised of mixed cell types, but it is now clear that epigenetic analyses that target specific cell types may be more informative, particularly since neurons are known to represent approximately only 10% of cells in CNS tissue. Thus, we have conducted a novel study of neuron-specific epigenetic signatures associated with Pb exposure in an isogenic mouse model (wildtype (a/a) mice of the viable yellow agouti strain). Utilizing post-mortem frontal cortex tissues from 10-month old mice exposed perinatally to Pb and controls, we optimized a Fluorescence Assisted Cell Sorting (FACS) assay to separate neuronal nuclei from non-neuronal nuclei in 3 pooled control samples (total n=9 mice) and 6 pooled Pb exposed samples (total n=19 mice). The exposure groups consisted of offspring exposed via the maternal drinking water to 0 ppm, 2.1 ppm, or 32 ppm of Pb two weeks before mating, throughout gestation, and three weeks after birth. Using NimbleGen Promoter Tiling Arrays, we probed DNA methylation levels in the neuron-specific

cell population at a genome-wide level. Using the bioinformatics bumphunting method and a family-wise error rate cutoff of 0.3, we report 3 novel exposure-dependent differentially methylated regions associated with the following genes: *Hnrnpc*, *Skint5*, and *Hnmt*. The role of *Hnmt* (histamine N-methyltransferase) is of particular interest, as it is associated with regulation of neurotransmitter levels. In environmental epigenetic studies of humans, target tissues of interest, such as the brain, are not available until post-mortem. Thus, future studies in the mouse will include an evaluation of brain-specific epigenetic targets in biologically available specimens such as blood in order to identify biomarkers of exposure and neurodegenerative disease risk.

Title: Effect of housing environment on adult neurogenesis in turtles (Chrysemys picta)

Authors: *A. S. POWERS[1], B. HANUSCH[1], A. AYUNRU[1], K. HANINGTON[1], J. GOMEREZ[2], F. KERIN[1], E. LEWIS[1]
[1]Psychology, SUNY Stony Brook, Stony Brook, NY; [2]Psychology, St. John's Univ., Jamaica, NY

Abstract: Adult neurogenesis has been shown to occur throughout the telencephalon in turtles (Perez-Canellas et al., 1997), but the effect of environmental variables on the amount of neurogenesis has not been extensively studied. An enriched living environment and exercise are two variables that have been shown to increase adult neurogenesis in mammals (e.g., Kempermann et al., 1997; Brown et al., 2003). We studied adult painted turtles, Chrysemys picta, housed in different conditions to determine whether there would be an effect on neurogenesis. The experiment had 3 groups of turtles: one housed in an enriched environment, including deep water, group housing, and plastic plants and a hollow log, one (called the exercise control group) given group housing and deep water but no plants or log, and one in which the turtles were housed in individual tanks and shallow water. To detect neurogenesis the turtles were administered 9 injections of BrdU (50 mg/kg) 3 times a week for three weeks at the start of the experiment. Turtles from each environment were euthanized at 1 day, 21 days and 42 days

after the last injection. The results from this experiment showed significantly more neurogenesis in the enriched environment and exercise control groups than in the individually housed turtles but no difference between the exercise control and enriched environment groups. Amount of neurogenesis did not differ by survival time. Thus exercise and social interaction by themselves are sufficient to increase adult neurogenesis in turtles, and adding objects that make the environment more stimulating does not increase the number of new neurons further. The results demonstrate that environmental factors influence neurogenesis in a reptile similar to the ancestors of mammals and suggest that the mechanisms that affect adult neurogenesis have been similar in evolution since before the appearance of mammals.

Title: Abnormal cerebellar synaptic organization induced by postnatal secondhand smoke exposure

Authors: ***P. P. MULDOON**, J. STAFFLINGER, A. OTTENS
Dept Anat. and Neurobio., Virginia Commonwealth Univ., RICHMOND, VA

Abstract: In the last decade, the incidence of secondhand cigarette smoke exposure has not declined for children in the U.S. as reported by the CDC. Evidence continues to mount that environmental tobacco smoke exposure (ETS) increases behavioral and cognitive problems and a risk for mental disorders in children, independent of maternal smoking during pregnancy. This represents a significant burden on society, through treatment and disciplinary costs and also through the loss of productivity. Thus, there is a need to identify the neurobiological relationship between ETS exposure and mental health disorders. The human deficits correlated with ETS exposure suggests cerebellar involvement, which is now regarded for its regulatory function in

executive control tasks. We hypothesize that late-forming and plastic cerebellar circuitry involved in regulating fronto-cortical domains is susceptible to postnatal ETS exposure with functional consequences for executive control tasks. To assess this hypothesis we exposed Sprague-Dawley male rat pups to daily ETS (0 or 100 ug/m3 total suspended particulate) from postnatal day 8 (PD8) through PD22. At PD24 behavioral testing was performed to quantify activity and attentional control in a novel environment. We assessed organizational perturbation within lateral cerebellar circuitry induced with ETS exposure using fluorescence microscopy. We found postnatal ETS exposure induced deficits in attention and inhibitory avoidance. Furthermore, ETS exposure was shown to decrease excitatory vesicular accumulation and synapses at the granular layer (GL). However, synaptic staining revealed an increase in inhibitory synapses and vesicular accretion in the molecular layer (ML). These results suggest there is less mossy fiber input into the GL and in turn less excitatory transmission into the ML. Simultaneously there is an increase in inhibitory synapses which correlates with an increase in GABA production within the ML. Together, these findings reveal the reduced GL mossy fiber input capacity along with an increased threshold for parallel fiber excitation in order to regulate Purkinje cell tonic inhibition, resulting in dysfunctional feedback in refining executive functions. Our data point to the significant effects of ETS inhalation during postnatal critical period initial formation of higher-order circuit, impacting cerebellar organization at both the synaptic and neurotransmitter levels. Future studies will assess the effect of ETS exposure within frontal cortical domains and the underlying biochemical networks involved in this process to help us to further understand the neurodevelopmental impacts of ETS exposure.

Title: Alterations in tryptophan metabolism following maternal intrauterine inflammation

Authors: *M. A. WILLIAMS, L. WOICHIECH, Z. ZHANG, K. RANGARAMANUJAM, S. KANNAN
Johns Hopkins Univ., Baltimore, MD

Abstract: Tryptophan is an essential amino acid, and required for synthesis of serotonin (5HT), but upregulation of an alternate pathway towards kynurenine production reduces the amount available. The kynurenine pathway in itself is neurotoxic, with metabolites such as quinolonic acid associated with oxidative stress and excitotoxicity. Serotonin is an important neuromodulator required for brain wiring. In this study, we evaluated if intrauterine inflammation activated the kynurenine pathway of tryptophan metabolism in fetal brains and placentas, which leads to injury and 5HT depletion. Pregnant rabbits were administered E.coli endotoxin along the uterus on G28 (term=G31). A control group received no intervention. Placenta and fetal brains were harvested after 24 hours (G29), and at postnatal day 1. To investigate the tryptophan pathway we measured the mRNA levels of major enzymes that are involved in the tryptophan pathways, including IDO, KAT and KMO, as well as cytokine IFN-γ. We found that *in utero* endotoxin exposure increased the expression levels of IDO by 20-fold at G29, and ~10 fold at PND 1. The enzyme KAT2 had 2 fold change at G29, but a decrease at PND 1. KMO has had a (~7 fold-change), accompanied with an increase of IFN-γ (~50 fold-change) at G29. The expression levels of IDO (~ 10 fold-change) and IFN-γ (~12 fold-change) are still significantly higher in endotoxin animals than controls at PND1; however, the expression levels of KAT (~2 fold-change) and KMO (~2 fold-change) were significantly decreased at PND1. These results indicate that the activation of tryptophan pathway might be different at G29 and PND1; therefore, these data not only validate the feasibility of the maternal KMO inhibitor treatment, but also provide the basis for the IDO inhibitor treatment at PND1. We have concurrently measured all tryptophan and kynurenine metabolites in the placenta and fetal brain using HPLC techniques. These results are consistent in showing that tryptophan is metabolized to a greater extent along the kynurenine pathway in animals exposed to endotoxin compared to controls. Meanwhile, *in utero* endotoxin exposure slightly increased kynurenine, but significantly increased kynurenic acid level. This indicates that *in utero* endotoxin exposure increased tryptophan metabolism in the placenta along the kynurenine pathway in endotoxin group. In conclusion, maternal intrauterine inflammation results in increased activation of the kynurenine pathway in the fetal and newborn brain. This pathway may be a potent therapeutic target for suppression of toxic metabolites and for restoring serotonin levels that is crucial for the normal development of the somatosensory cortex.

Title: Adult guinea pig ventricular neurogenesis and precursor cell migration

Authors: ***N. A. JARA**[1], M. CIFUENTES[2], F. MARTÍNEZ[1], K. SALAZAR[1], F. NUALART*[1]
[1]Univ. De Concepcion, Concepcion, Chile; [2]Univ. de Málaga, Málaga, Spain

Abstract: Introduction In the mouse brain, neuroblasts generated in the subventricular zone (SVZ), migrate to the olfactory bulb (OB) through a pathway called the rostral migratory stream (RMS). Although the RMS is not present in the human brain, a migratory pathway organized around a ventricular cavity (called extension of the lateral ventricles, eLV) that reaches the OB has been reported. A similar eLV structure is found in the adult guinea pig brain; however, neurogenesis and precursor cell migration has not been described in this species. Therefore, we have analyzed the neurogenic activity and precursor cell migration in the SVZ and eLV of the adult guinea pig brain. **Materials and Methods** We analyzed the SVZ, eLV and OB in 1, 6 and 12 month-old guinea pig brains. We performed bromodeoxyuridine (BrdU) labeling to analyze proliferation. Immunohistochemical analysis, confocal spectral microscopy and transmission electron microscopy were used to study the cytoarchitecture of the guinea pig SVZ and eLV. **Results** We identified neuroblasts (A cells, βIII tubulin +), precursors cells (B and C cells, BrdU +), and ependymal cells (E cells, vimentin +) in the SVZ and eLV. The eLV was lined by ependymal cells and was surrounded by migrating neuroblasts. The average number of neuroblasts per section increased progressively from the SVZ to the BO, reaching 2559 ± 164.5 neuroblasts in the OB. Ultra-structural analysis confirmed our results; the ependymal cells have cilia and microvilli on their apical surface, and neuroblasts and astrocytes were densely packed under the ependymal wall. After 24 h, BrdU labeling revealed that BrdU + cells were mainly located in the SVZ, with few BrdU + cells in the eLV and OB. In addition, the average number of BrdU + cells decreased in the SVZ and increased in the OB 1, 5 and 10 days after BrdU labeling, indicating that neuroblasts migrate from the SVZ to the OB. Finally, analysis of neurogenesis in 1, 6 and 12 month-old guinea pigs revealed that the eLV structure was preserved

in older animals; however, the average number of neuroblasts and BrdU + cells in the SVZ and eLV decreased progressively in older animals. **Conclusions** In the adult guinea pig brain, the eLV connects the LV with the OB in a fashion similar to that described in the human brain. A stream of migrating neuroblasts is organized around the eVL migration path that has no neurogenic potential. In older guinea pigs, neurogenesis decreases in a similar way to that described in other species. Therefore, we propose that the guinea pig brain may be used as a new neurogenic model with closest similarity to that observed in humans.

Title: Hippocampal neurogenesis in short- and long-lived rodents

Authors: D. E. PERAGINE[1], Y. YOUSUF[1], *M. M. HOLMES, PhD[2]
[2]Psychology, [1]Univ. of Toronto Mississauga, Mississauga, ON, Canada

Abstract: Species exhibiting remarkable adaptations, such as extended health and longevity, may reveal insights into physiology and pathogenesis that are not readily apparent in traditional animal models. Naked mole-rats (NMRs; Heterocephalus glaber) are the longest-living rodents known, with a maximum life span of 30 years- 10 times that of similarly sized laboratory mice. In addition to resistance to cancer, NMRs show attenuated declines in physical and cognitive function with advancing age. Although work with traditional short-lived laboratory rodents has established a link between age-related declines in neuronal turnover and cognition, longer-lived mammalian species exhibit low levels of neurogenic activity throughout life, suggesting that stable low rates of neurogenesis may help preserve cognitive function. To determine whether altered profiles of neurogenesis might be associated with longevity in NMRs, we compared cell proliferation and neurogenesis in NMRs and mice. At chronological and developmental stage-

matched time points (birth, infancy, weaning, sexual maturity, adulthood), brains were collected and immunohistochemically processed for Ki67 and Doublecortin (DCX), markers for cell proliferation and immature neurons, respectively. Preliminary data show comparatively low levels of hippocampal Ki67 and doublecortin (DCX) expression in NMRs relative to mice throughout early postnatal life and middle adulthood. Further, although mice exhibit striking declines in proliferative activity with increasing age, relatively stable rates are observed in NMRs. Future investigations will clarify other processes that preserve cognitive function in this species (e.g., resistance to pro-apoptic stimuli), and further develop the NMR as a model for adult neuroplasticity and successful cognitive aging.

Title: Adult neurogenesis in the olfactory bulb and hippocampus of the homing pigeon: A stereological lifetime study

Authors: V. MESKENAITE[1], *H.-P. LIPP[2,3]
[1]Physiol., Univ. of Zurich, Zurich, Switzerland; [2]Univ. Zurich, Zurich, Switzerland; [3]Physiol., Kwazulu-Natal Univ., Durban, South Africa

Abstract: Homing pigeons permit life time studies of brain structures because the age of the animals is routinely documented. This permits purchasing older birds without the need for long periods of housing. We have studied a sample of pigeons spanning the entire lifetime including development and ageing. Age levels included 1 month (n=6), 2 months (n=5), 6 months (n=5), 12 months (n=6), 24 months (n=4), 72-84 months (n=6) and 144-168 months (n=3). One hemisphere was used for assessing Giemsa-stained neuron numbers in the olfactory bulb (periglomerula and granule cell layer), and in the triangular area of the hippocampus, while the

other hemisphere was used for staining and quantification of neuronal proliferation by means of PCNA ((proliferating cell nuclear antigen)), and markers for young neurons such as doublecortin (DCX) and PSA-NCAM (polysialylated-neural cell adhesion molecule). In the *olfactory bulb*, *we observed a strong decrease in postnatal neurogenesis* during the first year of life. Levels of adult neurogenesis decreased further to 5-10% of the levels observed in the youngest pigeons., the number of olfactory neurons remaining fairly constant across age levels. Conversely, *in the hippocampus the number of mature neurons nearly doubled in old birds*, possibly due to increased proliferation. There was an overall reduction in the number of newly generated (DCX-positive) neurons, which possibly became integrated as adult cells. The observed decline in the olfactory bulb might be related to the *increasing attachment to their home loft*, while the changes in hippocampal neurons might reflect *increased navigational experience*.

Title: Protracted postnatal development of neuronal circuits in the hippocampus of naked mole rats

Authors: ***E. KEIMPEMA**[1,2], O. K. PENZ[1], J. FUZIK[2], R. ROMANOV[1], J. LARSON[3], T. J. PARK[3], T. HARKANY[1,2]
[1]Karolinska Institutet, Stockholm, Sweden; [2]Med. Univ. of Vienna, Vienna, Austria; [3]Univ. of Illinois at Chicago, Chicago, IL

Abstract: Naked mole rats are the longest-living rodents. Whether their longevity associates with altered postnatal neuronal turnover, diversification and network wiring remains unknown.

By using high-resolution and quantitative neuroanatomy, we show that neuronal immaturity, defined by molecular marks and the organization of synaptic connectivity and dendritic morphology of CA1-CA3 pyramidal cells and dentate granule cells, persists in the postnatal naked mole rat hippocampus until at least 4 years of age. Dendritogenesis, including dendritic spine formation, was particularly delayed. Likewise, we observed intense neurogenesis in the dentate subgranular zone with extensive migration of the resultant progeny, exceeding that in other rodents. Dentate neurogenesis ceased by 10 years of age and was associated with significant cell redistribution, neuronal apoptosis and gliosis in naked mole rats of advanced age. Correlated patch-clamp electrophysiology measurements in CA1 pyramidal neurons revealed protracted maturation of the hippocampal network, defined as the gradual acquiring of the ability to fire action potentials (APs) and by biophysical AP parameters in naked mole rats. In contrast, dentate granule cells exhibited relatively limited postnatal functional diversity, which we attributed to the rapid turnover and continuous network integration of this cell population. Overall, our data demonstrate that naked mole rats retain a heightened level of neuronal plasticity throughout a prolonged postnatal period. Moreover, our data identify the naked mole rat as a novel model for the analysis of the temporal and cellular control of neuronal network formation.

Title: Multicolor *in vivo* single cell tracking reveals the dynamic behavior of olfactory adult-born neurons during the pre-integration phase

Authors: Y. LIANG[1], K. RIECKEN[2], A. MASLYUKOV[1], D. GOMEZ-NICOLA[3], Y. KOVALCHUK[1], H. PERRY[3], B. FEHSE[2], *O. GARASCHUK[1]
[1]Univ. of Tübingen, Tübingen, Germany; [2]Res. Dept. Cell and Gene Therapy, Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany; [3]Ctr. for Biol. Sci., Univ. of Southampton, Southampton, United Kingdom

Abstract: The olfactory bulb (OB) is one of the brain areas that receive continuous adult-born neural progenitors (NPs) generated in the subventricular zone and the rostral migratory stream (RMS) throughout life, but the rules governing migration and integration of NPs as well as their migration patterns remain unknown. This is partly due to the difficulty of tracking single cells *in vivo* over long period of time. To monitor the migration of adult-born NPs over time, we established a two-photon-based optical imaging approach for precise identification of cell positions in the OB of live mice. This approach, which we called optical brain positioning system (oBPS), combines repetitive blood vessel imaging and red-green-blue (RGB) cell marking. Blood vessel imaging provides a consistent reference for the position of cells. RGB marking of adult-born NPs is achieved by simultaneous injection of three individual retroviral vectors encoding mCherry, Venus, and mCerulean fluorescent proteins in the RMS. RGB marking identified a group of cells expressing differential combinations of the three fluorescent proteins, assigning them a unique color hue and facilitating single-cell analysis. With this oBPS system, we were able to follow the fate of individual adult-born NPs from day-post injection (DPI) 6 onwards until DPI 60. We found that (i) adult-born cells first migrate vividly in the glomerular layer (up to 150 μm per half day) but virtually stop moving by DPI 30; (ii) the fate of cells during this pre-integration phase follows three main pathways: around one third of them settle down by DPI 30 making up the final population of integrated adult-born neurons, one third die before DPI 30, and the remaining cells likely migrate out of the field-of-view. Once in the glomerular layer, cells mostly migrate laterally, i.e. parallel to the surface of the OB. Thus, our study is the first to monitor the life cycle of adult-born NPs during the entire pre-integration phase. It reveals the surprisingly vivid exploratory behavior of adult-born NPs reflected by their long-range lateral migration in the glomerular layer of the OB. In addition, oBPS proves to be an effective tool for *in vivo* cell tracking and could also be applied to other parts of the brain, or the other tissues in live animals.

Title: Nestin expression and the proliferative potential of tanycytes and ependymal cells lining the walls of the 3rd ventricle in the adult rat brain

Authors: *R. E. KALIL[1], I. ZUTSHI[2], C. HASKEN[3], M. HENDRICKSON[1]
[1]Univ. of Wisconsin-Madison, MADISON, WI; [2]Univ. of California San Diego, San Diego, CA; [3]DePauw Univ., Greencastle, IN

Abstract: There is disagreement regarding the rate of cell proliferation in the ependymal cell layer lining the walls of the 3rd ventricle, and the potential of these cells to generate new neurons under normal conditions in the adult mammalian brain. To investigate the proliferative and neurogenic potential of ependymal cells and tanycytes in the walls of the 3rd ventricle, we conducted a comprehensive distribution mapping of the types and location of cells expressing the neural progenitor cell marker nestin along the entire rostral-caudal extent of the 3rd ventricle. We also determined whether ependymal cells and tanycytes in the adult rat brain proliferate under normal conditions or following an injury to the visual cortex. The distribution of proliferating cells was monitored by the incorporation of the thymidine analogue bromodeoxyuridine (BrdU) following seven daily injections of BrdU (150mg/kg) at 24 hour intervals or by the expression of Ki-67, and was compared to the distribution of cells expressing nestin. Abundant nestin was present in tanycyte cell bodies and processes and also was seen in isolated ependymal cells and in patches of ependymal cells in the walls of the 3rd ventricle. We observed very limited cell proliferation by ependymal cells or tanycytes as determined by BrdU incorporation. Typically fewer than 20 BrdU+ cells were seen throughout the rostral-caudal extent of the 3rd ventricle in each brain, and none of these cells expressed nestin. By contrast, more than 200 Ki-67+ cells were observed throughout the rostral-caudal extent of the 3rd ventricle in each brain and 13% of these cells co-expressed nestin. Most of these cells were tanycytes, but some appeared to be ependymal cells. After an injury of visual cortex, we saw no increase in cell proliferation as measured by BrdU incorporation in the walls of the 3rd ventricle. Thus, unlike the close association of nestin expression and BrdU+ cells in neurogenic regions of the brain, such as the subventricular and subgranular zones, as well as in neural progenitor cells in culture, none of the nestin-positive cells in the walls of the 3rd ventricle had incorporated BrdU following seven daily injections of BrdU. It is not surprising that the results with Ki-67 expression are different. While Ki-67 expression demonstrates that a cell has divided, it does not shed light on when this event occurred. In summary, the present results indicate that cell division in the walls of the 3rd ventricle is tightly controlled, but is not completely absent. Moreover, very few cells that have divided express nestin; indicating that the production of new neurons by cells located in the walls of the 3rd ventricle is not likely to be significant.

Title: Serotonergic (5-HT) stimulation of enteric neurogenesis: identification of target neuronal phenotypes and 5-HT4 mediation

Authors: *M. D. GERSHON, A. CHALAZONITIS, M. LIU, Z. LI
Pathology and Cell Biol., Columbia Univ. P & S, New York, NY

Abstract: The enteric nervous system (ENS) develops from neural crest-derived precursor cells (ENCDC). These ENCDC give rise to neurons that are born in a phenotype-related sequence. Because serotonergic neurons are among the first to terminally differentiate, they coexist with still-dividing ENCDC. As a result, 5-HT from enteric serotonergic neurons can influence the differentiation of those neurons that follow the withdrawal of serotonergic neurons from the cell cycle. Indeed, the total number of enteric neurons and particularly dopaminergic, GABAergic, and CGRP-expressing neurons, all of which are late-born, are deficient in transgenic (TPH2KO) mice, which cannot synthesize neuronal 5-HT and in mice that carry a gain-of-function mutation in SERT (G56A), which clears 5-HT from its receptors too rapidly. 5-HT4 agonists, including prucalopride, were found to stimulate enteric neurogenesis in wild-type adult mice but not in those lacking 5-HT4 receptors. We thus tested the hypothesis that 5-HT-promoted enteric neurogenesis is 5-HT4-mediated. ENCDC were isolated from E15 fetal mouse gut with antibodies to p75NTR and cultured in serum-free media. Neurons were identified immunocytochemically with antibodies to Hu proteins. 5-HT and the selective 5-HT4 agonists, prucalopride (2.5 μM) and BIMU-8 (2.5 μM), enhanced the development/survival of total enteric neurons to 135 ± 4 and 133 ± 2 % control; $p < 0.01$); however, prucalopride/BIMU-8 exerted significantly greater ($p < 0.01$) effects on development/survival of late-born neurons, expressing tyrosine hydroxylase (178 ± 17; 179 ± 12 % control; $p < 0.01$) or GABA (160 ± 3; 189 ± 19 % control; $p < 0.01$). These effects were not observed in early-born (calretinin) neurons. The 5-HT4 antagonist, GR113808 (1.0 μM), abolished the enhancement of neurogenesis in response to 5-HT, prucalopride, or BIMU-8. These observations suggest that 5-HT4 stimulation is sufficient to

account for the ability of 5-HT to promote enteric neurogenesis and that late-born enteric neurons are selectively 5-HT4-sensitive; however, further experiments are needed to determine whether other subtypes of 5-HT receptor also contribute to 5-HT-driven enteric neurogenesis.

Title: Alternative splicing and DNA methylation in the developing human brain

Authors: ***P. T. MANSER**[1], M. REIMERS[2]
[1]Dept. of Biostatistics, [2]Dept. of Psychiatry, Virginia Commonwealth Univ., Richmond, VA

Abstract: Recent studies of brain development have detected global changes in gene expression, alternative splicing, and DNA methylation (Kang et al, Nature 2011; Lister et al, Science 2013). An unresolved question is to what extent these coincident genomic and epigenomic changes are actually related. Cancer studies have established DNA methylation in promoter regions as a mechanism for controlling gene expression, but few genome-wide studies have found many such effects in normal tissues. Recent studies have implicated gene body CpG methylation in and around exons as a mechanism for promoting exon inclusion (Maunakea et al, Cell Research 2013). Motivated by these findings, we employ whole-genome expression data from developing brains from the BrainSpan Project to test for correlation between changes in alternative splicing and corresponding nearby changes in DNA methylation. We develop a set of general statistical methods using canonical correlation analysis on summary measures obtained from principal component scores to test for overall association of exon inclusion and DNA methylation. We perform further analysis using obtained canonical covariates to test if observed associations correspond to differences between brain regions or developmental changes over time, or a combination of the two, and test for the plausibility of cis-acting, specific associations using a

permutation test. These methods adapt to the often sparse and irregular coverage of the Illumina HumanMethylation450 BeadChip used in the BrainSpan data. Only a quarter of hg19 exons have a CpG probe within 250 bp, and only 16% of genes with 4 or more exons have a probe within 250 bp of more than half of their exons. Nevertheless, preliminary results show an enrichment of loci-specific associations between splicing and methylation for genes involved in axon guidance, post-synaptic density, and other genes known to have multiple isoforms. Additional studies using emerging technologies assaying DNA methylation at a denser sampling of CpG sites will help further elucidate DNA methylation's role in regulating alternative splicing over brain development. Our methods are readily adapted to other microarrays, sequencing assays, and epigenetic marks.

Title: Immunohistochemical detection of cyclin E in postmitotic neurons of the mouse adult hippocampal dentate gyrus

Authors: *Y. IKEDA[1], M.-A. IKEDA[2]
[1]Dept. of Anat., Aichi-Gakuin Univ. Sch. of Dent., Nagoya, Japan; [2]Section of Mol. Embryology, Grad. School, Tokyo Med. and Dent. Univ., Tokyo, Japan

Abstract: Cyclin E is a member of the G1 cyclins and is essential for the G1/S transition of the cell cycle in proliferating cells. However, it has been reported recently that cyclin E plays a role in synapse function and memory formation in the adult mouse central nervous system, indicating a cell-cycle independent role for cyclin E. We have previously shown that cyclin E is expressed not only by proliferating neurons but also by postmitotic neurons in various brain regions including the cerebral cortex and the cerebellum from embryonic development through adulthood. In the present study, we studied using immunohistochemistry the detailed localization of cyclin E in the adult mouse hippocampus, where new neurons are generated from precursor cells in the subgranular zone (SGZ) of the dentate gyrus. Cyclin E expression was limited to PCNA-negative postmitotic cells located in the SGZ. Cyclin E immunoreactivity was localized to the vertical process of morphologically radial glia-like cells, and some of the cyclin E-positive

cells showed co-localization with neural stem cell markers including nestin and GFAP. Furthermore, cyclin E immunoreactivity was detected in the nucleus of cells, which were double-stained with various stage-specific markers of neurogenesis. The numbers of nuclear cyclin E-positive cells in the SGZ reduced and increased with age and running, respectively, indicating a role for cyclin E associated with neurogenic activity. We also found that the majority of nuclear cyclin E-positive cells were double-stained with active caspase-3, a marker of apoptotic cells. Collectively, these results indicate that cyclin E is expressed in the vertical process of neural stem cells and the nucleus of apoptotic neurons in the adult mouse hippocampal dentate gyrus, suggesting that subcellular localization may be important for the role of cyclin E in each cell type.

Abstract: In vertebrates, the basic brain neural networks are defined during embryonic development. The brain growth spurt occurs postnatally, accompanied by the rapid increases in

cell number and brain volume. It remains unknown, however, how postnatal (post-hatch) neurogenesis contributes to the organization of neural network required for social behaviors. To address this subject, I focused on medaka fish (Oryzias latipes), which is a model animal for molecular genetics and show prominent post-hatch brain growth and behavioral development. First, I analyzed proliferation zones in the young (sexually immature) medaka brain and identified two zones that had not been identified in the adult brain. Next I intended to generate transgenic medaka fish in which post-hatch neurogenesis can be genetically modified. And I generated the transgenic line (HuC:loxP-DsRed-loxP-GFP) that HuC promoter drives specifically in newborn neural progenitors in the adult brain. Further when stochastic recombination was induced by micro-injection of Cre mRNA into the Tg embryos at the 1 cell stage, it resulted that visualization of clonally-related cells in compartmented regions in the telencephalon in the adult medaka brain. Also, heat induction of transgenic embryo (HSP:Cre) led to Cre-recombination in the nervous system. Interestingly, by using this both lines (HSP:Cre and HuC:loxP-DsRed-loxP-GFP), heat induction can induce different Cre-recombination pattern depending on the developmental stages when heat induction was performed. As a result of analyzing stochastic recombinated samples, I identified some clonal units in the telencephalon of adult brain. Finally, by using an infrared laser-evoked gene operator (IR-LEGO) system, induction of heat shock in a micro area in the developing brains led to visualization of clonally-related HuC-expressing cells in the adult medaka fish.

Abstract: Background: Hydrocephalus can develop secondarily to a disturbance in production, flow and/or absorption of cerebrospinal fluid. Experimental models of hydrocephalus are few and limited, and the effects of hydrocephalus on the subventricular zone are unclear. Objective: To analyze the effects of long-term obstructive hydrocephalus on the subventricular zone. Methods: We developed a new method to induce hydrocephalus by obstructing the aqueduct of Sylvius in the mouse brain (P60), thus simulating aqueductal stenosis in humans. The degree of ventricular dilatation and cellular composition of the subventricular zone were studied by immunofluorescence and transmission electron microscopy (n = 18 mice per group). In adult patients (age > 18 years), the sizes of the subventricular zone, corpus callosum, and internal capsule were analyzed by magnetic resonance images obtained from patients with and without aqueductal stenosis (n = 25 per group). Mice with 60-day hydrocephalus had a reduced number of Ki67+ and doublecortin+ cells on immunofluorescence, as well as decreased number of neural progenitors and neuroblasts in the subventricular zone on electron microscopy analysis as compared to non-hydrocephalic mice. Remarkably, a number of extracellular matrix structures (fractones) contacting the ventricular lumen and blood vessels were also observed around the subventricular zone in mice with hydrocephalus. In humans, the widths of the subventricular zone, corpus callosum, and internal capsule in patients with aqueductal stenosis were significantly smaller than age and gender-matched patients without aqueductal stenosis. Conclusion: Supratentorial hydrocephalus reduces the proliferation rate of neural progenitors and modifies the cytoarchitecture and extracellular matrix compounds of the subventricular zone. In humans, this similar process reduces the subventricular niche as well as the width of corpus callosum and internal capsule.

Title: Age-related changes of neurite density and fiber orientation dispersion in white matter during childhood brain maturation

Authors: *J. P. OWEN, Y.-S. CHANG, T. THIEU, N. POJMANN, P. BUKSHPUN, E. SHERR, P. MUKHERJEE
UCSF, SAN FRANCISCO, CA

Abstract: The human brain undergoes an extended period of postnatal development, with white matter (WM) maturation continuing through adolescence and even into adulthood. Studies using diffusion tensor imaging (DTI), a technique which provides information about tissue microstructure, have demonstrated widespread, nonlinearly increasing fractional anisotropy (FA) over age. However, DTI lacks the specificity to disentangle individual microstructural features such as myelination and axonal fiber density. Neurite orientation dispersion and density imaging (NODDI) offers advantages as a multi-compartmental biophysical model of WM microstructure (Zhang et al., 2012) that can infer the non-collinear properties of fiber orientation dispersion (OD) and neurite density (ND), corresponding to the degree of incoherence in fiber orientations and to the intracellular volume fraction, respectively. In WM, ND can be considered equivalent to axonal density. In this work, we study WM maturation in a group of 68 human subjects (ages 7-63 years, 29 female, 39 male) using both DTI and NODDI. We also quantify the test-retest reliability of FA, OD, and ND in 5 of these adult subjects who were each scanned 2-4 times. High resolution 3T structural MRI was acquired, as well as whole-brain diffusion-weighted MRI using 30 directions at b=1000 s/mm^2 and 64 directions at b=3000 s/mm^2. Postprocessing included motion and eddy current correction, brain extraction, and DTI as well as NODDI fitting to calculate maps of FA, OD and ND. Using Tract-Based Spatial Statistics (TBSS) in FSL, the FA maps from all subjects were registered to and skeletonized using FSL's MNI152-registered FMRIB FA template. Global values of FA, OD and ND were obtained for each subject by averaging over each whole-brain skeletonized WM map. Additionally, regional tract values were obtained for each subject from WM skeleton voxels using the ICBM-DTI-81 White Matter Labeled Atlas. We find that ND increases significantly and globally in WM throughout late childhood, adolescence and adulthood through middle age, while OD exhibits weaker increases globally in WM, and, in fast-maturing central white matter tracts, remains relatively constant through late childhood, adolescence and adulthood through middle age. ND and OD demonstrate comparable test-retest reliability to that of FA, with coefficients of variation of 1.8% (OD), 1.0%

(ND), and 1.1% (FA) for the global WM skeleton. We conclude that the rising FA of human white matter development from childhood to young adulthood is driven by large increases of ND, i.e., axonal density, which outweighs the smaller age-related increases of OD that would otherwise cause diminishing FA.

Title: Ectopic granule cells in the dentate gyrus of normal mice: Dependence on age, septotemporal location, and survival of hilar progenitors

Authors: *K. BERMUDEZ-HERNANDEZ[1,2], J. J. LAFRANCOIS[1], J. MORETTO[1], H. E. SCHARFMAN[1,2]
[1]The Nathan Kline Inst., Orangeburg, NY; [2]New York Univ. Sch. of Med., New York, NY

Abstract: The migration of neurons to their correct destination is essential for normal function. We and others have shown that mismigrated neurons in the dentate gyrus (DG) can develop in pathological conditions. In many rodent models of temporal lobe epilepsy (TLE) substantial numbers of mismigrated granule cells (GCs) are found in the hilus, and there is a positive correlation between seizure frequency and the numbers of these hilar “ectopic” GCs (hEGCs). Remarkably, it is not known to what extent mismigrated GCs exist normally. Furthermore, it is not clear if all hEGCs are caused by mismigration, because they may develop simply because hilar progenitors (and their progeny) survive. The goal of this study was to determine 1) whether hEGCs exist in normal mice, 2) their septotemporal distribution, and 3) if increasing survival of progenitors early in postnatal development could lead to an increase in hEGCs. To address these questions we quantified hEGCs, defined by the GC marker Prox1 and neuronal marker NeuN

using C57B6/J mice at postnatal day (P) 16 (n=4), P30 (n=5), and P60 (n=4). In addition, we increased survival of progenitors and their daughter cells by removing the proapoptotic gene BAX with a tamoxifen (TAM) injection at P2-P8 using NestinCreERT2 Baxfl/fl mice (NCBaxfl/fl). Animals were examined at P60 (TAM-treated, NCBaxfl/fl, n=7; TAM-treated, Baxfl/fl, n=7; vehicle-treated, NCBaxfl/fl, n=3; vehicle-treated, Baxfl/fl, n= 7). To quantify hEGCs along the septotemporal axis we separated one whole hippocampus from the rest of the brain and sectioned it perpendicular to the long axis (1 every 5th section). We also used conventional coronal and horizontal sections. The highest hilar Prox1 cell density was at P16, followed by P30 and then P60 (one-way ANOVA, $p< 0.0001$). Preliminary results suggest that at P16 most of the Prox1 cells in the hilus do not express NeuN but this proportion increases substantially after P30 suggesting a role of puberty (Fisher's exact test, $P<0.0001$). The density of Prox1 cells was highest in the septal hippocampus regardless of age (two-way ANOVA, $p<0.0001$). Also, increasing the survival of nestin-expressing progenitors and their daughter cells postnatally increased hilar Prox1 cell density at P60 (One-way ANOVA, $p= 0.0003$). The results suggest that 1) hEGCs exist normally and continue to develop during puberty, 2) the septal DG is the primary site of hEGCs and 3) hEGCs can form by increasing survival of hilar progenitors. We suggest that early life is a time when the DG is susceptible to hEGC formation because of a large population of hilar progenitors at that age.

Title: Human and monkey striatal interneurons are derived from the medial ganglionic eminence but not from the adult subventricular zone

Authors: D. QI, *Z. LIU, C. WANG, Y. YOU, X. ZHOU, S. WEI, Z. ZHANG, W. HUANG, F. LIU, Z. YANG
Fudan Univ., Shanghai, China

Abstract: In the adult rodent and monkey brain, newly-born neurons in the subventricular zone (SVZ) in the wall of the lateral ventricle migrate into the olfactory bulb (OB) via the rostral migratory stream (RMS). However, a recent study reported that there are constantly generating neurons in the adult human striatum from the SVZ. In contrast, by taking advantage of the continuous expression of the zinc finger transcription factor Sp8 from the neuroblast stage through differentiation into mature interneurons, we found that the adult human SVZ does not generate new interneurons for the striatum.In the adult human SVZ and RMS, very few neuroblasts were observed and most of them expressed Sp8. Neuroblasts in the adult rhesus monkey SVZ-RMS-OB pathway also expressed Sp8. In addition, we observed that Sp8 was expressed by most adult human and monkey OB interneurons. However, very few Sp8+ cells were in the adult human striatum. This suggests that neuroblasts in the adult human SVZ and RMS are destined for the OB, but not for the striatum. BrdU-labeling results also revealed few if any newly-born neurons in the adult rhesus monkey striatum. Finally, on the basis of transcription factor expression, we provide strong evidence that the vast majority of primate interneurons in the striatum are generated from the medial ganglionic eminence during embryonic developmental stages, as they are in rodents. We conclude that, although a small number of neuroblasts exist in the adult human SVZ, they do not migrate into the striatum and become mature striatal interneurons.

Abstract: In the adult rodent and monkey brain, newly-born neurons in the subventricular zone (SVZ) in the wall of the lateral ventricle migrate into the olfactory bulb (OB) via the rostral migratory stream (RMS). However, a recent study reported that there are constantly generating neurons in the adult human striatum from the SVZ. In contrast, by taking advantage of the continuous expression of the zinc finger transcription factor Sp8 from the neuroblast stage through differentiation into mature interneurons, we found that the adult human SVZ does not generate new interneurons for the striatum.In the adult human SVZ and RMS, very few neuroblasts were observed and most of them expressed Sp8. Neuroblasts in the adult rhesus monkey SVZ-RMS-OB pathway also expressed Sp8. In addition, we observed that Sp8 was expressed by most adult human and monkey OB interneurons. However, very few Sp8+ cells were in the adult human striatum. This suggests that neuroblasts in the adult human SVZ and RMS are destined for the OB, but not for the striatum. BrdU-labeling results also revealed few if any newly-born neurons in the adult rhesus monkey striatum. Finally, on the basis of transcription factor expression, we provide strong evidence that the vast majority of primate interneurons in the striatum are generated from the medial ganglionic eminence during embryonic developmental stages, as they are in rodents. We conclude that, although a small number of neuroblasts exist in the adult human SVZ, they do not migrate into the striatum and become mature striatal interneurons.

Title: The fine structure of adult neural stem cells in the hippocampal neurogenic niche

Authors: *J. MOSS[1], E. BUSHONG[2], M. H. ELLISMAN[2], N. TONI[1]
[1]Dept. of Fundamental Neurosciences, Univ. of Lausanne, Lausanne, Switzerland; [2]Natl. Ctr. for Microscopy and Imaging Res. (NCMIR), Univ. of California, San Diego, CA

Abstract: New neurons are born into the dentate gyrus throughout adult life. They develop from a pool of self-renewing radial glia-like (RGL) stem cells, which divide and differentiate into mature granule cells that are capable of functionally integrating into the hippocampal circuit. The RGL stem cells that give rise to new neurons have a very curious morphology. From their subgranular cell bodies, they extend a substantial primary process radially through the densely-packed granule cell layer to the molecular layer. This process then splits into secondary processes that branch extensively, forming a dense plexus of fine glia-like processes. This complex structure raises a couple of questions: 1) Does their structure enable the stem cell to interact with other components of the neurogenic niche? 2) What signals could they be receiving, and for what purpose? To begin answering these questions, we first examined the fine structure of RGL stem cell processes using light and electron microscopy. Nestin-expressing RGL stem cells were labelled in a Nestin-GFP transgenic mouse, using either an immunoperoxidase or immunogold protocol, before imaging. Analyses showed that the fine processes of the stem cell possessed mitochondria-containing varicosities at regular intervals, which gave rise to further processes that wrapped local synapses in a glia-like fashion. However, due to the large number of stem cell processes, very few astrocytic processes could infiltrate the same region. Determining the neurochemical nature of the stem cell-wrapped synapses is currently underway. Processes also wrapped around nearby blood vessels, with a pronounced thickening and more cytosolic mitochondria where they met. When the primary process of the stem cell grew into a region containing a blood vessel, its regularly branching tree of processes became warped, with some secondary processes targetting the blood vessel and others maintaining a regular structure separately. Analysing the fine structure of RGL stem cell processes has revealed a close relationship with both local synapses and blood vessels within the neurogenic niche. This suggests that RGL stem cells could use their fine processes to assess their local environment and determine if new neurons were needed, or might survive, in their vicinity.

Title: Survival and maturation of the developmentally-born cell population in the rat dentate gyrus

Authors: *S. P. CAHILL, R. Q. YU, J. S. SNYDER
Dept. of Psychology, Univ. of British of Columbia, Vancouver, BC, Canada

Abstract: The discovery that neurons are added to the adult brain of nearly all mammals examined, including humans, has had profound effects on our understanding of the potential for plasticity in the brain. In the dentate gyrus, adult-born neurons have enhanced plasticity and contribute to the mnemonic and emotional functions of the hippocampus. Furthermore, the stages of adult neurogenesis and the factors that regulate neuron addition in adulthood have been relatively well-characterized. In contrast, less is known about how developmentally born cells integrate and survive over time and how these processes are regulated by experience. Since the dentate gyrus is comprised of large numbers of adult-born and developmentally-born cells, identifying the properties of these two populations is essential for understanding how the dentate gyrus, as whole, contributes to behavior. To address this question we used BrdU to label dentate gyrus neurons born on postnatal day 6 in rat pups, the peak of dentate gyrus development. We quantified BrdU+ cells in 2 and 6 month-old rats and found 30% fewer BrdU+ neurons at the 6 month time point, indicating substantial loss of mature, developmentally-born cells throughout adulthood. This contrasts with adult-born cells, which show stable survival after reaching maturity. Despite the significant death of developmentally-born cells, our preliminary results suggest that this cell death can be offset by exercise between 2 and 6 months of age. Ongoing experiments will additionally examine the survival and maturation of developmentally-born cells at earlier timepoints, similar to the work that has been done in characterizing adult neurogenesis. Collectively, our findings indicate that the survival and turnover of developmentally-born cells greatly influences the composition of the adult dentate gyrus. The sensitivity of these cells to experience also suggests they may make novel contributions to dentate gyrus plasticity throughout adulthood. These findings are relevant for understanding the role of the dentate gyrus in learning and memory as well as conditions such as aging and disease where neurons are lost.

Title: Calorie restriction prevents age-related decreases in neurogenesis and preserves the neural stem cell niche

Authors: ***D. M. APPLE**, R. S. FONSECA, C. ZHU, S. MAHESULA, E. KOKOVAY

Abstract: The aging brain faces many challenges- memory and cognitive deficits, structural changes, and decreased plasticity. Aging is a major risk factor for increased susceptibility to damage from brain insults like stroke, inflammation, and disease. As the brain ages, it loses the capacity to make new neurons, which decreases its ability to respond to damage. Protecting the brain's potential to produce new neurons from neural stem cells is paramount for maintaining healthy brain aging. Calorie restriction (CR) can improve physiological markers of health during aging, including extending lifespan and protecting against age-related damage to the brain. The largest source of neural stem cells in the adult brain is harbored in the subventricular zone, but it is unknown if this neural stem cell population is altered by CR. We sought to determine the effect of CR on neurogenesis and neural stem cell survival in the subventricular zone of young and aged mice. Consistent with published reports, aged mice fed standard control chow showed fewer subventricular zone derived neurons in the olfactory bulb, indicating that aging impairs neural stem cell function. CR preserved neural stem cell function and resulted in a significant increase in neurogenesis in aged mice compared with ad libitum- fed controls. Furthermore, we observed a marked increase in cellular senescence in the subventricular zone in aged mice on control diet compared to young mice. This was significantly reduced in aged CR mice, which displayed rare senescent cells with expression levels similar to young mice. Confocal imaging and fluorescent staining of subventricular zone wholemounts revealed an increase in both the total number and reactivity of microglia in the aged control mouse, suggesting increased

inflammation in the neural stem cell niche during aging. Remarkably, these age-related inflammatory markers were not observed in the CR aged mice, which appeared no different from young control and young CR mice included in the study. These initial experiments have revealed a protective role for CR in the aging subventricular zone, and are an important first step in understanding how CR may be an effective therapeutic intervention for the aging or damaged brain.

Title: Inflammation in the aging neural stem cell niche

Authors: *R. SOLANO FONSECA[1], R. RAGHUNATHAN[2], A. DUGAN[1], E. KOKOVAY[1]
[1]Univ. of Texas Hlth. Sci. Ctr. At San A, San Antonio, TX; [2]Boston Univ., Boston, MA

Abstract: The subventricular zone (SVZ) is the largest reservoir of neural stem cells (NSCs) in the adult brain. Neurogenesis is reduced during aging and this decline in NSC function is thought to contribute to reduced brain function. Here we propose immune activation as a contributor to age-related declines in NSC function. We observed a sharp decrease in neurogenesis in mice between the ages of six and twelve months. Neuroblast number was also reduced with age. Microglia are the prominent immune cells in the brain. Microglia were observed throughout the SVZ niche and were observed at the level of the ependymal compartment and the vasculature plexus. At the ependymal compartment, microglia processes can be observed intercalated between ependymal cells and close to pinwheel structures. Microglial activation results in the

release of proinflammatory cytokines. Interestingly, the number of microglia cells in the SVZ was observed to increase during aging. Furthermore, both morphological changes and increased CD68 expression were observed during aging, indicative of microglia becoming more activated. In conditioned media (CM) experiments, a higher amount of cleaved Caspase-3 staining was observed in NSC cultures using microglia CM, compared to controls indicative of higher levels of apoptosis. In addition, β-tubulin staining revealed a reduction in neurogenesis when microglia CM was used compared to controls. Our results suggest that during aging there is increased inflammation in the SVZ which may be an important contributor to declines in neural stem cell function.

Title: Rapid generation of sub-type specific neurons and neural network from human pluripotent stem cells derived neurosphere

Authors: *A. N. BEGUM[1], Y. HONG[1,2]
[1]Stem cell and Nanotoxicity Lab, Col. of Vet. Med., [2]Grad. Col. of Biomed. Sci., Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Rapid and efficient generation of sub-type specific neurons and neural networks from neurosphere provide the platform for disease modeling and cell therapy. In neurotransplantation, neurospheres are commonly used as neuroprogenitors but neurosphere derived subtype specific neurons or their region specificity is not yet well established. Neurosphere derived neuronal culture usually stays as clump which makes them very difficult to study. Here, we describe a detailed protocol for direct differentiation of different layers of cortical, pyramidal, GABAergic, glutamatergic, cholinergic and dopaminergic neurons from human embryonic and induced pluripotent stem cells (h/iPSCs) derived neurosphere. In this protocol, we provide a total 27 days of neuronal differentiation timeline including generation of fully functional neurons which is

faster than traditional protocol takes about 80-days. The neurons derived from this protocol have fully functional synapses which spontaneously active to fire action potentials and form neural network *in vitro*. Two critical additional steps are novel in this protocol, first step is to initiate the neuronal differentiation with knockout serum replacement medium (KSRM) and incubate the cells at 10% CO2. We found 10% CO2 culture condition increased 2-folds neuroprogenitors gene expression compared to 5% CO2. Second, we introduced an AdSTEP mechanical procedure to generate smaller fragments that facilitates the robust and homogenous neural population which always been challenging for neurosphere based neuronal culture. Furthermore, we also provide side by side comparison of our neuroshere with standard neuroectoderm based culture and found neuroprogenitors from neurosphere stable overtime and continuously can give rise large percentage of neurons compared to neruoectoderm based neuronal culture. Therefore, neurosphere based neuronal culture is valuable tool to study molecular mechanisms of neurogenesis, neural development and cellular therapeutics for a variety of neurological diseases.

Title: 17q21.31/WNT3-WNT9b CNVs accelerates dopaminergic neuron differentiation from hPSCs

Authors: *C.-T. LEE, A. A. KINDBERG, R. M. BENDRIEM, L. T. WORDEN, M. P. WILLIAMS, T. DRGON, B. S. MALLON, B. K. HARVEY, C. T. RICHIE, R. S. HAMILTON, G. R. UHL, W. J. FREED
Cell Neurobiol. Res. Br., IRP, NIDA, NIH, DHHS, BALTIMORE, MD

Abstract: Prolonged culture of hPSCs can lead to chromosomal abnormalities as well as more subtle genetic alterations, any of which can affect the properties of hPSC lines. We examined associations between copy number variations (CNVs) on chromosome 17 and hPSC mesodiencephalic dopaminergic (mDA) differentiation. Five karyotypically-normal hPSC lines (BG01, 02, 03, ES02, 04) and one trisomy 17 line (BG01V2) were examined. All displayed similar survival rates and normal morphology. BG01V2 and BG03 showed enhanced rates of proliferation, and lost pluripotency more rapidly than other cell lines following withdrawal of

basic fibroblast growth factor (bFGF). BG01V2 and BG03 also displayed rapid mDA differentiation, with earlier generation of $LMX1A^+$ mDA progenitors and TH/ $TUJ1^+$ DA neurons. Since BG01V2, with trisomy 17, underwent rapid mDA differentiation, CNV analysis was focused on chromosome 17. A genomic duplication located at 17q21.31 was identified in BG03, encompassing the *WNT3-WNT9* gene cluster, two candidates for involvement in mDA differentiation. Additional copies of *WNT3* and *WNT9B* in both BG01V2 and BG03 were confirmed by qPCR. We also screened an additional 18 hPSC lines for extra copies of *WNT3*/*WNT9B*. Among several hPSC lines with increased levels of *WNT3* and/or *WNT9B* DNA, CT3 was examined and showed rapid differentiation similar to that of BG01V2 and BG03. WNT3 and WNT9B act *via* the β-catenin (canonical) and the Rho/JNK (non-canonical) signaling pathways, respectively. To examine the roles of *WNT3-WNT9B* CNVs in mDA differentiation, we used canonical (DKK-1) and non-canonical (SP600125) signaling inhibitors as well as lentiviral vectors to overexpress or silence *WNT3* and *WNT9B* expression. In hPSC with amplified *WNT3-WNT9B*, DKK-1 treatment or WNT3 knockdown reversed both enhanced proliferation in the undifferentiated state, and accelerated mDA differentiation, decreasing mDA markers including LMX1A, TUJ1, and TH in cells with amplified *WNT3/WNT9B*. SP600125 treatment or WNT9B knockdown reversed the accelerated loss of pluripotency in hPSCs with amplified *WNT3-WNT9B*. Conversely, in control hPSCs WNT3 overexpression in increased undifferentiated proliferation and mDA differentiation, while WNT9B overexpression accelerated departure from pluripotency. Thus amplification of *WNT3* and *WNT9B* causes multiple changes in hPSC function and mDA differentiation. Enhanced non-canonical Rho/JNK pathway signaling *via* WNT9B promotes early differentiation and departure from pluripotency, while enhanced canonical/β-catenin signaling *via* WNT3 accelerates subsequent mDA specification *via* up-regulation of LMX1A.

Abstract: Neurons, astrocytes, and oligodendrocytes-the three major cell types that comprise the central nervous system-are generated from common multipotent stem cells. Many reports have shown that astrocytes can be generated from various tissue sources including human pluripotent stem cells (PSC). In this presentation, we describe a chemically defined medium culture system for rapidly generating astrocytes from neural precursor cells derived from human embryonic stem cells. We found that neural and astrocyte precursor stage had the advantage for making pure astrocytes. Gene expression patterns were investigated in astrocytes generated by our method. We have tried to investigate the role of some genes during astrocyte differentiation.

Title: Using human embryonic stem cells to understand *in vitro* cortical excitatory neurogenesis and lineage

Authors: ***S. KU**, J. CLOSE, B. GREGOR, J. GRIMLEY, A. JAYABALU, A.-R. KROSTAG, B. LEVI, R. MARTINEZ, R. MAY, V. MENON, H. MULHOLLAND, A. NELSON, K. NGO, N. SHAPOVALOVA, M. SMITH, C. THOMPSON, E. THOMSEN, A. WALL, Y. WANG
Allen Inst. For Brain Sci., Seattle, WA

Abstract: *In vivo* human brain development remains one of the greatest challenges of scientific understanding, and while previous efforts at the Allen Institute for Brain Science have focused on the adult human brain, the *In vitro* Human Cell Types program is currently taking an alternative approach by studying *in vitro* differentiation and development using human pluripotent stem cells. Specifically, using a modified version of a previously developed method for neural induction via dual-SMAD inhibition, we are differentiating embryonic stem cells (ESCs) to forebrain cortical progenitors followed by maturation into cortical excitatory neurons. At pre-determined time points, cells are collected and analyzed by flow cytometry,

immunocytochemistry, Fluidigm qRT-PCR, and population and single-cell RNAseq to interrogate the gene expression changes that occur and/or changes that may be causal. Additionally, we employ a cell line engineering platform that allows for the efficient generation of targeted, genome-modified ESC lines of interest, including reporter and knockout lines. The use of these reporter lines then allows us to isolate specific cell populations of interest to further investigate their gene expression profiles as well as developmental potential/lineage. These approaches, together with various computational methods for analyzing these data, will allow us to generate hypothetical "maps" of neuronal differentiation and cell lineage relationships. Subsequently, iterative testing of these hypothetical maps using the same analytical tools we have developed as well as engineered reporter or knockout ESC lines will allow us to refine our lineage map, ultimately helping to further our understanding of cortical development.

Title: Authentic midbrain dopamine differentiation of pluripotent stem cells requires the coordinated regulation of En2, Foxa2 and Lmx1a expression

Authors: ***J. CAI**, E. W. KOSTUK, L. M. IACOVITTI
Farber Inst. Neurosci, Dept Neurosci, Thomas Jefferson Univ., PHILADELPHIA, PA

Abstract: Midbrain dopamine (mDA) neurons derived from human pluripotent stem cells (hES or hiPSC) are a promising cell source to be used in cell replacement therapy of Parkinson Disease (PD) or as a PD cell model. In recent years, small molecule inhibitors and agonists have been added to the differentiation protocols to produce mDA neurons, including the BMP

inhibitor dorsomorphin (DM), TGF β inhibitor SB431542 (SB) and SHH agonist purmorphamine (Pur). Previously, we developed a protocol which mimics mDA differentiation *in vivo* by combining these molecules with the growth factor FGF8. Here, using a careful time course study, we examine the effects of individual or combined molecules on mDA differentiation in monolayer hES cell cultures. We find that all four substances in our cocktail are necessary to produce a true mDA phenotype in stem cells. DM alone promotes pan-neurogenesis including GABAergic and Glutamergic neurons. Neither SB nor Pur alone efficiently drive neurogenesis or an mDA phenotype in cells. Only the combined treatment of all 4 reagents yielded cells labeled by mDA markers Lmx1a, Foxa2 and TH. Importantly, these cells also expressed high levels of En2 both at the neural progenitor stage and the mDA neuron stage. This is the first demonstration that in addition to Lmx1a and Foxa2, En2, must be expressed in cells with an authentic mDA phenotype, a proposition supported by our mouse developmental studies. Finally, in our previous studies, the transcription factor SMAD-interacting protein (SIP1) was identified as a key player regulating mDA differentiation following induction by SMAD inhibitors DM/SB in our cocktail. Importantly, expression levels for all 3 mDA-specifying genes (Lmx1a, Foxa2, En2) were dramatically reduced in SIP1 knockdown experiments, indicating their coordinated regulation by SIP1. Ongoing studies are aimed at understanding the pathways regulating an authentic mDA differentiated phenotype in stem cells.

Biol., Yamaguchi Univ. Sch. of Med., Ube, Japan; [4]UMR7216 Epigenetics and Cell Fate,, CNRS, Paris, France; [5]Univ. Paris Diderot, Paris, France; [6]Dept. of Cell and Neurobiology, Keck Sch. of Med., USC, Los Angeles, CA

Abstract: Prenatal environmental challenges, such as maternal stroke and drug use affect fetal cortical development, thereby increase the risk of intellectual disability, epilepsy and so on. Heat Shock Factor 1 (HSF1) - Heat Shock Protein (HSP) signaling (HSF1-HSP signaling) is required to protect the embryonic cortex from exposure to a variety of environmental challenges, thereby reduces the risk of the mental disorders (Hashimoto-Torii K. et al, Neuron, 2014). In contrast to general assumption that HSF1-HSP signaling is equipped equally by most types of the cells for their protection, here, we show that HSF1-HSP signaling is activated at various levels among the cells in the fetal cortices exposed to the environmental challenges and that this variable activation may be a cause of cortical dysplasia. First we tested HSF1-HSP signaling activation in human iPSCs-derived neural stem/progenitor cells (NSPCs) under exposure to ethanol, hydrogen peroxide, and methyl mercury by quantifying the number of HSP70 mRNA using single molecule Fluorescence *In situ* Hybridization (smFISH). In contrast to the consistent expression of housekeeping genes including GAPDH, HSP70 expression shows significant variability among NSPCs in response to these environmental challenges. This result suggests that HSF1-HSP signaling is activated at different level in individual cells by a variety of environmental challenges. By generating *in vivo* mouse fluorescence reporter system for the HSF1-HSP signaling, we also confirmed the heterogeneity of the activation in fetal cortices exposed to environmental challenges. We next examined potential effects of the bursty activation of the signaling that is induced in a part of cells exposed to the challenges on cortical development. By introducing constitutively active form of HSF1 (caHSF1) into normal embryonic cortex, we found that the pyramidal neurons electroporated with the caHSF1 impaired the radial migration. Importantly, we also found that the impaired neuronal migration caused by exposure to challenges is mitigated by reducing such bursty activation of the HSF1-HSP signaling. Altogether, these results demonstrate that a part of cortical cells may activate protective signaling at excess level in response to prenatal environmental challenges, and that this excess activation adversely affects the cortical development.

Title: Expression of 5-HT receptors in human blastocysts and ESCs

Authors: *A. SAMARA[1,2], S. STRÖM[1,2], L. ANTONSSON[3], R. LAMPELA[3], J.-T. KIEHN[4], J. C. GLOVER[1,2,5]
[1]Univ. of Oslo, Oslo, Norway; [2]Norwegian Ctr. for Stem Cell Res., Oslo, Norway; [3]Karolinska Intitutet, Stockhom, Sweden; [4]Univ. of Lübeck, Lübeck, Germany; [5]Sars Intl. Ctr. for Marine Mol. Biol., Bergen, Norway

Abstract: Serotonin (5-hydroxytryptamine, 5HT) is a major neuromodulatory neurotransmitter and hormone in nearly all animal species. In mammals, 5HT has been implicated as a regulator of neurodevelopmental processes and alterations of the fetal 5HT supply can have adverse effects on neural circuit formation [1]. The physiological effects of serotonin range from regulation of subcortical sensory and motor systems, to regulation of higher cognitive functions. Deregulation of serotonin is implicated in a myriad of neuropathologies, including pain syndromes, motor, sleep, eating and mood disorders. The effects of serotonin are exerted via 7 subfamilies of 5HT receptors (5HTRs) [2]. The 5HTRs comprise 6 families of GPCRs (5HT-1, 2, 4, 5, 6, and 7) and one ligand-gated ion channel (5HT3). Little is known, however, about the effects of 5HT in human embryonic stem cells (hESC). To address this question, after confirming the expression of 5HT receptors in day 5 human blastocysts, we tested 15 hESC lines, namely HS181, 207, 306, 360, 364, 380, 401, 415, 420, 429, 799, 980, 999, 1001 and H9, for expression of all 5HTRs and 4 of them were tested for changes in cell signaling and gene expression after exposure to 5HT. METHODS Cell culture: In brief, hES cell lines were either cultured on human foreskin fibroblasts in 20% KO-SR in KO-DMEM supplemented with bFGF, or on laminin coated dishes in NutriStem hESC XF medium; 100 μM 5HT was added to hESC culture medium for 24h. Real time RT-PCR was performed to assess the expression of 5HTRs. RESULTS Transcripts of all 5HTRs subtypes are present in hESCs and were all upregulated after culture medium supplementation with 5HT for 24hrs. Moreoever, exposure to 5HT resulted in upregulation of gene expression of stem cell markers, proneural genes, 5HT specification-

related transcription factors and serotonergic pathway genes. DISCUSSION Currently, very few 5HTR ligands are subtype-selective and development of novel, specific 5HT antagonists is needed. Pharmaceutical R&D has mainly been compromised by a lack of experimental platforms. Characterization of 5HTR expression profiles is important for developing appropriate tools for 5HTR subtype-specific assays. References [1] Bonnin et al. (2007) Nature Neuroscience 10:588-597. Title: Development and characterization of scalable human induced pluripotent stem cell-derived midbrain dopaminergic neurons for drug discovery and disease modeling

Authors: ***L. CHASE**, C. MCMAHON, J. MA, J. GRINAGER, N. MEYER, C. CHAVEZ, B. MELINE, J. LIU, C. CARLSON, K. MANGAN, W. WANG, B. SWANSON

Abstract: Since the discovery of human induced pluripotent stem cells (iPSCs), much excitement and interest has been created around this technology as a platform for generating pluripotent stem cell lines from a range of specific genetic backgrounds, both normal and diseased. Using an optimized episomally-derived human iPSC platform, we have developed highly consistent and scalable differentiation protocols for making various types of human neurons. As described here, based upon previously published work (Kriks et al. 2011), we have further optimized and developed a scalable method for the generation of differentiated, cryopreserved human midbrain dopaminergic neurons (iCell DopaNeurons). This protocol provides a consistent platform to study various aspects of midbrain dopaminergic neuron biology, including Parkinson's disease. Phenotypically, iCell DopaNeurons are floor plate-derived midbrain dopaminergic neurons. During differentiation, these cultures go through a highly pure midbrain progenitor phase as shown by high level expression of forkhead box A2 (FoxA2) and the LIM homeobox transcription factor 1a/b (Lmx1). Upon further differentiation,

midbrain dopaminergic neurons are generated as identified by expression of microtubule-associated protein 2 (Map2), FoxA2, Lmx1 and tyrosine hydroxylase (TH). Utilizing a genetic-based selection strategy, the differentiating dopaminergic neuron cultures are purified to >90% neurons as determined by expression of Map2 and the absence of the progenitor marker nestin. Upon thaw, iCell DopaNeurons quickly acquire a branched neuronal morphology and display midbrain dopaminergic markers. In addition, these cultures maintain a high level of dopaminergic neuron purity for extended culture post-thaw. Functionally, these cells display characteristic neuronal electrophysiological properties, including proper ion channel activity, fire both evoked and spontaneous action potentials and show excitatory post-synaptic currents. In addition, through the use of multielectrode arrays, these cells display characteristic excitatory phenotypes with responses to known pharmacological agents. Finally, as a proof-of-concept for the ability to scale out a neuronal differentiation process, episomally-derived human iPSCs from various donors were created and differentiated into a highly purified neuronal population, exemplifying the potential application of this technology to panels of donors as a means to study larger human populations.

Title: Genome-engineering human induced pluripotent stem cell derived 3D retinas to model photoreceptor development and disease

Authors: *K. WAHLIN[1], J. MARUOTTI[2], V. RANGANATHAN[2], C. KIM[2], V. SLUCH[2], S. SRIPATHI[2], C. BERLINICKE[2], D. J. ZACK[3]

Abstract: Background and Significance. Retinal degenerative diseases, such retinitis pigmentosa (RP), cause dysfunction and death of photoreceptor (PR) cells leading to blindness. For most retinal degenerations there is no cure and significant gaps exist in our understanding of how PR loss occurs. To address this we are developing gene-modified human induced pluripotent stem cell (hiPSC) retinal cell-reporters and RP-associated hiPSCs that will help to identify pathways promoting retinal differentiation and potentially uncover pathways leading to PR survival. The feasibility of this approach is supported by recent work showing that hiPSCs can be coaxed into becoming retinal eyecup-like structures with complex laminar morphology and photoreceptor-like cells. Our approach bridges three technologies: (1) hiPSCs to generate 3D-differentiated retinas, (2) small molecule chemical screening to identify pathways that increase PR generation, and (3) genome-editing using CRISPR technology to generate genetically matched retinal reporters and disease-based mutant hiPSCs. A main goal of our work is to identify novel mechanisms for PR development that could increase the efficiency and pace of PR generation and provide insight into human ocular development. Methods. To differentiate hiPSCs toward a retinal fate we have adopted and further modified a forced aggregate approach pioneered by Nakano et al (2012) whereby stem cells are dissociated and re-aggregated to a defined size. In the presence of small molecules to mimic pathways intrinsic to retinal development and matrigel to mimic the ECM environment of the retina *in vivo*, human retinal eyecups are generated that parallel human retinal development. To engineer retinal reporters (e.g. SIX6-H2BGFP) into our cell lines we have adopted the CRISPR/Cas9 genome editing molecular scissor technology to knock-in fluorescent proteins in frame into the 3'-end of retinal gene coding sequences. The CRISPR/Cas9 system has also been used to generate CRX mutations similar to those found in human patients with Leber congenital amaurosis (LCA), and autosomal dominant RP. Results. We can now reliably generate retinal eyecups with complex laminar morphologies that develop exuberant outgrowth of both rod and cone outer segment-like structures, hallmark features of mature neural retinas. Using the above genome-editing approach we have also generated several retinal reporter cell lines, one of which is a SIX6-H2BGFP iPSC line that is a reliable marker for early retina. The eyecup protocol together with these CRISPR/Cas9 reporter lines will be used to identify and characterize pathways that accelerate retinal formation.

Title: Optogenetics reveal delayed afferent synaptogenesis on grafted human induced pluripotent stem cell-derived neural progenitors

Authors: *N. AVALIANI[1], A. T. SORENSEN[1], M. LEDRI[1], J. BENGZON[1], P. KOCH[2], O. BRUSTLE[2], K. DEISSEROTH[3], M. ANDERSSON[1], M. KOKAIA[1]

Abstract: Reprogramming of somatic cells into a pluripotent stem cell state have given new opportunities for cell replacement therapy and disease modeling in a number of neurological disorders. It still remains unknown, however, to what degree the grafted human induced pluripotent stem cells (hiPSCs) differentiate into a functional neuronal phenotype and if they synaptically integrate into the host circuitry. Here we present a detailed characterization of the functional properties and synaptic integration of hiPSC-derived neurons grafted in an *in vitro* model of hyperexcitable epileptic tissue, namely organotypic hippocampal slice cultures (OHSC), and in adult rats *in vivo*. The hiPSCs were first differentiated into long term self-renewing neuroepithelial stem (lt-NES) cells, which are known to form primarily GABAergic neurons. When differentiated in the OHSCs for six weeks, lt-NES cell-derived neurons displayed neuronal properties such as TTX-sensitive sodium currents and action potentials (APs), as well as both spontaneous and induced postsynaptic currents, indicating functional afferent synaptic inputs. They had a distinct electrophysiological profile compared to host cells in the OHSCs with higher input resistance, lower resting membrane potential and APs with lower amplitude and a longer duration. To investigate the origin of synaptic afferents to the grafted lt-NES cell-derived neurons, the host neurons were transduced with Channelrhodopsin-2 (ChR2) and optogenetically activated by blue light. Simultaneous recordings of synaptic currents in grafted lt-NES cell-derived neurons using whole-cell patch-clamp technique at 6 weeks after grafting revealed limited synaptic connections from the host neurons. Longer differentiation times, up to 24 weeks

after grafting *in vivo*, revealed more mature intrinsic properties and extensive synaptic afferents from host neurons to the It-NES cell-derived neurons, suggesting that these cells require extended time for the differentiation/maturation and synaptogenesis. However, even at this later time-point, the grafted cells maintained a higher input resistance. These data indicate that grafted lt-NES cell-derived neurons receive ample afferent input from the host brain. Since the lt-NES cells used in this study show a strong propensity for GABAergic differentiation, the host-to-graft synaptic afferents may facilitate inhibitory neurotransmitter release, and normalize hyperexcitable neuronal networks in brain diseases, e.g. such as epilepsy.

Title: Somatic cell lines with targeted eGFP insertion into mouse Tph2 locus as a model for serotonergic transdifferentiation

Authors: ***N. ALENINA**[1], V. FISHMAN[2], S. MIGLIARINI[3], B. PELOSI[3], A. RANJAN[1], O. SEROV[2], M. BADER[1], M. PASQUALETTI[3]

Abstract: The investigation of serotonergic (5-HT) neuron activity and its relationship to disease has been limited by a lack of physiologically relevant *in vitro* cell models. Differentiation of pluripotent stem cell lines or transdifferentiation of somatic cells carrying a 5-HT neuron-specific reporter provides a platform for such studies and can serve as a model for drug discovery. In this study we aimed to generate 5-HT neurons from somatic cells directly or via formation of induced pluripotent stem (iPS) cells using a serotonergic reporter mouse line. As a source of somatic cells we took primary mouse embryonic fibroblasts (MEFs) carrying the eGFP gene targeted to the endogenous Tph2 locus (Tph2:eGFP MEFs, Migliarini et al., 2013). Using these MEFs we first generated iPS cells by transfection with a single polycistronic lentivirus carrying Oct4, Sox2, cMyc, and Klf4 (OSKM) genes driven by a doxycycline-inducible promoter. The resulting iPS cells showed ES cell-like morphology and expressed the

pluripotency-associated genes Nanog and Oct4, but not eGFP. To test the potential of Tph2:eGFP-iPS cells to produce 5-HT neurons we induced neuronal differentiation by formation of embryoid bodies following replating on PDL/Laminin substrate. First eGFP-positive (eGFP+) cells with neuronal morphology appeared 14 days after induction of differentiation. Immunohistochemical analysis revealed that all eGFP+ cells express the neuronal marker, Tuj1, and produce serotonin. We detected a high expression of 5-HT markers, such as Tph2 by qPCR in the eGFP+ cell population isolated by FACS, further confirming the 5-HT nature of eGFP-expressing cells. We next took advantage of Tph2:eGFP MEFs to monitor the transdifferentiation of somatic cells to 5-HT neurons by two different strategies: (1) direct conversion using a neuron-specific cocktail of reprogramming factors (Ascl1, Brn2, Myt1l, (ABM)) in combination with transcription factors important for serotonergic differentiation, (2) via induction of pluripotency genes in culture conditions permissive for the formation of 5-HT neurons. Induction of neuronal genes (ABM) led to the robust generation of neurons, but not of eGFP+ cells. In contrast, transfection of Tph2:eGFP MEFs with OSKM lentiviruses and cultivation in LIF-free conditions in neuronal differentiation medium led to the appearance of eGFP+ neurons after 25 days. In conclusion, we generated a useful model system to monitor 5-HT neurons in *in vitro* reprogramming experiments. To our knowledge, this is the first successful transdifferentiation of somatic cells to serotonergic phenotype. References: Migliarini et al., 2013, Mol Psychiatry 18(10):1106-18

Title: Directed differentiation of human induced pluripotent stem cells to sensory neurons by combined small molecule inhibitors

Authors: *S. CAI[1,2], Y. S. CHAN[1], D. K. Y. SHUM[2]
[1]Dept. of Physiology, LKS Fac. of Med., [2]Dept. of Biochemistry, LKS Fac. of Med., The Univ. of Hong Kong, Hong Kong, China

Abstract: Human induced pluripotent stem cells (iPSCs) hold great promise for cell therapies and tissue engineering. iPSC-derived neural cells provide prospects for studying neurodevelopment and modeling neurological diseases. A prerequisite for these studies is a reproducible protocol that efficiently yields an abundant number of neural cell types. However, differentiation of iPSCs with extrinsic factors is a slow, step-wise process, mimicking the complex timing of human development. Progress has been made in identifying signaling pathways that direct the differentiation of iPSCs into specific lineages. Using a combination of small molecule inhibitors, we attempt to develop a new protocol to generate sensory neurons from human iPSCs. Human iPSCs were exposed to small molecule inhibitors. The iPSC-derived sensory neurons were maintained for two weeks in growth factors required for their survival. After differentiation, over 90% of the total cell population expressed the neuron-specific protein, Tuj-1 and neurofillament. Nearly 80% of the total cell population co-expressed peripherin and Brn3a, the specific markers for sensory neuron. Therefore, we demonstrated that a combination of small-molecule inhibitors of signaling pathways promotes highly efficient peripheral neural induction from human iPSCs. Our *in vitro* model of iPSC-derived sensory neuron provides a promising strategy for controlled production of sensory neurons and may serve as a useful tool for studying human neurodevelopment and modeling neurological diseases.

Title: Differentiation of retinal ganglion cells and photoreceptor precursors from mouse iPS cells carrying a Math5/Atoh7 lineage reporter

Authors: *X. YANG[1], B.-B. XIE[2], X. ZHANG[1], T. HASHIMOTO[1], A. TIEN[1], A. CHEN[1], J. GE[2]

Abstract: The neural retina constitutes a critical part of the visual system, which provides the majority of sensory inputs in humans. Various retinal degenerative diseases can result in the permanent loss of retinal neurons, especially the light-sensing photoreceptor cells and retinal ganglion cells (RGCs), which are the projection neurons connecting the retina with the higher visual centers in the brain. In optic nerve neuropathy and glaucoma, RGCs undergo cell death leading to decline of the vision. The repair of RGC damage is particularly challenging, as both RGC specification and the subsequent axonal growth and projection require complex and precise regulation. To begin addressing the serious roadblocks in RGC production and repair using stem cell technology, we have established mouse iPS cells that are genetically marked for a transcription factor, Math5/Atoh7, which is critical for RGC fate specification. Math5-Cre knock-in mice were crossed with Rosa.YFP cre reporter mice to derive Math5-Cre(KI);Rosa.YFP MEFs. Lentiviruses expressing the Yamanaka factors under TetO control were then used to induce the MEFs into Math5-Cre; Rosa.YFP iPS cells that express pluripotent markers and are capable of generating teratomas in SCID mice. Embryoid bodies of Math5-Cre.Rosa.YFP iPSCs were formed under anterior neural induction conditions, and further differentiated under retinal neurogenic conditions. Immunocytochemistry detected neurons co-expressing various RGC markers and YFP with extensive neurites and/or axons, indicating that these neurons were derived from Math5 lineage. Consistent with previous *in vivo* cell lineage studies, Math5 YFP-expressing cells also gave rise to a subset of photoreceptor precursors. Furthermore, FACS analyses showed that inhibition of Notch signaling in the Math5 iPSC cultures enhanced YFP reporter positive cells, and increased the Brn3a+YFP+ cells from 8.1+0.8 to 12.5+0.9 %, and Crx+YFP+ population from 7.3+1.1 to 16.4+1.9 %. Together, these results indicate that the Math5 reporter iPS cells can be used to demarcate a sub-lineage derived from retinal progenitor cells, and to study the development and survival of RGCs and photoreceptors.

Title: Activation of trans-synaptic signaling and network formation in human stem cell-derived neurons

Authors: *K. HUBBARD, P. BESKE, E. GLOTFELTY, T. HAMILTON, P. MCNUTT
USAMRICD, APG, MD

Abstract: Synaptically active neurons derived from human pluripotent stem cells hold great potential as a physiologically relevant platform for studying development, synaptogenesis and responses to neuromodulatory conditions. However, methods to reproducibly generate synaptically active populations with emergent network behaviors have not been described. We produced human stem cell-derived neurons (hSNs) using a well-described differentiation protocol and evaluated their morphological and functional characteristics. hSNs expressed and appropriately compartmentalized neurotypic markers and electrophysiological characterization demonstrated immature neuronal characteristics. Although transmission electron microscopy revealed the presence of pre- and post-synaptic architectures, evidence of synaptic activity was not observed. These data suggested that despite expressing many of the characteristics required for synaptic activity, hSNs produced using this method remained functionally immature. To address the discrepancy between apparent morphological maturity and functional immaturity, we used a developmentally inspired approach to identify cellular processes involved in neuronal specification and patterning *in vivo* in an attempt to identify compounds that had the potential to accelerate neuronal maturation *in vitro*. We determined that a temporally phased application of a subset of these compounds produced hSNs with significantly improved morphologies, intrinsic electrical characteristics and, most importantly, AMPA receptor-mediated post-synaptic currents. Additionally, we tested the ability of two commercially available human stem cell-derived neuron models to form functioning neuronal networks. Both commercial lines expressed and appropriately compartmentalized neurotypic markers and expressed intrinsic electrical properties consistent with a neuronal identity, however neither demonstrated evidence of AMPA receptor-mediated post-synaptic currents. These data suggest that hSNs produced using developmentally inspired conditions may provide an improved method to generate synaptically active, defined

populations of human neurons appropriate for the development of novel therapeutics, toxin screening and basic research. *Disclaimer: The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government*.

Abstract: Recent advances in human induced pluripotent stem cells (hiPSCs) offer new possibilities for biomedical research and clinical applications. Differentiated neurons from hiPSCs are expected to be good tools for developing new methods of treatments for various neurological diseases. However, the detail processes of neuronal development from hiPSCs have not been known. In this study we analyzed development of hiPSCs-derived neurons, particularly focusing on their early developmental stages. We cultured iCell Neuron (Cellular Dynamics International) and compared their development with that of the primary cultured neurons derived from rat hippocampus. In 2 days *in vitro* (DIV) culture of the rat neurons, we observed three different stages which were stages 1, 2 and 3 in developmental classification proposed by Dotti. Most developed stage 3 neurons had several short neurites with one long neurite, which is destined for an axon. According to the classification of Dotti, stage 3 neurons are characterized by this one long neurite. However in the DIV 2 iCell Neuron, we observed a few stage 3 neurons

and most of the neurons were in their stage 1 or 2. This suggests that the human neurons develop slower than the rat neurons morphologically. To investigate if the axonal differentiation had occurred even though iCell Neuron showed slower development, we used anti-phosphorylated neurofilament. There were quite a few neurons with phosphorylated neurofilament positive neuritis (axons) in DIV 2 iCell Neuron. This indicates that although the axonal growth speed of iCell Neuron is slower compare to that of rat neurons, the polarity of iCell Neuron was normal. We further double labeled these cells with drebrin and F-actin to see what makes this difference between iCell Neuron and rat neurons. The main structural components of filopodia and lamellipodia are F-actin, which is modulated with an actin-binding protein drebrin. We found that the localization patterns of F-actin and drebrin in growth cones of iCell Neuron were similar to those of rat neurons. Moreover to test if there are any differences between those neurons in terms of reaction to a drug, we treated both neurons with Cytochalasin D (Cyto D), an inhibitor of actin polymerization. The effects of Cyto D on both neurons were comparable. These results indicate that iCell Neuron develops comparably to the rat neurons in regard to axonal differentiation, but the growth speed of axon is slower.

Title: MicroRNA profiling during human brain development

Authors: ***M. E. JONSSON**[1], J. NELANDER[2], M. ÅKERBLOM[1], A. KIRKEBY[2], M. PARMAR[2], J. JAKOBSSON[1]
[1]Lund University, Mol. Neurogenetics, Lund, Sweden; [2]Lund University, Developmental and Regenerative Neurobio., Lund, Sweden

Abstract: MicroRNAs (miRNAs) have been shown to be involved in developmental processes and specification of different cell types. We set out to identify and investigate the expression of miRNAs during the human neural development by using isolated neural progenitors from both differentiating human embryonic stem cell (hESC) cultures and human embryos. hECSs were differentiated and regionalized towards neural progenitors of ventral forebrain, ventral midbrain

and ventral hindbrain. Small RNAs were then isolated from the different neural progenitor populations, as well as from three non-neuronal cell populations (hESCs, human lung fibroblasts and mesendodermal cells). We performed global miRNA profiling using next-generation sequencing, providing us with a spatial miRNA fingerprint of ventralized neural progenitors along the anterior-posterior axis as well as potential pan-neuronal miRNAs. Although *in vitro* differentiation of hECSs can recapitulate many aspects of the developing human nervous system we next wanted to validate the expression of the miRNAs in corresponding *in vivo* progenitors. This was achieved by dissecting corresponding brain regions from human embryos at different ages during neurogenesis (5-11 weeks post conception) and performing a multiplex qRT-PCR miRNA array. By this approach, we could again look at the spatial distribution of miRNAs and thus confirm their expression in human fetal brain, but also the temporal distribution. Our data support the existence of microRNAs that are regulated by either temporal or spatial aspects of development. We are currently performing gain- and loss-of-function studies in hESCs to investigate the functional role of specific miRNAs with these properties.

Title: The generation of subgroups of GABAergic interneurons in 3D alginate hydrogel

Authors: *J. KIM[1], S. ANDERSON[1,2]
[1]The Children's Hosp. of Philadelphia, Philadelphia, PA; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Since dysfunction of GABAergic interneurons has been associated with schizophrenia and autism, the generation of distinct ventral interneuron types has important clinical implications. In rodents, the parvalbumin (PV) and somatostatin (SST) expressing subgroups account for 60% of cortical interneurons (45% PV, 15% SST). Both subgroups originate mainly in the medial ganglionic eminence (MGE) of the basal forebrain. Evidence from the Anderson lab suggests a strong bias for SST+ interneurons to originate from ventricular zone (VZ) divisions of radial glial cells (RGC), while PV+ interneurons are generated from subventricular

zone (SVZ) divisions of intermediate progenitor cells (IPCs). Embryonic stem cells have great potential in studying the fate determination of cortical interneurons because they have ability to self-renew as well as to differentiate into specific interneurons given the appropriate signals. In a previous study from the Anderson lab, 2D stem-cell cultures, FACS sorted for a fluorescent reporter of interneuron-fated precursors and transplanted into neonatal neocortex of mice, mainly produced SST interneurons, recapitulating the VZ-like microenvironment. If so, a 3D system might better recapitulate the SVZ-like microenvironment, resulting in enhanced production of PV-expressing interneurons. We chose 3D alginate hydrogel because alginate is a major component of the ECM in the brain and has the similar surface stiffness to the brain tissue. To test our hypothesis using 3D alginate hydrogel, we are growing mouse embryonic stem cells of a dual-reporter line; Nkx2.1-mCherry for MGE progenitors, and Lhx6-GFP for post-mitotic, fate committed interneurons. The line is grown in either 2D or 3D (alginate) culture, and then MGE-like progenitors or newly born interneurons isolated by FACS are assessed by marker analysis for VZ or SVZ cells and by fate analysis 30 days after transplant into neonatal neocortex. If successful, the system will be an excellent platform for further study of cortical interneuron genesis and fate determination.

Title: Direct differentiation of human pluripotent stem cells into cerebellar Purkinje cells

Authors: *K. IMAIZUMI, T. SONE, W. AKAMATSU, H. OKANO
Dept. of Physiology, Keio Univ., Tokyo, Japan

Abstract: Purkinje cells (PCs) are the sole output from the cerebellar cortex and the dysfunction of PCs leads various neurological diseases including ataxia, autism and multiple sclerosis. To model cerebellar disorders *in vitro* for drug discovery, PCs derived from patients with such cerebellar disorders have been expected. Although recent reprogramming technologies facilitated making iPSCs from the somatic cell of patients, induction of PCs from human pluripotent stem

cells have not been reported. Here, we aim to establish an efficient method to generate PCs from human pluripotent stem cells. We first demonstrated the induction of neural progenitors with specific regional identities. We showed that it was possible to control the anteroposterior identities, ranging from the telencephalon to the spinal cord, and the dorsoventral identities at any given anteroposterior position by combinatory treatment of various patterning factors during neural induction. Using this system, we successfully induced neural progenitors with the characteristics of the dorsal anterior hindbrain where the cerebellum anlage arises. To accelerate the differentiation and maturation of PCs, we next overexpressed master genes of cerebellar development into the cells with characteristics of the dorsal anterior hindbrain. 15 days later of overexpression, we detected PCs markers, such as calbindin, along with increased LHX1/5 expression. These results indicate that PC-like cells might be efficiently generated from human pluripotent stem cells. Our study will elucidate not only the pathogenesis of cerebellar disorders, but also the mechanism of cerebellar development.

Title: Assessing functional phenotypic complexity of stem cell-derived neuronal culture network activity in relation to brain region-specific primary cultures

Authors: *A. GRAMOWSKI, K. JÜGELT, C. EHNERT, A.-M. PIELKA, A. PODßUN, B. M. BADER, O. SCHROEDER

Abstract: The option of using human stem cells and even personalized patient cultures will bridge in-vitro assays closer to man. Primary neuronal cultures have a long tradition and are well characterized and validated. There is a plethora of literature data documenting their physiological relevance in research and drug discovery. Neuronal cell cultures derived from murine and human stem cells are in the focus of international research now. Yet, one of the most important issues is their physiological relevance. This question can not be answered in general, but a lot of empirical data contribute to a more and more comprehensive picture. We aim to understand and compare the difference of electrical functional activity patterns from primary murine neuronal cell

cultures and those cultures derived from embryonic stem cells cultivated on micro-electrode arrays (MEA). As a result of their phenotypic receptor and neuron type composition, primary neuronal cell cultures show very specific and complex activity pattern after four weeks *in vitro*. This complexity results from a high level of organization in network cultures, which is present in primary cultures but distinguishable from those derived from stem cells. Thus, we are able to compare but also classify the complexity of stem cell-derived activity patterns in comparison to the current standard of primary cells. We compared primary neuron/glia cultures from different brain tissues such as frontal cortex, hippocampus, hypothalamus, midbrain, a midbrain/frontal cortex co-culture, spinal cord with dorsal root ganglia, and murine stem cell derived neuronal networks grown on MEAs for 4 weeks *in vitro* and a randomly generated spike train pattern generated with a Poisson process. Primary cell cultures show brain region-specific activity pattern which can be clearly distinguished by pattern recognition methods. We describe and analyze these activity patterns with 204 spike train parameters computed by in-house software NPWaveX. We show that the pattern complexity from stem cell-derived cultures is sorted between those generated with a randomly generated Poisson process spike train and primary cultures. Thus, we provide a tool to optimize the culture condition towards a higher functional network complexity.

Title: Neurofluor™ Cdr3: A fluorescent probe for the detection of live CNS and human pluripotent stem cell derived neural progenitor cells

Authors: *V. M. LEE, C. K. H. MAK, S. LLOYD-BURTON, A. C. EAVES, T. E. THOMAS, S. A. LOUIS
Res. & Develop., STEMCELL Technologies Inc, Vancouver, BC, Canada

Abstract: Identification and phenotypic characterization of neural cell types derived from either the central nervous system (CNS) or human pluripotent stem cells (hPSCs), including embryonic and induced pluripotent stem cells, is heavily reliant on antibodies and mRNA probes. Although these reagents can be highly effective and specific, their protocols are labor intensive, often requiring optimization, and involve fixation and permeabilization steps that sacrifice cell samples. Simple reagents that can quickly and selectively label live neural progenitor cells (NPCs) in tissues and cell cultures are therefore highly desirable. We have developed NeuroFluor™ CDr3, a ready-to-use fluorescent membrane-permeant probe that specifically labels live NPCs. NeuroFluor™ CDr3 was developed based on CDr3, a boron-dipyrromethane (BODIPY) derivative compound that was first identified in a screen for human and rodent CNS-derived NPC probes (Yun et al. 2012; Leong et al. 2013). Here, we confirm that NeuroFluor™ CDr3 selectively labels NPCs from embryonic rodent CNS and further demonstrate its utility in the detection of hPSC-derived NPCs. NPCs were generated from hPSCs via an embryoid body (EB) protocol, using STEMdiff™ Neural Induction Medium (NIM) and AggreWell™800. In this method neural rosettes, a morphological hallmark of *in vitro* neural differentiation were efficiently generated. These rosettes contain CNS-type NPCs that express PAX6 and Nestin. NeuroFluor™ CDr3 was diluted in NIM at various concentrations, added directly to cultures containing neural rosettes, and incubated for 2 hours at 37oC. After 2 washes, NeuroFluor™ CDr3 signal was observed with a fluorescent microscope. We found that NeuroFluor™ CDr3 used at either 0.5 or 1 μM, specifically labeled cells within the neural rosettes structures but not the surrounding cells. Finally, we generated adherent monolayer NPC cultures from E18 rat cortices using the NeuroCult™ Proliferation Kit. NeuroFluor™ CDr3 was applied directly to monolayer NPC cultures in the NeuroCult™ Proliferation medium, incubated, and washed as above. All of the cells in these cultures were positive for the neural progenitor marker, Nestin and the majority (>95%) were co-labeled by NeuroFluor™ CDr3 as visualized by fluorescent microscopy. Together, these data demonstrate that NeuroFluor™ CDr3 is a useful tool for the detection of live hPSC- and rodent CNS-derived NPCs in culture. Because NeuroFluor™ CDr3 is compatible with flow cytometry protocols, it can be applied in cell sorting strategies for the isolation and enrichment of NPCs directly from live cultures and CNS tissue samples.

Title: The role of miRNAs in the developmental timing of embryonic stem cell-derived retina

Authors: *A. HOSHINO, A. LA TORRE, L. E. HOOD, T. A. REH
Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Retinal degenerative diseases are a diverse group of disorders that affect millions of people worldwide and can lead to irreversible vision impairment and blindness. In many diseases, patients initially lose one type of retinal neuron (commonly the photoreceptors), followed by the loss of other cell types. Although significant progress has been made in understanding the molecular mechanisms behind retinal degeneration, current therapies do not restore vision after retinal cells are lost. Cell therapy may thus be a promising treatment option to replace lost neurons and to recover vision. While many sources of retinal cells have been suggested, their self-renewal and pluripotent properties make embryonic stem cells (ESCs) an ideal source for generating large numbers of photoreceptors through directed differentiation. We and other groups have therefore developed protocols to differentiate ESCs into retinal lineages; these protocols recapitulate key stages of retinal development, such as the formation of the optic vesicle, optic cup, and production of different retinal neurons in a stereotypic manner. Although these results are promising, it takes several weeks to months to produce photoreceptors from mouse and human ESCs, respectively; hence speeding up differentiation will make ESCs a more viable therapeutic option. Recent work has suggested that microRNAs (miRNAs) play an important role in controlling developmental timing in the mouse retina; however, the role of miRNAs during retinal differentiation of ESCs has not yet been studied. Our laboratory has identified key miRNAs (Let7, miR-9, miR-125b, termed Late Progenitor miRNAs) that increase during retinal development, and upon precocious overexpression, can accelerate the timing of mouse neurogenesis. The current project was designed to determine whether LP-miRNAs play a similar role during retinal differentiation of ESCs. Here, we characterized the expression patterns of LP-miRNAs in the retinal cells derived from mESCs using RT-qPCR and miRNA sensors. Our analysis shows that LP-miRNAs are upregulated and functional in mESCs from the earliest stages of retinal differentiation. We then manipulated miRNA expression in the mESCs and found that early changes in miRNA levels altered the timing of key retinal differentiation events.

These data suggest that miRNAs play an important role during directed retinal differentiation of mESCs, and that manipulation of miRNAs can potentially be employed to derive retinal neurons more efficiently.

Abstract: The selective loss of GABAergic inhibitory interneurons is characteristic of numerous neurodegenerative diseases. Absence of these inhibitory subtypes creates an electrical imbalance in the hippocampal and cortical neural circuits. Our long term goal is to replenish these inhibitory interneuron subtypes using an embryonic stem cell (ESC) source. During embryonic development, these inhibitory interneuron progenitors arise from a transient ventral forebrain structure known as the medial ganglionic eminence (MGE) and are characterized by the expression of Nkx2.1. We have optimized an adherent monolayer protocol for the generation of Nkx2.1+ neural progenitors from both mouse and human ESC lines using sonic hedgehog treatment. The Nkx2.1+ enriched cell population expresses elevated levels of MGE markers, including Nkx2.1 and Nkx6.2, based upon qRT-PCR analysis. Transcriptome analysis using high throughput mRNA sequencing is underway to further characterize the Nkx2.1+ cell population. To test the differentiation potential of the Nkx2.1+ cells *in vitro*, we used co-culture with mouse cortical astrocytes and obtained an enriched population of interneurons in which 75% of the

MAP2+ cells are also GABA+ after 8 weeks. Preliminary studies examining the fate of human ESC-derived Nkx2.1+ progenitors transplanted into the mouse hippocampus demonstrate the expression of neuronal markers 3 weeks post-transplant.

Title: Differentiation of human stem cells to retinal ganglion-like cells using a crispr/cas9 engineered reporter line

Authors: *V. M. SLUCH[1], V. RANGANATHAN[2], C. BERLINICKE[2], R. MARTIN[3], H.-Q. MAO[3], D. ZACK[2]
[1]Mol. Biol. and Genet., [2]Ophthalmology, Johns Hopkins Sch. of Med., Baltimore, MD; [3]Dept. of Materials Sci. and Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Purpose: A number of diseases lead to retinal ganglion cell (RGC) death and vision loss, the most common of which is glaucoma. Once the optic nerve is damaged, few avenues of intervention exist since the mammalian optic nerve does not regenerate. One ambitious goal is to use cell replacement therapy to restore vision. Human pluripotent stem cell (hPSC)

differentiation could, in theory, provide the necessary RGCs for this strategy. In addition, human stem cell-derived RGCs could make possible an approach for medically relevant drug screening that would have advantages over the current use of rodent RGCs. In addition, such cells could provide insights into human RGC development, gene regulation, and neuronal biology. Here, we describe a protocol for differentiation of hPSCs to RGC-like cells that express a variety of RGC-enriched markers, exhibit spontaneous transient calcium activity typical of neurons, grow projections of over several millimeters *in vitro*, and can be cultured on nanofibers to direct neurite outgrowth. Methods: H7 human embryonic stem cells were genetically engineered using the CRISPR/Cas9 nuclease system to contain a membrane Cherry fluorescent reporter downstream of BRN3B, an RGC-enriched transcription factor. This augmented cell line was differentiated in N2B27 neuronal medium in the presence of 2% Matrigel. Following differentiation, we were able to use fluorescent-activated cell sorting (FACS) to isolate the BRN3B+ RGC-like cells. We analyzed the cells using qPCR, immunostaining, and calcium imaging. Results: By day 30 of differentiation, BRN3B reporter expression was evident, the cells displayed long neurites, and the fluorescent cells could be purified using FACS. The cultures were enriched for BRN3B, BRN3A, SNCG, NEFH, NRN1, and RBPMS expression by qPCR. Additionally, we were able to detect low levels of melanopsin expression. Calcium imaging showed spontaneous calcium activity, typical of neuronal electrical activity. Immunostaining confirmed the presence of cells double positive for MAP2 and BRN3A, neuronal and RGC-enriched markers, respectively. When cultured long term, these cells sprouted neurites of several millimeters in length, and their growth could be directionally guided by aligned nanofibers. Conclusions: We were able to effectively differentiate hPSCs to RGC-like cells. Using CRISPR technology, we generated a stem cell line containing a human RGC reporter, which enables FACS-sorting to obtain isolated RGCs. This study provides a robust method for generating hPSC-derived human RGCs, which can be used for drug screening, developmental and biological studies, as well as cell replacement experiments.

Title: A modeling approach to investigate the emergent behavior of motor neurons and glia from 3D stem cell aggregates

Authors: *R. L. SWETENBURG, III[1], D. E. WHITE[2], M. L. KEMP[2], T. C. MCDEVITT[2], S. L. STICE[1]

Abstract: Progenitor and tissue-specific stem cell domains emerge in development, persist into adulthood and can potentially be harnessed for therapeutic purposes. In the primitive spinal cord, a Sonic Hedgehog (Shh) gradient originating from the notochord and floor plate create distinct progenitor domains in the ventral neural tube. *In vivo*, the motor neuron progenitor (pMN) domain gives rise to motor neurons (MN) early and oligodendrocytes late, both of which are implicated in human health and disease including spinal cord injury and muscular dystrophy. Necessary, but poorly understood, for the preservation of progenitors and this glial switch is Notch signaling, a form of juxtacrine signaling often controlling asymetric division and daughter cell fate in stem and progenitor populations. Pluripotent stem cells (PSC) have the unique ability to form most cells of the body. 3D PSC aggregates, or embryoid bodies (EB), are extremely useful tools for deriving downstream cells types from PSCs. The inherent emergent behavior exhibited by EBs results in heterogeneous, organotypic cell clusters which can be controlled and manipulated with the use of small molecules and growth factors. However, their size, inconsistency of differentiation and heterogeneity make them difficult to interrogate. Using the HBG3 PSC line, which includes a green fluorescent protein driven by a MN specific promoter, we derived MNs and oligodendrocytes from EBs over a 10 day culture period by patterning with retinoic acid and a Shh agonist, purmorphamine. DAPT, a Notch inhibitor, was used to mimic development. To better grasp the spatiotemporal emergence of these cell types, we employed a non-reductionist, evidence-based, computational modeling approach by visualizing pMN progenitors (Olig2+), MNs (GFP+) and oligodendrocytes (Olig2+/Nkx2.2+) with immunocytochemistry. Intact EBs were imaged in suspension using high-resolution, confocal microscopy. A number of metrics were derived from the images for further investigation. Notch inhibition increased the number of MNs, dependent on temporal application of DAPT. DAPT treatment yielded less progenitors based on the inhibitor. The average number of MN clusters was increased in the absence of Notch signaling. Progenitor clustering followed an inverse trend to MN clustering. This data implies that MNs are being produced at the expense of progenitors in the absence of Notch signaling. Further, a principal component analysis show distinct trajectories of the treatments which, along with a computational model, will allow us to make more inferences into how these cells behave in an *in vitro* model and possibly translate to the clinic.

Title: Metabolomics and neurite outgrowth as data rich developmental neurotoxicity assays in a pluripotent stem cell derived human neural model

Authors: *A. MAJUMDER[1], S. WALLACE[1], X. WU[2], M. AMOSU[2,3], K. LU[3], M. A. SMITH[2,3], S. L. STICE[1]
[1]Aruna Biomed. Inc., Athens, GA; [2]Regenerative Biosci. Ctr., Univ. of Georga, Athens, GA; [3]Envrn. Hlth. Sci., Univ. of Georgia, Athens, GA

Abstract: A vast majority of chemical entities, ranging from pesticides to compounds of therapeutic interest, remain untested for potential toxic outcomes on human neural development. Current methods for evaluating developmental neurotoxicity (DNT) rely heavily on animal based testing and non-uniform cell lines, are often prohibitively expensive, and provide suboptimal predictive value. To fill this critical gap we evaluated a robust, species representative and physiologically relevant cellular system, combined with high content imaging (HCI) and metabolomics, to address human DNT. Scalable and uniform populations of undifferentiated neural progenitor cells (hNP1TM), differentiated neurons (hN2TM) and astrocytes (hAstroProTM), derived from human embryonic stem cells (hESC) were used to represent a neurodevelopmental continuum and evaluated for toxin induced changes in neurite outgrowth, metabolomic signatures and viability. To address developmental stage specific neurotoxicity, Bis-1, a known neurotoxin, was applied to cultures either during or post neuronal differentiation, as well as in neuron-astrocyte co-cultures to represent neural tissue. Differentiation and neurite outgrowth were measured using HCI. For all of the above, Bis-1 induced reduction in neurite outgrowth were observed at concentrations that did not lower neuronal viability. However, Bis-1 treatment during differentiation selectively reduced the Sox1+ neural progenitor fraction, without affecting more mature HuC/D+ neuronal fraction, suggesting stage specific differences in susceptibilities. Additionally, significant differences in Bis-1 induced toxicity between neuron only and neuron-astrocyte co-cultures were observed, reinforcing the need for better tissue representation in DNT studies. For metabolomics assays cells were treated pre- and post

differentiation, and both media and cells were analyzed by GC-MS. PLS-DA scores plots for Bis-1 show a dose response, and Bis-1 and other toxicants demonstrate class changes and show that changes in metabolomic profiles were induced at doses of test compounds significantly lower than those affecting viability. Thus, like neurite outgrowth, metabolomic profiling provides a more sensitive measure of DNT than a traditional viability assay. Further, it is a data-rich approach for toxic outcomes even when no prior knowledge of compound class or mechanism of action is available. The two approaches provide a powerful advancement in neurotoxicity assessment.

Title: Involvement of cannabinoid receptors or muscarinic acetylcholine receptors on differentiation into neural progenitor cells in mouse induced pluripotent stem cells

Authors: ***T. ISHIZUKA**, A. OZAWA, M. ARATA, Y. WATANABE
Dept. of Pharmacol., Natl. Def. Med. Col., Tokorozawa, Saitama, Japan

Abstract: Previous studies reported that anandamide, an endogeneous cannabinoid (CB), promotes differentiation of neural progenitor cells (NPCs). On the other hand, stimulation with muscarinic acetylcholine receptor (mAch receptor) agonists increased differentiation of immature neurons in adult mice. Mouse induced pluripotent stem (iPS) cells display properties of self-renewal and differentiation into various cells including NPCs. The present study examined whether stimulation with either CB receptors or mAch receptors affects differentiation of mouse

iPS cells into NPCs. Mouse iPS cell differentiation was initiated by embryoid body (EB) formation. All-trans retinoic acid (ATRA; 1 microM), HU210 (a CB1 receptor agonist), HU308 (a CB2 receptor agonist), or carbachol (a mAch receptor agonist) was added to the EB cultures for 4 days, and then EBs were transferred to fibronectin-coated dishes and then cultured for 7 days. The differentiation potential from mouse iPS cells into NPCs was evaluated by Nestin expression using immunofluorescence staining and western blot analysis. Treatment with either HU210 (3 nM) or HU308 (3 nM) inhibited ATRA-induced Nestin expression. Pretreatment with rimonabant (0.1 microM; a CB1 receptor antagonist) blocked the inhibitory effect of HU210. Pretreatment with SR144528 (0.1 microM; a CB2 receptor antagonist) also blocked the inhibitory effect of HU308. On the other hand, the treatment with carbachol (10 microM) inhibited ATRA-induced Nestin expression. In addition, the pretreatment with atropine (10 microM) significantly blocked the inhibitory effect of carbachol. Thus, the stimulation with either CB receptors or mAch receptors may inhibit ATRA-induced differentiation of mouse iPS cells into NPCs.

Title: Differential expression of human endogenous retrovirus-k env in pluripotent stem cells and neural cells

Authors: ***T. WANG**, M. MEDYNETS, E. CHOI, W. LI, A. NATH
NINDS/NIH, Bethesda, MD

Abstract: Background: Human endogenous retrovirus (Herv) gene sequences occupy almost 7% of the human genome and have been termed “junk DNA”. Amongst them, Herv-K is believed to be the most recently incorporated virus into the human genome. Although incidental Herv-K gene expression has been reported in a variety of pathological conditions, it’s potential expression and role in physiological conditions has not been investigated. Objective: To study the expression and function of Herv-K components in pluripotent stem cells and during the

process of neuronal differentiation. Methods: We used Sendai virus factors containing Yamanaka transcriptional factors to generate induced pluripotent stem cells (iPSC) from human fibroblast cells and CD34 hemopeotic stem cells. The iPSC were further differentiated to neural stem cells and neural cells using induction media. Herv-K expression was detected by RT-PCR, immunostaining and Western-blot assay. The function of Herv-K envelope (Env) was studied by blocking its expression using siRNAs and specific antibodies and then followed by colony formation and morphological studies. The possible interacting ligands of Herv-K Env were studied using co-immunoprecipitation and Western-blot assay. Results: We found that Herv-K components, especially cell membrane Env expression, were increased after iPSC generation compared to the source cells such as fibroblasts and CD34 cells. The expression of Env decreased dramatically after iPSC were differentiated to neural stem cells and neurons. The increased expression of Herv-K was also confirmed in embryonic stem cell line W9. Interestingly, treatment with antibodies against Env resulted in fewer stem cell colonies. When Env expression was blocked by siRNA, there were significant morphological changes in iPSC and ES. Further, Env was co-immuoprecipitated with CD98HC, a protein that plays an important role in cell adhesion and stem cell maintenance. Western-blot assays showed that blocking Env using siRNA resulted in decrease in CD98HC expression. Conclusion: These results indicate that Herv-K Env is expressed in pluripotent stem cells and decreases during neural cell differentiation. It may play an important physiological role in maintaining the pluripotent stem cells by interacting and regulating other factors expressed on stem cells such as CD98HC.

Title: Neural precursors derived from mouse ips cells extensively remyelinate the demyelinated central nervous system

Authors: S. MOZAFARI[1], C. LATERZA[2], A. MARTEYN[1], C. DEBOUX[1], C. BACHELIN[1], G. MARTINO[2], *A. S. BARON VAN EVERCOOREN[1]
[1]ICM, INSERM U1127, CNRS UMR 7225, UPMC UM 75, Paris, France; [2]Inst. of Exptl. Neurology–DIBIT 2, Div. of Neuroscience, San Raffaele Scientific Inst., Milan, Italy

Abstract: Experimental studies have shown that loss of myelin, results in axonal loss and disability. Furthermore, remyelination can restore lost electrical conductance in demyelinated axons. Finding of an expandable, autologous and reliable source of myelin-forming cells to enhance remyelination is a priority in treating the degenerative component of demyelinating diseases like Multiple Sclerosis (MS). Induced pluripotent stem cell-derived neural progenitor cells (iPSC-NPCs) have been developed recently from reprogrammed somatic cells. However, the remyelination potential and safety of these cells remain to be well-addressed. The main goal of this study is to fully characterize mouse iPS-NPCs *in vitro* and *in vivo* after transplantation. We first used mouse embryonic neural progenitor cells (mENPCs) as control and characterized iPS-NPCs derived from mouse fibroblasts for their expression of major markers of immature or mature neural cells. Moreover, to investigate the behavior of cells in demyelination context, we induced a focal area of demyelination using Lysolecithin in the spinal cord of adult *ShivererRag* mouse and transplanted the cells in the lesion site 48 hours after demyelination. Animals were sacrificed 1, 2, 6 and 10 weeks post graft to assess survival, migration and differentiation potential of the grafted cells. Our results show that miPS-NPCs similarly to mE-NPCs expressed the immature markers of naturally committed neural progenitor cells *in vitro* at the level of both protein and mRNA transcripts. Moreover, our data from transplantation studies in demyelination context revealed that the grafted iPS-NPCs similar to embryonic cells survived, integrated, timely migrated, and extensively differentiated from immature to mature cells. Grafted cells remyelinated the host axons as confirmed by immunostaining and electron microscopy. Furthermore, no tumor was observed following engraftment. There is a competitive differentiation into bona fide mature myelinating oligodendrocytes. No obvious difference was observed between mE-NPCs vs miPS-NPCs.Our work should help increasing the knowledge about the biology of mouse and in future studies, human iPS-NPCs to establish whether these cells are a useful tool for testing personalized therapies or in regenerative biomedicine in demyelinating diseases like MS.

Title: Synaptic function of chromosome 21-encoded microRNAs

Authors: *H. MCGOWAN[1], N. MLYNARYK[3], C.-W. LU[2], Z. PANG[2]
[1]Child Hlth. Inst. of New Jersey, Piscataway, NJ; [2]Child Hlth. Inst. of New Jersey, New Brunswick, NJ; [3]Rutgers Univ., New Brunswick, NJ

Abstract: The formation and maintenance of appropriate synaptic connections is a highly regulated process, with misregulation resulting in disordered cognition. Given the emerging information about non-coding RNAs, synaptic functions are likely to be regulated at least in part by these molecules, including microRNAs (miRNAs). miRNAs have been implicated in synaptogenesis, and thus, over- or under-expression of miRNAs in the brain could conceivably contribute to synaptic dysfunction. Human chromosome 21 (HSA21) codes for 5 known miRNAs, and Trisomy 21 (TS21) is the most common genetic form of intellectual disability. Thus, TS21 provides a unique model to study the effect of miRNA overexpression on the functionality of synapses. The objective of this project is to elucidate if and how the overexpression of HSA21 miRNAs leads to dysfunction in synaptic transmission. Furthermore, our preliminary evidence that suggests these miRNAs may affect synaptic integrity via a methyl CpG binding protein 2 (MeCP2)-dependent pathway. Utilizing the induced pluripotent stem (iPS) cell and induced neuronal (iN) cell technologies, we will study the synaptic implications of this miRNA-MeCP2 pathway in human neurons. We have analyzed the 3' UTR of MeCP2 and found putative targeting sites for 4 out of the 5 HSA21 miRNAs, and we have confirmed by dual luciferase assay that they do indeed target MeCP2. In addition, our preliminary findings by qPCR and immunohistochemistry (IHC) suggest that these miRNAs are overexpressed and that MeCP2 is decreased in T21 patient-derived iNs versus control. After further verification of the negative correlation between HSA21 miRNA and MeCP2 expression levels, we will morphologically and functionally characterize the TS21 synapse to support our preliminary electrophysiology data, which suggests impaired synaptic signaling. We will then establish a cause-effect relationship between HSA21 miRNA overexpression and synaptic defects using Tough Decoys to antagonize the miRNAs and "rescue" expression level of MeCP2 and the synaptic function of TS21-iN cells. Furthermore, in order to isolate the synaptic effects of this

miRNA-MeCP2 pathway alone, we will repeat these analyses by overexpressing HSA21 miRNAs in control iNs. Our approach will not only broaden our knowledge of the biological functions of miRNAs, it will also provide insight into mechanistic and molecular bases for the treatment of TS21.

Abstract: In order to reach the goal of personalized medicine, the control and observation of cell types derived from pluripotent human stem cells must achieve a resolution that consistently distinguishes the cellular behavior of individual genomes. Here we show that pluripotent cell lines derived from multiple human genomes have distinct transcriptional dynamics as they self-renew and initiate differentiation. RNA-seq data was obtained from 6 cell lines in conditions that support self-renewal or differentiation to mesendodermal and neuroectodermal fates. Microarray expression data from these same 6 lines and an additional 15 lines was also obtained. Conventional principle component analysis (PCA) of the patterns of transcription within the pluripotent state reveals bias in individual lines that predicts their differentiation efficiency to mes-endoderm or neur-ectoderm. With a novel data analysis approach that incorporates a non-negative matrix factorization algorithm (CoGAPS) we identified individual genome-specific signatures present in pluripotency and in differentiation. These analytic technologies discover stable genome-specific transcriptional dynamics with functional consequences in early human

neural development. This work opens the door to interrogate the cellular mechanisms, genetics, and pharmacology of human brain development from a powerful novel perspective.

Title: Classical MHCI immune proteins promote synapse elimination at the developing neuromuscular junction

Authors: M. M. TETRUASHVILY[1], M. A. MCDONALD[3], *L. M. BOULANGER[2]
[1]Mol. Biol., [2]Mol. Biol. and Princeton Neurosci. Inst., Princeton Univ., Princeton, NJ; [3]U.C. San Diego, San Diego, CA

Abstract: The mammalian neuromuscular junction (NMJ) undergoes prominent developmental synapse elimination, during which supernumerary motor neuron (MN) axons are retracted to produce mature patterns of connectivity. Despite the critical role of synapse elimination in the maturation of motor function, the molecular mediators of this process remain elusive. Specific immune proteins, members of the class I major histocompatibility complex (MHCI), regulate synapse elimination in the developing mammalian visual system, and are highly expressed in adult MNs. We found that MHCI is expressed during synapse elimination at the developing NMJ, and that synapse elimination is impaired in mice genetically lacking cell-surface expression of most MHCI proteins (β2m-/-TAP-/- mice). In these broadly MHCI-deficient mice, significantly more motor end plates remain multiply-innervated relative to WT at postnatal day

15 (P15), when synapse elimination is normally complete. Multiply-innervated NMJs are still apparent in MHCI-deficient adults (P29-60) and aged animals (P365), suggesting that loss of MHCI persistently disrupts synapse elimination at the NMJ. One key unanswered question is which of the dozens of classical and/or nonclassical MHCIs are involved in synapse elimination at the NMJ. We are addressing this question in three ways: (1) by profiling the expression of specific MHCI genes at the NMJ before, during, and after synapse elimination, (2) by determining the extent of synapse elimination in mice lacking the classical MHCI genes, H2-Kb and H2-Db, and (3) by monitoring synapse elimination in mice that overexpress H2-Db specifically in neurons. Since MHCI is upregulated at the NMJ during aging-related denervation, understanding how MHCI contributes to synapse elimination at the developing NMJ could ultimately identify mechanisms of pathological synapse loss during neuromuscular aging.

Abstract: Visual subcortical connections develop terminal field specificities through the selective elimination of misplaced axons and the maintenance of correct axonal branches, processes that underlie the use-dependent fine-tuning of topographical maps. In the present work, we studied the impact of a dietary restriction of omega-3 fatty acids on the development of eye specific segregation and topographical specificity of retinofugal pathways. We also studied the impact of low omega-3 diets on the differentiation of retinal layers and cholinergic markers in the retina. Female Lister Hooded rats and their litters were fed with either control (soy oil) or restricted (coconut oil) omega-3 diets. At various postnatal ages, rat pups received eye injections of neuronal tracers to visualize retinal axons at their brain targets. Lipid analysis indicated that the experimental diet led to a selective reduction in DHA content in the visual system. Omega-3 restriction induced an increase in the density of retinal axons in the superficial layers of the SC. This effect was observed throughout the stratum griseum superficiale (SGS), including the ventral and intermediate SGS layers at PND13, PND28 and PND42. The same pattern of expanded terminal fields was observed in the retinogeniculate pathways. The supplementation with fish oil (DHA) for two weeks was able to reverse the abnormal expansion of the retinocollicular projection. We also studied possible mechanisms involved in the loss of synaptic stabilization. Restricted omega-3 groups showed, in the visual layers of the SC decreased levels of GAP-43 phosphorylated form (pGAP-43) consistent with a reduction in synaptic stabilization. Omega-3 restriction increased the content of AMPAR subunits (GluR1 and GluR2) and decreased NMDAR (NR1, NR2A and NR2B) subunits. Omega-3 restricted groups showed a decrease in RXRα content and CREB phosphorylation (pCREB) in the visual layers of the superior colliculus. Retinal differentiation was also affected by omega-3/DHA deprivation. We describe a reduction in rhodopsin immunolabeling and also a reduced labeling of cholinergic markers such as VAchT in the inner nuclear layer and β2-nicotinic receptors in the ganglion cell layer and inner nuclear layer. The data indicate, therefore, that the chronic dietary restriction of omega-3 fatty acids delays axonal elimination, interfering with the maintenance of synaptic connections in the visual system. The data also indicate that the development of the retina is also delayed, specially the development of retinal cholinergic transmission.

Title: Accelerated gsk-3β activity in prefrontal cortex enhances ltd in a neurodevelopmental schizophrenia model

Authors: *B. XING, W.-J. GAO
Neurobio. & Anat., Drexel Univ. Col. of Med., PHILADELPHIA, PA

Abstract: Schizophrenia is recognized as a neurodevelopmental disorder that results in the emergence of cognitive symptoms during early adolescence. Accumulating evidence suggests that glycogen synthase kinase-3β (GSK3β) play an important role in brain development and synaptic plasticity, and is implicated in schizophrenia. However, it remains unclear how GSK3β changes during critical developmental periods and whether the change involves synaptic plasticity in prefrontal cortex (PFC). Here we show that GSK3β and its serine-9 phosphorylation levels undergo large fluctuations in rat PFC during development and the change of GSK3β activity during this period contributes to the long-term depression (LTD) induction. GSK3β and its inhibitory serine-phosphorylation (Ser 9) in the PFC peaked around the first postnatal week and declined rapidly from the second to sixth weeks of age, when the adult levels were reached. In prenatal methylazoxymethanol acetate (MAM, E17) exposed rats, a neurodevelopmental disruption model of schizophrenia, phosphorylated GSK3β (Ser 9) significantly decreased to adult levels around postnatal day 21 (P21), indicating an accelerated GSK3β activity in the PFC during development. In the saline control animals, LTD could only be induced by low-frequency stimulation with paired pulses in adolescent (~P45) rat medial PFC slices but not in juveniles (P21). Interestingly, the decrease of serine-phosphorylation in the juvenile (P21) MAM-exposed rats appeared to enhance the induction of LTD. In contrast to the saline controls, LTD could be induced in both juveniles and adolescents due to their comparable phosphorylated GSK3β levels. GSK3β inhibitor SB216763 blocks the induction of the age-dependent LTD. These data demonstrate the importance of GSK3β for synaptic plasticity in the PFC, suggesting that abnormal activation of GSK3β signaling during the critical period may contribute to cognitive deficits related to schizophrenia. Title: Functional synapse elimination plays a role in large-scale somatotopic refinement in the sensory thalamus of developing mice

Authors: *Y. TAKEUCHI[1], Y. KATAYAMA[1], M. MIYATA[1,2]

Abstract: Functional synapse elimination and strengthening are crucial developmental processes in the formation of precise neuronal circuits in the somatosensory system, but the underlying alterations in topographical organization are not yet fully understood. To address this issue, we here generated transgenic mice in which afferent fibers originating from the whisker-related brain region, called the maxillary principal trigeminal nucleus (PrV2), were selectively visualized with genetically expressed fluorescent protein. We found that functional synapse elimination drove and established large-scale somatotopic refinement, even after the thalamic barreloid architecture is formed. Before functional synapse elimination, the whisker sensory thalamus was innervated by afferent fibers not only from the PrV2, but also from the brain stem nuclei representing other body parts. Most notably, only afferent fibers from PrV2 onto a whisker sensory thalamic neuron selectively survived and were strengthened, whereas other afferent fibers were preferentially eliminated via their functional synapse elimination. This large-scale somatotopic refinement was, at least partially, dependent on somatosensory experience. These novel results have uncovered a previously unrecognized role of developmental synapse elimination in the large-scale, instead of the fine-scale, somatotopic refinement even after the initial segregation of barreloid map.

Title: Systematic analysis of the wiring process indicates a vital role for homeostatic control of dendritic excitability

Authors: *P. A. RHODES
Evolved Machines, Mountain View, CA

Abstract: The activation of an object-specific pattern in IT 120 ms following retinal activation elegantly implies that wiring embeds cortical function. However, despite decades of experimental discovery detailing individual mechanisms at play in the wiring process, including axonal search and competition, dendritic spikes and other local events that contribute to synaptic disintegration and stabilization, these mechanisms have not yet been synthesized to build predictive understanding of the self-organization of neural circuits. To begin a systematic program addressing this goal simulations were developed incorporating the mechanisms enumerated above, and the wiring process quantified during the presentation of parameterized artificial sensory input. An array of branched nonlinearly activated neurons was innervated by a population of axons representing the output of a simulated visual or olfactory sensor array. Upon formation each synapse was associated with an initial stability value, with a set of eight independent wiring parameters defining the increment or decrement of stability that occurred upon the joint conjunction or disjunction of axonal, branch and cell firing. When this stability value declined below a floor the connection was eliminated and the newly vacant dendritic location innervated by a randomly redrawn axonal partner. In this system the unsupervised self-organization of wiring unfolded in time. In some parameter regimes the initially random wiring first gave way to a period where each branch was dominated by axons associated with a distinct feature (i.e. a set of correlated inputs), so that cell firing initially signified the joint presence of at least a threshold number of co-active features. If but only if cell firing per se furnished additional stability reward, then competition and cooperation between the various branches gradually resulted in a common feature innervating all of them, with neuronal output coming to signify the presence of just one feature (i.e. a simple cell). The results also robustly indicated that wiring self-organization required an intermediate level of branch firing: not only did too little activity fail to elicit the rewards and penalties that prompted selective synaptic disintegration, but too much activity also prevented self-organization from occurring. The cell and branch firing rates within which selective wiring developed was observed to be between 1% and 10%. These results support the conjecture that the information-rich self-organization of neural wiring likely requires the homeostatic regulation of branch excitability that is found ubiquitously in neural systems.

Title: Formation of rich clubs in neuronal functional networks *in vitro*

Authors: *M. S. SCHROETER[1], P. CHARLESWORTH[2], M. KITZBICHLER[1], O. PAULSEN[2], E. BULLMORE[1]
[1]Behavioral and Clin. Neurosci. Instiute, Cambridge, United Kingdom; [2]Dept. of Physiology, Develop. and Neurosci., Cambridge University, United Kingdom

Abstract: Recent studies demonstrated that the structural backbone of the human brain follows a "rich-club" organization. This complex topological feature implies that highly connected regions, hubs of the large-scale brain network, are more densely inter-connected with each other than with nodes of lower degree. Demonstrating high centrality, rich-club nodes were also traversed by a majority of short-paths between regions, underlining their potential importance for efficient global exchange of information between functionally specialized areas of the brain. Though hub neurons have already been described at the micro-scale of brain connectivity, their role in shaping functional synchronous activity and forming microcircuit wiring during development is not yet fully understood. The present study aimed at investigating the role of hubs during network development *in vitro*, using multi-electrode local field potential coupling during spontaneous neuronal activity of dissociated primary hippocampal neurons. Emergence of functional connectivity is demonstrated by a significant increase in average connectivity strength and network size over the first 4 weeks *in vitro*. Furthermore, we found a pronounced rich-club coefficient in more mature networks. Rich-club connectivity is central to the functional network: Results show that rich-club nodes connect early in development, demonstrating structural similarities to network models grown with a preferential-attachment, "rich-get-richer", rule. Moreover, rich-club nodes of mature networks play an important role as leader or broker for initiating and shaping spontaneous activity in the network. Cascades of spontaneous activity preferentially started from, or traversed via, rich-club nodes, but not from nodes of the periphery. These results potentially indicate that the rich club topology of hub nodes may play an important role in coordinating functionally specific dynamics at the local microcircuit level.

Title: Detecting pairwise correlations in spike trains: an objective comparison of methods and application to study of retinal waves

Authors: ***C. CUTTS**, S. J. EGLEN
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: We present a computational study objectively comparing measures for quantifying pair-wise correlations in neuronal spike times. We use a detailed case study of the developing retinotopic map to demonstrate the benefits of our results. In this case study, we make use of existing published data. Quantification of the degree of correlations between recorded neuronal spikes is a key part of analysis of experimental data in a wide range of systems. Correlations in neuronal spike times are thought to play a key role in information processing since the output of an individual neuron is small and unreliable therefore several neurons may be required for reliable processing. One example is the developing retinotopic map, where correlations in spontaneous retinal activity have been implicated in its formation. In this field, recordings are made on multi-electrode arrays and the correlations calculated pair-wise across the array. Correlations are then compared against the separation of the electrodes where the neurons were recorded and this is then compared, along with the associated retinotopic map, across different genotypes. From this, inferences are made about the role of correlated activity in map formation. Many measures have been proposed to summarise these correlations and there is a standard measure used to quantify correlations in spontaneous retinal activity - the Correlation Index (Wong et al Neuron, 1993). We show that the Correlation Index is unbounded above and

confounded by firing rate. We specify properties which a measure should have in order to fairly measure correlation. We then propose a novel measure, the Tiling measure. This measure is then tested, together with 34 previously published measures, blindly and extensively for the required properties. On the basis of this testing and analytical analysis, we propose a measure to replace the Correlation Index. We re-analyse data from key studies which investigated the role of spontaneous retinal activity in map formation and show that re-analysis of the data using a measure of correlation which is independent of firing rate can significantly change the conclusions.

Title: Prenatal serotonin levels can affect the development of the prefrontal control of the dorsal raphe nucleus

Authors: S. E. GROSS, A. CHEN, V. F. LU, M. B. GREENBERG, *S. JANUSONIS
Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: The dorsal raphe nucleus (DRN) is a major source of serotonin (5-HT) in the brain and it is controlled by several forebrain regions. The DRN receives a major projection from the medial prefrontal cortex (mPFC). This projection has been implicated in several mental disorders associated with serotonergic dysfunction (autism spectrum disorders, major depressive disorder, schizophrenia, and others). The activity of DRN-projecting neurons in the mPFC is regulated by a number of neurotransmitter receptors, among which three serotonin receptors (5-HT1A, 5-HT2A, 5-HT4) directly affect their firing rates. We have shown that prenatal perturbations of 5-HT levels result in altered 5-HT4 receptor expression in the embryonic telencephalon, and that some of these effects are mRNA splice variant-specific (Chen et al., 2012). Recently, we have found that acute prenatal exposure to fluoxetine (a selective serotonin reuptake inhibitor) decreases the mRNA levels of the 5-HT1A, 5-HT2A, and 5-HT4 receptors in the embryonic telencephalon (Chen and Janusonis, submitted). Taken together, these findings suggest that

abnormal 5-HT levels in prenatal development can affect the activity of mPFC neurons that send their axons to the DRN. This, in turn, may disrupt the activity-dependent formation of mPFC-DRN synapses and lead to a dysfunctional prefrontal control of behavior later in life. In this study, we investigated (i) whether prenatally-induced changes in the expression of serotonin receptors persist in the adult mPFC and (ii) whether a decrease in the expression of one serotonin receptor (5-HT4) during development can affect the structure of mPFC-DRN synapses. In the first part of the study, timed-pregnant C57BL/6 mice were exposed to fluoxetine, and the mRNA levels of the 5-HT1A, 5-HT2A, and 5-HT4 receptors were analyzed in the mPFC of adult offspring with quantitative reverse-transcription PCR (qRT-PCR). In the second part, the density of mPFC-DRN synapses was investigated in mice with a null-mutation in the 5-HT4R gene (B6.129P2-Htr4(tm1Dgen)/J). The mPFC terminals in the DRN were labeled by using the vesicular glutamate transporter 1 (vGluT1) as the marker, and synapses were quantified with confocal microscopy and an algorithm for automated colocalization detection (Costes et al., 2004). Adult 5-HT4+/- mice (but not 5-HT4-/- mice) had a significantly higher density of synaptic contacts between mPFC terminals and 5-HT-positive neurons in the ventromedial DRN. It suggests that a prenatally induced decrease in the expression of some serotonin receptors may result in permanent changes in the prefrontal control of brain serotonin signaling.

Title: Role of cyclic AMP signaling in synaptic refinement at the *Drosophila* NMJ

Authors: F. VONHOFF, *H. S. KESHISHIAN
MCDB Dept., Yale Univ., New Haven, CT

Abstract: Neural activity plays a key role in synaptic plasticity and refinement. In the vertebrate visual system, low frequency calcium and cyclic nucleotide oscillations refine early topographic maps. At the *Drosophila* neuromuscular junction (NMJ) refinement also occurs in an activity-

dependent manner. Oscillatory neural activity and presynaptic calcium signaling modulate the motoneuron's response to the retrograde chemorepellent Sema-2a for the removal of off-target synapses in a CaMKII-dependent fashion. In addition, mutations of the calcium-dependent adenylyl cyclase rutabaga (*rut*), and the cAMP phosphodiesterase dunce (*dnc*) increase the frequency of miswired NMJs. We find that in *rut* mutants 60% of the ectopic synapses are from an octopaminergic type II motoneuron, while 40% arise from type I motoneurons. By contrast, in *dnc* mutants more than 80% are from the octopaminergic neuron. RNAi knockdown of *rut* in neurons phenocopies the frequency and the distribution of the ectopic contacts in *rut* mutants, indicating a presynaptic role of *rut* in synaptic refinement. However, the miswiring phenotype observed in *rut* mutants can be partially rescued by expressing rut in either neurons or muscles, indicating that *rut* signaling is also involved in a retrograde signal from the muscle. Overexpression of rut and dnc in either neurons or muscles also significantly increases the frequency of ectopic synapses, suggesting that cAMP levels are tightly regulated (both high and low) on both synaptic sides. We have also observed increased frequency of ectopic synapses after neuronal RNAi knockdown of the regulatory subunit R1 of PKA, a target of cAMP. As rut is dependent on Ca activity, we are testing whether cAMP levels must also oscillate for normal refinement. For live imaging experiments we use embryos mutant for the *mhc1* gene to suppress movement, monitoring Ca activity with GCaMP5. Low frequency (0.01Hz) Ca oscillations are evident in both native and ectopic contacts. We are also testing whether cAMP must oscillate by using the photoactivated adenylyl cyclase bPAC to rescue *rut*. At moderate expression levels we can suppress ectopic contacts in *rut* mutants following a protocol that mimics the native Ca oscillation (15 sec on:150 sec off); no rescue is observed without bPAC activation. We are also using the FRET based cAMP sensor epac1-camps as a tool for *in vivo* imaging of endogenous cAMP levels at motoneuron growth cones. These results show that as in vertebrates, synaptic refinement in *Drosophila* is dependent on dynamic signal transduction mechanisms that engage both Ca and cyclic nucleotide oscillations.

Title: A role of calcium influx through GluN2B receptors in the critical period plasticity for corticospinal synapse elimination

Authors: *T. OHNO[1], N. ISOO[1], M. ISOWAKI[1], S. FUKUDA[1], M. MISHINA[2], M. SAKURAI[1]
[1]Dept Physiol, Teikyo Univ. Sch. Med., Tokyo 173-8605, Japan; [2]Dept Mol Neurobiol & Pharmacol, Grad Sch. Med, Univ. Tokyo, Tokyo 113-8655, Japan

Abstract: Neuronal plasticity is generally active in young age and some of them decline or disappear after a short time window so called "critical period". Once the period is closed, loss of plasticity limits modifiability of function in adulthood and it will never be re-opened throughout life. Molecular mechanisms for such temporal restriction on neuronal plasticity, however, still remains poorly understood. It is well known in thalamic and cortical synapses that shift of NMDA receptor subunit composition from GluN2B (2B) to GluN2A (2A) occurred during early postnatal development, raising possibility that this shift is involved in the closure of critical period. However, the involvement of NMDA subunit shift in ending critical period is questioned in barrel and visual cortex. In this study, utilizing *in vitro* slice co-culture model of corticospinal projection system that shows 2B-dependent synapse elimination possessing critical period, we tried to identify specific biological mechanism that closes the critical period. In order to selectively activate the corticospinal axons, we infected the cortical slices with AAV-CaMKII-hChR2 (H134R)-EYFP and optogenetically stimulated with LED light (465 nm). This method also allows live imaging of EYFP labeled- corticospinal axons. We also employed calcium imaging to evaluate the amount of calcium influx through 2B channels. Slices were stained with calcium-sensitive dye, fluo-4 AM and optical measurements of fluorescence changes of the dye were performed using high speed camera system. We first confirmed the presence of 2B-2A-shift in cultured spinal cord, that is, synaptic 2B declined markedly toward the end of the critical period. In 2A knockout mice that express 2B at high level throughout life showed elongation of critical period. Up-regulation of synaptic 2B in wild type mice by proBDNF or spermine application re-opened the once closed critical period. As opposed to synaptic 2B, glycine receptors in the spinal cord gradually increase during postnatal development accoding to *in vivo* study. Partial reduction of inhibitory input by strychnine, which enhanced the amount of Ca influx through 2B channels without up-regulating synaptic 2B, also extended the critical period suggesting that the development of inhibitory inputs also play an important role in determining the critical period. Our findings, however, indicate that decline of 2B plays a pivotal role in closing the plastic time window and the development of inhibitory input might also be an important player in regulation of critical period length through modulation of 2B activity.

Title: Defining the role of neurotrophins in the neonatal hippocampus

Authors: A. JALLOH[1], *B. J. CATLOW[1], D. A. PAREDES[1], L. GRAND[1], J. CHUNG[2], T. Y. N. NG[2], R. D. MCKAY[1]

Abstract: During the period of programmed neuronal death in the neonatal hippocampus (HPC), neurotrophins (NT) trigger neuronal activity and this activity promotes neuronal survival through Akt signaling. Later in development, Akt is no longer rate-limiting but a MAPK/STAT3 pathway is required for circuit formation. In this study, levels of the NT brain derived neurotrophin factor (BDNF) and neurotrophin-3 (NT3) were measured in dissected HPC throughout post-natal (P) development using ELISA. In addition, antibodies against phospho epitopes of Akt, MAPK, and STAT3 were used to map the ontogeny of expression in the developing rat HPC by immunofluorescence and western blot analysis. Clear increases in BDNF and NT3 occur both in early P development and later after the first P week. Akt, MAPK, and STAT3 show distinct patterns of developmental expression in the HPC, which corroborate the role of early Akt activity and a later requirement for STAT3. To analyze the electrophysiological consequences of BDNF exposure, *in vitro* slice recordings were performed at P4 and P6 on the HPC of rat pups. 64 channel Multielectrode Arrays recorded single neuronal extracellular spiking activity from the HPC. This approach showed that BDNF immediately increased the frequency of action potential firing of HPC neurons on P4. Application of the same BDNF dose 2 minutes after the first administration changed the firing mode of neurons from single units to bursting mode, suggesting intrinsic change of the neurons. To define the effects of BDNF *in vivo*, multichannel extracellular recordings from HPC areas were obtained with a 4-shank multichannel silicon probe implanted into the P2 and P7 HPC of wild type and BDNF+/- knock-out rats. Significantly increased HPC oscillatory activities were found in all frequency ranges of P7 compared to P2 neonates. Beta and low-frequency gamma oscillation power showed the most significant increase, most prominently in CA3. Increased single unit firing activity of CA1 and CA3 neurons characterized gamma bursts and were related to micro muscle twitches during active sleep. These data show neuronal activity elicits two distinct phases of second messenger responses in the post-

natal hippocampus. The mechanism of genetic risk associated with psychiatric disorders has been modeled by systems that model early events in dissociated neuronal cell culture, in the system we report, neuronal activity can be controlled by delivering exogenous compounds (including NT) or by physiological inputs to the post-natal hippocampus *in vivo*. This approach opens new ways to link disruption in the early steps of neuronal functional maturation to later global dysfunction of brain circuits.

Title: Neuromodulatory state-dependent plasticity in striatal development

Authors: *Y. KOZOROVITSKIY, R. PEIXOTO, B. SABATINI
Neurobio., Harvard Med. School/HHMI, BOSTON, MA

Abstract: Dopamine signaling is poised to influence the development of striatal excitatory drive, because dopaminergic fibers are present in the striatum long before most excitatory synapses are formed. Among its many actions, dopamine impinges upon intracellular cascades implicated in cellular and circuit development, such as the activity of Protein Kinase A (PKA). We found that *in vivo* activation of D1 type dopamine receptors (D1Rs) rapidly increased the number of dendritic spines and synapses on direct pathway spiny projection neurons (dSPN), and this effect required PKA activity. To distinguish cell-autonomous and circuit-level requirements for synaptogenesis, we induced and monitored the growth of new dendritic spines using 2-photon glutamate uncaging, while imaging SPN dendrites in acute brain slices. We found that activation of Gs-coupled receptors was sufficient to enhance synaptogenesis. Finally, we utilized an

optogenetic strategy to demonstrate the relevance of this PKA-dependent, fast plasticity form in the developing corticostriatal circuits *in vivo*.

Title: Cell-autonomous function of connexin 36 in dendritic refinement of barrel cells during postnatal development

Authors: *W. LUO[1,2], H. MIZUNO[1,2], S. ITOHARA[3], T. IWASATO[1,2]
[1]Div. of Neurogenetics, Natl. Inst. of Genet., Mishima, Japan; [2]Dept. of Genet., Grad. Univ. for Advanced Studies (SOKENDAI), Mishima, Japan; [3]Lab. for Behavioral Genet., RIKEN Brain Sci. Inst. (RIKEN BSI), Wako, Japan

Abstract: In immature neocortex, the expression of connexin 36 (Cx36), a neuron-specific gap junction protein, and electrical coupling between cortical neurons increase during first two weeks of postnatal development, and then decline during the following two weeks, when the number of chemical synapses increase most rapidly. Besides these characterized developmental profiles, whether and how gap junction participates in neural circuit formation remains unclear. To address this issue, we utilized whisker-barrel circuit as a model system. In layer 4 (L4) of mouse somatosensory cortex, spiny stellate neurons (barrel cells) extend their dendrites toward barrel center to make synapses with thalamocortical axon terminals. This dendritic asymmetry, which is established during early postnatal stage in an activity-dependent manner, enables each barrel cell to process information from one whisker. Here, we characterized the role of gap junction in whisker-barrel circuit formation, especially the role of Cx36 in dendritic refinement of barrel

cells. Firstly, we blocked endogenous Cx36 function by transfecting dominant negative form of Cx36 (mutant Cx36) into most or sparse L4 neurons. Morphological analysis under both conditions showed that, in barrel cells over-expressed with mutant Cx36, the dendritic length inside the barrel was smaller than that in control barrel cells, while the dendritic length outside the barrel was rarely different. These results indicate that Cx36 functions cell-autonomously to regulate dendritic refinement of barrel cells by enhancing their dendritic orientation through extending their inside dendrites. We also over-expressed mutant Cx36 into most L4 neurons from 2nd postnatal week, after barrel cell dendrites acquired orientation bias. Histological analysis revealed that the inside dendritic length in barrel cells which loose functional Cx36 from 2nd postnatal week was smaller than that in control barrel cells, indicating that Cx36 may function from 2nd postnatal week to regulate dendritic refinement of barrel cells. Further analysis will be performed to characterize the molecular and cellular mechanisms of Cx36-dependent dendritic refinement of barrel cells.

Title: Topographic map plasticity by a Spatial-Temporal-Spatial transformation of sensory input

Authors: *M. HIRAMOTO[1], H. CLINE[2]
[1]The Scripps Res. Inst., La Jolla, CA; [2]The Scripps Reserach Inst., La Jolla, CA

Abstract: Topographic maps are spatial representations of the sensory environment that are located throughout the CNS and are thought to allow efficient computation within brain circuits. Current models do not provide an adequate explanation for the role of activity in map formation. Using the visual system of Xenopus, we show that the spatial distribution of retinal ganglion cells axons in the CNS is specified by the temporal order of retinal ganglion cell activity in a colinear manner. Spatial information in the visual scene is transformed into the temporal sequence of activation of retinal ganglion cells. Subsequently the temporal sequence of activity in retinal cells is transformed into the spatial arrangement of afferents in the target. The Spatial-

Temporal-Spatial (STS) transformation ensures that topographic projections are scaled across available target area.

Title: Role of Sema7A in maturation of sensory cortical circuits

Authors: *N. KEZUNOVIC, I. CARCEA, T. AHMED, R. MESIAS, P. BURMAN, H. MORISHITA, J. D. BUXBAUM, G. W. HUNTLEY
Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Early sensory experience exerts profound control over cortical circuit maturation during an early 'critical period' (CP) of heightened cortical plasticity. Disturbances in CP circuit maturation are thought to contribute to cognitive and psychiatric disorders. The molecules that promote circuit maturation during CPs are poorly understood. Sema7A is an atypical member of the Semaphorin family that is GPI-linked, is expressed principally postnatally, and is enriched in sensory cortical areas during the CP. Accordingly, we investigated the role of Sema7A in circuit maturation in mouse somatosensory (barrel) and visual cortex. We found that Sema7A is highly expressed by L4 spiny stellate cells and GABA neurons. In barrel cortex, genetic ablation of Sema7A disrupts barrel cytoarchitecture and impairs the generation of appropriately oriented L4 spiny cell dendrites. Thalamocortical axon ingrowth to L4 is unaffected. Additionally, Sema7A ablation leads to imbalances in the ratio of excitation-to-inhibition evoked by thalamocortical input to L4, which is likely due to delayed maturation of GABAergic inhibition. Levels of GAD65/67 are lower and labeling of GABA-circuit markers is sparser in both S1 and V1 of Sema7A knockout mice compared with wildtype (WT) mice. In V1, it is known that the onset of

GABA inhibition is important for initiating the CP for ocular dominance (OD) plasticity. Thus, we predicted that delayed GABAergic inhibition in V1 of Sema7A KO mice would affect OD plasticity. As expected, brief (4d) monocular deprivation (MD) during the CP failed to alter OD in the absence of Sema7A, indicating that mutant V1 circuits are insensitive to experience-dependent maturation. In humans, microdeletions in 15q24, which include SEMA7A, lead to autism and sensory perceptual deficits. Together, these data suggest that Sema7A is a critical molecular mediator of experience-driven local circuit maturation during the CP, deficits in which may lead to autism and related cognitive and perceptual abnormalities.

Title: An optogenetic screen for temporal spike patterns reveals an instructive role for neuronal activity in plasticity at the axon initial segment

Authors: M. D. EVANS, A. S. LOWE, *M. S. GRUBB
King's Coll London, MRC Ctr. Dev. Neurobiol., London, United Kingdom

Abstract: Neuronal activity is vital in many aspects of brain development. In most cases it is known to be ‘permissive’, where a certain level of spiking is required for a particular maturational or plastic event to occur. In far fewer cases is it known that neuronal activity is ‘instructive’, with particular patterns of spiking sculpting particular developmental outcomes. The gold standard for this permissive versus instructive distinction is to compare the effects of activity patterns that differ in their spatial or temporal structure while maintaining equal overall firing rates. However, it has proven difficult to control ongoing neuronal activity with sufficient scope or precision to fully explore the dependence of any particular phenotype on specific patterns of spiking. Here we took advantage of optogenetic technology to undertake an

exhaustive screen of temporal patterns in spike firing, mapping the activity pattern space associated with plasticity at the site of action potential initiation, the axon initial segment (AIS). We sparsely transfected dissociated hippocampal neurons with a channelrhodopsin-2-YFP construct that rendered them light sensitive. At 10 days *in vitro* we pharmacologically blocked circuit-driven spontaneous activity, then employed 3h chronic photostimulation using custom-built LED arrays. Individual flash stimuli were of 5ms duration at an intensity known to produce reliable spiking in our transfected neurons. Inter-stimulus intervals (ISIs) were drawn randomly from a negative binomial distribution, accounting for all second-order structure in a stimulus train by describing temporal patterns in terms of two independent parameters: mean ISI, or 'rate', and the squared coefficient of variation of ISI, or 'burstiness'. Cultures were subsequently fixed, stained for cell-type markers and the AIS scaffolding protein ankyrin-G, imaged, and quantitatively analysed for AIS length in dentate granule cells (DGCs). We found clear evidence that the frequency of stimulation alone cannot account for activity-dependent changes in DGC AIS length. A 2-dimensional distribution of AIS length according to pattern rate and burstiness displayed a clear 'hotspot' where particular combinations of input frequency and temporal structure were capable of reducing the length of the AIS over a 3h time period. Our optogenetic activity screen therefore demonstrates the instructive nature of neuronal activity in inducing length changes at the AIS, and goes further by precisely demarcating the input pattern parameters that produce this form of activity-dependent plasticity.

Title: Early chronic loud noise exposure alters the metabolic profile and expression of synaptic proteins in the developing chick auditory cortex analogue

Authors: ***V. KUMAR**[1], T. C. NAG[1], U. SHARMA[2], P. KUMAR[2], N. R. JAGANNATHAN[2], S. WADHWA[1]
[1]ANATOMY, [2]NMR AND MRI, ALL INDIA INSTITUTE OF MEDICAL SCIENCES, NEW DELHI, India

Abstract: Development of the functional (tonotopic) organization and signal processing capabilities in the auditory cortex (ACx) critically depend on the early sensory experiences. With inevitable increase in the exposure to chronic high intensity sound, it has become a major public health concern, especially for fetuses and neonates. Here we report the effects of chronic loud noise exposure (110 dB) during the embryonic development of chick (Gallus gallus domesticus) on the metabolic profile and synaptic proteins of the auditory cortex analogue (AuL). Fertilised eggs were exposed to loud noise from embryonic day 10 until hatching. Expression pattern of the synaptic proteins were studied by immunohistochemistry, western blotting and qPCR and metabolic profiling by 700 MHz 1H NMR spectroscopy of post hatch day-1 auditory cortices. Protein expression analysis showed a significantly reduced expression of synaptophysin, PSD 95, gephyrin and GABA-A γ-2 subunit but an enhanced expression of AMPA GluA-2 subunit in the noise exposed group. Multivariate regression analysis (Principal Component Analysis and Partial Least Square-Discriminant Analysis) of the concentration data of 18 metabolites quantified through NMR spectroscopy showed a separate clustering of the control and noise exposed samples. Statistical analysis (R2=0.95, Q2=0.88) showed a difference in metabolic profiles between the two groups suggestive of a metabolic perturbation following chronic loud noise exposure. Noise exposure significantly reduced the levels of GABA, energy metabolites-glucose, β-hydroxybutyrate, NAD and ATP and neuromodulators aspartate and taurine. The levels of glutamate and glutamine were significantly higher in noise exposed group as compared to control. Overall the prenatal chronic loud noise exposure increased the excitatory to inhibitory (E/I) neurotransmission related component ratio and reduced the expression of synaptic stability and plasticity maker in the AuL. Increased excitation and poor inhibition not only alter the spectrotemporal and spatial encoding of different sound frequencies but also lead to excitotoxicity, as indicated by the reduced levels of N-acetyl aspartate, thus explaining the decreased AuL neuronal number reported in our earlier stereological study (Sanyal, et al., 2013. Int. J. Dev. Neurosci.). Depleted levels of major energy metabolites indicated an enhanced neuronal activity due to chronic exposure to high intensity sound. Thus early chronic loud noise significantly alters the E/I ratio and metabolic profile which affects the functional development of the auditory cortex and associated behavior (Sanyal et al., 2013. PloS One).

Title: Early-life febrile seizures induce a precocious expression of KCC2 and impairment of excitatory synapse formation

Authors: *P. N. AWAD[1,2], B. CHATTOPADHYAYA[1], N. SANON[1], J. SZCZURKOWSKA[3], E. BAHO[1,2], J. NUNES CARRIÇO[1], S. DESGENT[1], L. CANCEDDA[3], L. CARMANT[1,2], G. DI CRISTO[1,2]
[1]CHU Sainte Justine Res. Ctr., Montreal, QC, Canada; [2]Neurosciences and Pediatrics, Univ. de Montréal, Montreal, QC, Canada; [3]Neurosciences and Brain technologies, Inst. Italiano di Tecnologia, Genoa, Italy

Abstract: Febrile seizures affect about 5% of children during the first year of life. Atypical febrile seizures, particularly febrile status epilepticus, correlate with a higher risk of developing cognitive deficits and temporal lobe epilepsy as adults, suggesting that they may permanently change the developmental trajectory of neuronal circuits. In fact, the presence of a cerebral malformation predisposes to the development of atypical febrile seizures and temporal lobe epilepsy. The mechanisms underlying these effects are not clear. Cation-chloride cotransporter KCC2 decreases intracellular Cl^- levels and renders GABA responses hyperpolarizing. Recent data suggest that KCC2 also modulates excitatory synapse development. Here, we demonstrated that KCC2 expression is altered by early-life febrile status epilepticus and investigated the functional impact of this alteration on subsequent synapse formation. We analyzed KCC2 expression and spine density in the hippocampus of a well-established rodent model of atypical febrile seizures, combining a cortical freeze lesion at post-natal day 1 (P1) and hyperthermia-induced seizure at P10 (LHS rats). 86% of these LHS males develop epilepsy and learning and memory deficits in adulthood. At P20, we found a precocious increase in KCC2 protein levels, accompanied by a negative shift of EGABA following high-frequency stimulation. In parallel, we observed a striking reduction in dendritic spine density and of mEPSC amplitude and frequency in CA1 pyramidal neurons. To investigate whether KCC2 precocious overexpression plays a role in spine alterations, we mimicked it in hippocampal organotypic cultures by biolistic transfection and *in-vivo* by *in-utero* electroporation. We found that both manipulations decreased spine density. Finally, to causally link KCC2 increased expression to spine loss in the LHS model, we blocked KCC2 *in vivo* by *in utero* electroporation of shRNA, and induced the dual pathologies as explained above. We are currently investigating whether reducing KCC2 expression levels in LHS rats rescues spine density loss. Our results show so far that an increase

of KCC2 levels induced by early-life seizure seem to affect spine formation and may be a contributing factor to the occurrence of hippocampal atrophy and associated cognitive deficits in LHS rats. Funded by CIHR, Savoy foundation and CHU Sainte-Justine Foundation.

Title: The role of Tsc1 in the development of cortical GABAergic connectivity

Authors: ***M. CHOUDHURY**[1,2], J. N. CARRIÇO[1], M. BERRYER[1,2], G. DI CRISTO[1,2]
[1]CHU-Sainte-Justine Res. Ctr., MONTREAL, QC, Canada; [2]Univ. of Montreal, Montreal, QC, Canada

Abstract: The mTOR pathway has been implicated in controlling several aspects of neurodevelopment by regulating the rate of protein-synthesis. Mutations in the regulatory components Tsc1 and Tsc2 of mTOR-Complex1 (mTORC1) cause Tuberous Sclerosis (TSC) in humans. The majority of TSC patients develop neurological problems including seizures, mental retardation and autism. Recent studies investigated the role of mTOR pathway dys-regulation in excitatory cortical cells, however its role in the development of cortical GABAergic interneurons and the specific contribution of altered GABAergic cells in disease manifestation remain largely unknown. Here, we investigated whether and how Tsc1 knockout perturbs GABAergic circuit development, both *in vitro* and *in vivo*. We found that pS6 immunolabeling, a marker of mTORC1 activation, increased specifically in cortical Parvalbumin-positive, basket GABAergic cells (BCs) during the peak of their synaptic maturation phase, between the 2nd and the 4th postnatal week postnatal *in vivo*. To investigate the role of mTORC1 activation in BC development, we knocked down Tsc1 expression, by transfecting CRE-GFP driven by a

promoter specific for BCs in cortical organotypic cultures prepared from Tsc1flox mice. Tsc1 knockdown *in vitro* caused a precocious increase in bouton density and terminal branching formed by mutant BCs, which was reversed by Rapamycin treatment. These data suggest that mTOR pathway hyperactivation affects the timing of BC synapse maturation. To investigate the role of mTORC1 in GABAergic cells *in vivo*, we bred Tsc1lox mice with Nkx2.1-CRE mice. Nkx2.1 is expressed by GABAergic neurons derived from the medial ganglionic eminence, which include BCs. At P18, Tsc1fl/fl::Nkx2.1Cre mice showed both mTORC1 hyperactivation in BCs and increased expression of VGAT, a presynaptic GABAergic marker. These data suggest that BCs may form boutons prematurely in these transgenic mice. Behavioral studies are currently underway to investigate possible deficits in working memory and social behavior.

Title: Role of SYNGAP1 in GABAergic synapse development

Authors: *M. H. BERRYER[1], B. CHATTOPADHYAYA[2], J. ANTOINE-BERTRAND[3], N. LAMARCHE-VANE[3], F. HAMDAN[4], G. DI CRISTO[2], J. MICHAUD[2]

Abstract: SYNGAP1, which codes for a Ras GTPase-activating protein (GAP), is a component of the NMDA receptor complex. We have previously shown that heterozygous loss-of-function mutations in SYNGAP1 cause nonsyndromic intellectual disability (NSID) with or without epilepsy and autism. Constitutive knockdown of Syngap1 in mice results in a hyperactivation of Ras, increase of ERK phosphorylation, excess number of GluR1 at the surface of post-synaptic

membrane, altered dendritic spine development and impaired long term potentiation associated with cognitive and behavioral deficits. Several recent studies have shown that impairment of glutamatergic synapse development contribute to the cognitive phenotype in Syngap1+/- mice. Whether Syngap1 affects GABAergic cell synapse development, thus contributing to excitation/inhibition imbalance and cognitive deficits, is unknown. Here, we show that Syngap1 is expressed by GABAergic neurons. We further show that single-cell knockout of Syngap1 in basket cells, a prominent subtype of GABAergic neurons, in cortical organotypic cultures affects GABAergic axon branching and perisomatic synapse formation. To dissect the role of Syngap1 in GABAergic cell development *in vivo*, we generated conditional knockout mice by breeding Syngap1flox/flox with Tg(Nkx2.1-Cre) mice, which express CRE exclusively in GABAergic neurons derived from the medial ganglionic eminence. We are currently characterizing the cognitive and social behavior of Tg(Nkx2.1-Cre);Syngap1flox/+ mice versus Syngap1+/- mice. All together, our data suggest that Syngap1 modulates GABAergic synapse development. The behavioral phenotype associated with Syngap1 haploinsufficiency may thus be caused at least in part by a decrease of its expression in inhibitory neurons.

Title: Dynamic changes in the connectivity of MGE-derived cortical interneurons during postnatal development

Authors: ***S. N. TUNCDEMIR**[1], F. J. STAM[2], F. OSAKADA[2], M. GOULDING[2], E. CALLAWAY[2], G. FISHELL[1]
[1]Neurosci., New York Univ., New York, NY; [2]Salk Inst. for Biol. Sci., La Jolla, CA

Abstract: The complex functions of the cerebral cortex rely on highly connected networks of excitatory neurons, integrated together by a diverse population of GABAergic cortical interneurons (cIN). Assembly of this network involves a series of events that are co-regulated by

genetic programs and neuronal activity. Yet, an understanding of how diverse cIN populations incorporate into cortical circuitry has lagged behind. Low threshold-spiking SST and fast-spiking PV cINs are the two most abundant cINs subtypes in the cortex derived from the medial ganglionic eminence (MGE), and largely populate the (early born) deep cortical laminae. Although previous studies have ascribed a latent maturation of FS-PV cINs; it is increasingly clear that during early postnatal development, SST cINs contribute to the emergence and synchronization of network activity. Using monosynaptic rabies virus tracing and optogenetics, we found significantly denser thalamic inputs (TC) to the L5/6 SST cINs during the first postnatal week. In contrast, deep layer SST cINs in juvenile mice receive only weak TC inputs; yet receive dense intracortical input from layer 5/6 and layer 2/3 pyramidal neurons (PyrN). Interestingly, we found that immature SST-cINs receive strong monosynaptic TC inputs compared to adjacently positioned FS-PV cINs and PyrNs in L5/6, which are rapidly destabilized at the end of the first postnatal week, resulting in a shift in the TC feed-forward inhibitory drive from SST cINs to PV-cINs. We suggest that maturation of TC feed-forward inhibition is associated with exuberant transient functional connectivity onto SST cINs that is later pruned to achieve predominantly FS-PV mediated feed-forward inhibition in the adult. As such, we hypothesize that dynamic patterns of TC input onto two distinct cIN types directly regulate their incorporation into the cortical network.

Abstract: Schizophrenia etiology is thought to involve the interaction between genetic and environment factors during brain development. Despite significant progress in understanding both genetic susceptibility and neuronal circuit dysfunction in schizophrenia, fundamental gaps exist in our knowledge about how circuitry mechanisms may interact with genetic susceptibility to affect neuronal development. Disrupted-in-schizophrenia 1 (DISC1), a risk gene for major mental disorders, regulates various processes of neuronal development, including adult hippocampal neurogenesis, deficiency of which alone is sufficient to cause cognitive and affective behavior deficits. We found that DISC1 knockdown-induced glutamatergic synapse formation defects of newborn neurons in the adult hippocampus required GABAergic input-induced depolarization. Rabies virus-mediated retrograde tracing and optogenetic analyses further identified aberrant GABAergic synaptic inputs from parvalbumin-expressing (PV+) and somatostatin-expressing (SST+) interneurons. Functionally, optogenetic suppression of SST+ neuron activation rescued dendritic defects of DISC1-deficient newborn neurons, but not glutamatergic synapse formation. In contrast, suppression of PV+ neuron activity partially rescued DISC1 deficiency-induced glutamategric synaptic formation defects, but not aberrant dendritic development. Therefore, distinct neuronal circuit interacts with the genetic susceptibility to manifest different aspects of aberrant neuronal development.

Title: Postnatal development of parvalbumin-positive GABA neurons in mouse prefrontal cortex

Authors: *G. GONZALEZ-BURGOS, T. MIYAMAE, T. TIKHONOVA, D. A. LEWIS
Psychiatry, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Parvalbumin-positive (PV) GABA neurons significantly shape neocortical circuit development and are crucial regulators of neural activity in mature cortical cell networks. Comparing the development of the two main PV neuron subtypes, basket cells (BCs) and chandelier neurons (ChNs), is thus essential to understand the roles of ChNs and BCs in regulating the emergence of cortical network activity. Furthermore, distinctive developmental trajectories of ChN and BC function would suggest that PV neuron subtypes could be differentially affected by environmental factors that increase the risk of mental illnesses such as schizophrenia. Recent studies suggested that relative to BCs, ChNs originate later in development. If so, then developing ChNs may achieve a mature functional state later than BCs, unless ChN function develops at a faster rate. To distinguish between these possibilities, we began studying the postnatal development of PV neuron function in mouse prefrontal cortex (PFC). We performed targeted patch clamp recordings from GFP-labeled neurons in brain slices prepared from the PFC of G42 mice, a mouse strain in which GFP is expressed exclusively in PV neurons. The recorded neurons were filled with biocytin to characterize their morphology post-hoc. As suggested in previous studies, we found that as early as postnatal day 15 (P15) biocytin-filled PV neurons could be classified as ChNs or BCs based on the presence or absence, respectively, of characteristic vertical cartridges of axonal boutons. In current clamp recordings, we examined the intrinsic properties of the recorded neurons measuring multiple parameters, including input resistance (Rin), action potential (AP) threshold, AP duration at half maximal amplitude, after hyperpolarization (AHP) amplitude and a spike frequency adaptation coefficient (SFA). These parameters were measured from PV neurons of P15 to P45 mice, and the trajectory of change was fit with exponential functions. Some parameters did not change with age (AP threshold, AHP), but others exhibited a similar type of change in BCs and ChNs. For instance, in both ChNs and BCs, Rin, AP duration and SFA decreased significantly with age until reaching a plateau. However, preliminary curve fit analysis showed that, consistent with a later developmental origin of ChNs, the plateau state was reached later in ChNs compared with BCs. These preliminary results indicate that in PFC circuits the intrinsic excitability of PV neurons, which is crucial for activity-dependent development of PV neuron signaling, matures following different time courses in BCs and ChNs.

Title: Activity-dependent cortical interneuron circuit formation

Authors: *T. KARAYANNIS, R. PRIYA, S. TUNCDEMIR, G. J. FISHELL, N. V. DE MARCO GARCIA
Neurosci., NYU Neurosci. Inst. and Smilow Neurosci., New York City, NY

Abstract: Neuronal microcircuits within the superficial layers of the mammalian cortex provide the cellular substrate for associative cortical computation. Inhibitory interneurons constitute an essential component of the circuitry and are fundamental for the integration of local and long-range information. Nevertheless, the mechanisms by which these interneurons integrate into the developing circuit are not known. Using a monosynaptic rabies-based approach, optogenetics and electrophysiology, we report that, during early development, superficially positioned Reelin-expressing neurogliaform interneurons in the somatosensory cortex receive innervation from both cortical and thalamic excitatory populations. Interestingly, the inputs from the latter seem to predominantly activate NMDA receptors subtypes that are necessary for driving the proper axo-dendritic morphological development of neurogliaform cells, as well as for setting the balance between their intracortical and thalamic inputs. These results reveal that sensory-driven activity shapes the assembly of specific cortical interneuron circuits.

Title: Excitatory input to cortical GABAergic interneurons during development

Authors: *R. DENG[1], P. O. KANOLD[2]
[1]Biol. Sci. Grad. Program, [2]Dept. of Biol., Univ. of Maryland, College Park, MD

Abstract: GABAergic interneurons are important for shaping sensory computation in mature brain, but are also important in regulating the critical period during brain development. During development, neural activity contributes to the maturation of GABAergic neurons, but the source of this activity on GABAergic neurons is unknown. Excitatory inputs onto GABAergic neurons could contribute to this activity. During the early developmental period, subplate-neurons (SPN) are the first population of neurons exhibiting mature electrical properties and participate in transient circuits relaying neural activity from thalamus to excitatory cortical neurons. Since SPN ablation prevents the maturation of GABAergic function we hypothesize that SPN may provide excitatory input to GABAergic neurons during brain development and thereby aid in the maturation of GABAergic neurons. We use a mouse expressing gad2cre driven red fluorescence protein to identify cortical GABAergic interneurons in the middle cortical layers of mouse auditory cortex. We then investigate the presynaptic sources of glutamatergic input to these GABAergic interneurons by laser-scanning photo stimulation (LSPS) during postnatal development (P5 to P13). We find that a fraction of gad2cre labeled GABAergic interneurons receive excitatory input from SPN and the fraction of GABAergic interneurons receiving excitatory input from SPN was larger in older mice (P9 to P13) during the period of GABAergic maturation and during the critical period than in neonatal mice (P5 to P7). Thus, excitatory inputs from SPN might regulate neuronal activity dependent development of GABAergic interneurons by providing excitatory input in early development. Therefore, removal of SPN's input to GABAergic neurons in early development removes this excitation and thereby might prevent GABAergic maturation, leading to cortical hyperexcitability.

Title: Enrichment of PSD-MAGUKs in nascent dendritic spines

Authors: *J. T. LAMBERT, T. C. HILL, K. ZITO
Univ. of California, Davis, Davis, CA

Abstract: Animals have a remarkable capacity to change their behavior to suit a wide range of circumstances. At the cellular level, this behavioral flexibility is made possible because individual neurons modify their connectivity in response to varying patterns of synaptic activity in a process termed experience-dependent plasticity. During experience-dependent plasticity, the selective stabilization of new dendritic spines is linked tightly with functional changes in neural circuits. High-frequency stimulation that induces long-term potentiation (LTP) has been shown to increase the stability of new spines, but the molecular mechanism of this activity-dependent structural stabilization is ill-defined. Here, we begin to characterize the molecular composition of new spines compared to mature spines. We used time-lapse two-photon imaging of CA1 pyramidal neurons expressing DsRed-Express and EGFP-tagged postsynaptic proteins, focusing on the membrane associated guanylate kinases (MAGUKs) PSD-93, PSD-95, SAP-97, and SAP-102. We assessed the relative enrichment of these postsynaptic proteins in new spines compared to spines that were present and stable throughout the imaging session. We found that all four PSD-MAGUKs are less enriched in new spines compared to their persistent neighbors. This difference is a function of spine age, not of spine size, as persistent spines were similarly enriched regardless of size. Intriguingly, PSD-MAGUKs enriched in new spines at different rates. GFP-SAP-97 and GFP-SAP-102 enriched within 3 hours of spine outgrowth ultimately reaching levels similar to neighboring, persistent spines. Notably, GFP-PSD-93 is unenriched in new spines, but enrichment increases gradually, reaching mature levels by 6 hours. GFP-PSD-95 did not enrich in new spines over the entire course of the time-lapse (7.5 hours). Current experiments are focused on characterizing the effects of stabilization-inducing activity on the enrichment of PSD-MAGUKs in new spines.

Title: Experience-dependent axon targeting and guidance molecule expression in mouse olfactory system

Authors: *N. N. GONG[1], H. MATSUNAMI[2]
[2]Mol. Genet. and Microbiology, [1]Duke Univ., Durham, NC

Abstract: Olfactory sensory neurons (OSNs) that express the same olfactory receptors (ORs) are scattered in the olfactory epithelium, yet their axons coalesce into just a few bundles of axons, or glomeruli, on each olfactory bulb, a process that is still not fully understood. Previous work indicates that both activity-dependent and –independent mechanisms are involved in OSN axon fasciculation and targeting, but whether olfactory experience plays a role is unclear. This study aimed to determine the effect of early postnatal odor experience on expression of axon guidance molecules and subsequent OSN axon targeting, focusing on two related ORs, M71 and M72, that normally converge into nearby yet separate glomeruli on the olfactory bulb. First, mice were exposed to acetophenone, a cognate ligand for both receptors, for 16-hours per day from the day of birth until the mice were 21 days old. Strikingly, stimulation affected M71- and M72- OSNs so that the axons of these OSNs coalesced onto the same glomerulus. Double-label fluorescent *in situ* hybridization was then used to compare the expression levels of known axon guidance molecules, including Kirrel2, Kirrel3, EphA5, ephrinA5, and BIG-2, in OSNs. The data suggest postnatal stimulation with acetophenone influences expression of certain axon guidance genes involved in OSN targeting: in mice stimulated with acetophenone, M71-OSNs exhibited significant downregulation of Kirrel3 expression, while in M72-OSNs, Kirrel2, ephrinA5, and BIG-2 expression were significantly downregulated. Next, the relationship between OR responsivity of M71, M72 and a series of M71/M72 chimeras *in vitro* and published axon targeting data *in vivo* of OSNs expressing these ORs was examined. A significant correlation was found between OR responsivity *in vitro* and glomerular targeting *in vivo*, further supporting our hypothesis that ligand-dependent OR activation has a critical role in determining axon targeting. Together, our study reveals an experience-dependent component involved in OSN targeting in the olfactory bulb.

Title: Differential requirement of presynaptic release for eye-specific and topographic retinal maps

Authors: *A. REBSAM[1], A. ASSALI[1], M. BENNIS[2], P. KAESER[3], T. C. SÜDHOF[4], P. GASPAR[1]

Abstract: Projections of Retinal Ganglion Cells (RGCs) in their main targets, the dorsal Lateral Geniculate Nucleus (dLGN) and the Superior Colliculus (SC), are organized in eye-specific domains and with precise topography. Projections are initially intermingled and are refined into their final territories during the first postnatal weeks. Alteration of spontaneous neural activity in the retina disrupts both eye-specific segregation and retinotopy. However, the cellular mechanisms linking neural activity to map refinement remain poorly understood. Here we examine the role of presynaptic release on the refinement of retinal projections. To distinguish between the synaptic and non-synaptic effects of activity blockade, we perturbed specifically the presynaptic release at retinal terminals by a conditional deletion of Rim 1 and 2 in RGCs. The removal of Rim proteins is known to strongly reduce calcium-dependent neurotransmitter

release, without affecting spontaneous release. Our tracing studies indicated that Rim conditional double knock-out (Rim cDKO) mice have defects in eye-specific segregation in the dLGN but no major topographic defects in the SC. This result suggests that segregation but not gross topography involves calcium-dependent synaptic release. Interestingly, ipsilateral projections in the SC do not form patches and extend more laterally in Rim cDKO compared to control mice, suggesting that ipsilateral projections could be more sensitive to the perturbed presynaptic release. Our results show that retinal synaptic release is important for eye-specific segregation and for the organization of ipsilateral projections.

Title: Activity-dependent regulation of liprinα1 during synapse development

Authors: *H. HUANG[1,2,3], K.-O. LAI[1,2,3], A. FU[1,2,3], N. IP*[1,2,3]
[1]Div. of Life Science,HKUST, Hong Kong, China; [2]Mol. Neurosci. Center, HKUST, Hong Kong, China; [3]State Key Lab. of Mol. Neuroscience, HKUST, Hong Kong, China

Abstract: The liprinα family proteins, originally identified as interacting protein of the receptor protein tyrosine phosphatase LAR (LAR-RPTP), are suggested to play an indispensable role in dendrite development and formation of excitatory synapse. However, the regulation and function of liprinα1 in neural development remains unclear. We found that liprinα1 was highly expressed at the post-synaptic fractions during early postnatal stages, when activity-dependent synapse development actively occurs. Furthermore, liprinα1 was identified as an *in vivo* substrate of Cdk5, and this phosphorylation was regulated in cultured neurons by neuronal activity.

Interestingly, phosphorylation of liprinα1 in the mouse visual cortex was also modulated during eye opening, suggesting that liprinα1 phosphorylation might be involved in activity-dependent synapse development *in vivo*. Importantly, knockdown of liprinα1 in cultured hippocampal neurons led to defects in dendritic arborization and reduction in spine density. Together, our results reveal a novel mechanism of activity-dependent synapse development that involves phosphorylation of liprinα1.

Abstract: In various animal species, some instinct behaviors, such as mating behaviors and social behaviors, dynamically alter in an age-dependent manner. It has been well-known that endocrine systems regulate the behavioral and physiological alteration according to age. However it remains largely unknown how neural reshaping contributes the behavioral alteration. To approach this issue, we have focused on a transcription factor, Mblk-1, which is a possible candidate that is responsible for neural reshaping. mblk-1 was originally identified in honeybee as a gene specifically expressed in the higher-order brain center (mushroom body), which is associated with behavioral alteration according to age-dependent division of labor in the workers (Takeuchi et al., Insect Mol. Biol. 10, 487-494, 2001). Furthermore a nematode homologue of Mblk-1 (mbr-1) is required for the neural reshaping (pruning), which occurs from the larval to adult stages (Kage and Hayashi et al., Curr. Biol. 15, 1554-1559, 2005). Although vertebrate homologues of Mblk-1 are also identified, their roles in the nervous system have not been studied. We began to investigate the vertebrate homologue using medaka fish, because medaka fish exhibit remarkable behavioral alteration according to their age (Imada et al., PLoS ONE, 5, e11248, 2010), and detail neuronal morphology is observable in the medaka brain. Here we

report identification of cDNAs for three medaka homologues of Mblk-1 (Mbo-1, 2, 3) and their expression analysis. First qRT-PCR using various adult tissues showed that the medaka homologues were expressed mainly in the nervous system and/or reproduction organ. *In situ* hybridization showed that mbo-1 was expressed prominently at the habenula and the preoptic area, which are suggested to be involved in emotional and reproductive behaviors. Now we generated mbo mutant strains using CRISPR/Cas system to examine whether these homologues are involved in the neural reshaping and behavioral alteration.

Title: Injury-induced decline of intrinsic regenerative ability revealed by quantitative proteomics

Authors: ***S. BELIN**[1], H. NAWABI[1], C. WANG[1], P. WARREN[2], H. SCHORLE[3], C. UNCU[2], Z. HE[2], J. STEEN[2]
[1]Neurol., [2]Pathology, Boston Childrens Hosp., Boston, MA; [3]Dept. of Developmental Pathology, Univ. of Bonn Med. Sch., Bonn, Germany

Abstract: The inability of the mature central nervous system (CNS) to regenerate suggests a loss of function in the injury response associated with aging. Intense focus has been directed toward understanding the mechanisms responsible for the regenerative failure of adult neurons in the mammalian CNS, and on overcoming such failure. A particular emphasis was placed on the role of the inhibitory environment and the role of development-dependent mechanisms, which. identifying several molecular regulators. However, manipulations of these pathways result in limited axon regeneration *in vivo*, suggesting that other major molecular factors are yet to be discovered. In this study, our hypothesis was that the injury response in the adult CNS inhibits the regenerative capacity of retinal ganglion cells (RGCs). Thus we systematically characterized injury-triggered responses RGCs. We performed a quantitative proteomic analysis of a pure fraction of neurons obtained after FACS sorting YFP positive RGC before and after optic nerve injury. Using bioinformatics analyses, we generate a map of cellular functions and pathways specifically regulated by injury. In addition, we obtained a list of potential upstream regulators

potentially essential for neuron survival and regeneration. While our study reveals a network of injury-response signaling hubs, including known regeneration regulators such as mTOR, calcium, and MAPK, novel molecules were also identified. We focused on one of the new potential regulators, the c-myc transcription factor, which is down regulated by axotomy. c-myc appears to be an important regulator that orchestrates both neuronal survival and axon regeneration in RGCs. Forced expression of c-myc in RGCs, either before or after injury, promotes RGC neuronal survival and axon regeneration. As our protemics study highlighted the simultaneous alteration of several pathways by injury, we decided to overexpress c-myc in a context of PTEN and Socs3 deletion. Surprisingly, modulating this combination of factors dramatically increases axon regeneration in the model of optic nerve injury with a substantial increase in the number of axons entering and crossing the chiasma. Altogether, our results describe the first quantitative proteomics of a pure RGC *in vivo* population, revealing the major effect of injury in CNS neurons. Our study highlights several new potential key players of neuron survival and axon regeneration which might represent novel targets for developing neural repair strategies in the adult CNS.

Title: Musashi 1 expression in regenerating axolotl retina

Authors: *E. A. DEBSKI, J. MAYNOR, M. SINDALL
Univ. of Kentucky, Lexington, KY

Abstract: The axolotl salamander is able to repair damage to its retina caused by injury. We have been examining the process by which it does so following optic nerve and ophthalmic artery transection. These manipulations induce a severe degeneration of the retina that reduces this structure to a rudiment within1-2 weeks. Over the course of the next 6-8 weeks, the lost cells are replaced and the neural circuitry is re-built. To help identify stem cell populations involved in this process, we have been examining patterns of Musashi 1 expression during the regeneration process. Musashi 1 is a RNA-binding protein that is expressed in the retina in both

stem/progenitor cells and some differentiated cell types (Kaneko and Chiba (2009) Neurosci Lett. 450:252-257). In central sections of the control retinas of juvenile axolotls, Musashi 1 immunoreactivity is reliably found in a subset of small cells within the retinal pigment epithelium and surrounding cell bodies in the outer nuclear layer. In contrast to reports in other species, the outer nuclear layer staining is not contained within the cell bodies of photoreceptors. Rather, it appears to be continuous with occasionally observed staining in Müller radial glia and thus most likely represents the apical ends of these cells. In lateral retinal sections, glial staining with Musashi 1 can continue into the inner plexiform and retinal ganglion cell layers. Three days after retinal injury, Musashi 1 immunoreactivity extends to a large area of the retinal pigment epithelium. While glial cell immunoreactivity is indistinguishable from that seen in controls, bright irregular shaped spots of immunoreactivity are seen throughout the retinal layers. By one week after injury, Musashi 1 positive cells with the large inclusions characteristic of macrophages are seen along the inner limiting membrane. Macrophage-like Musashi 1 positive cells are abundant by the time that the retina is reduced to a rudiment and Müller glial cell staining is maintained in a manner consistent with their changed morphology at this stage. We are in the process of extending our observations to later time points when cells are being born to rebuild the retina. However, our results to date indicate that Musashi 1 may play an important role in the injury response resulting in retinal degeneration. Furthermore, the maintenance of Musashi 1 expression in Müller radial glial at a time of tremendous cell death suggests that it may help ensure the survival of these cells and/or be needed in the subsequent repair process.

Title: Rubrofugal projections: Novel mediators of spontaneous recovery after spinal cord injury

Authors: *C. S. SIEGEL, S. M. STRITTMATTER, W. B. CAFFERTY
Neurol., Yale Univ., New Haven, CT

Abstract: Spinal cord injury (SCI) results in irreversible devastating functional impairments. Damaged axons fail to regenerate after SCI because of the inhibitory environment in the mature central nervous system (CNS) and the low intrinsic growth capacity of adult neurons. As an

alternative to regeneration, plasticity of intact circuits represents a potent route to recovery of function after SCI. Previous data from our lab demonstrated that the intact corticospinal tract (CST) could functionally sprout into the denervated side of the spinal cord in the absence of nogo receptor 1 after unilateral pyramidotomy (uPyX). We sought to determine whether sprouting of intact circuits could restore function after complete CST lesion. To test this, adult wild type (n=20) and *ngr1*$^{-/-}$ (n=20) mice received bilateral pyramidotomies (n=10 bPyX, n=10 sham/genotype). Mice were behaviorally assessed via grid walking, fore limb tape removal and footprint analysis pre-surgically and on days 2, 4, 7, 14, 21, 28 and 35-post lesion. Seven days before the end of the experiment, mice received Biotinylated Dextran Amine (BDA) microinjections into their left side Red Nucleus to trace rubrofugal projections, and Alexa-Fluor488-conjugated Dextran microinjections into their right side sensorimotor cortex to trace the corticofugal projections rostral to the lesion. Wild type mice demonstrated persistent deficits throughout the experimental period, while *ngr1*$^{-/-}$ mice demonstrated a trend toward enhanced functional recovery. The density of intact cortico-rubro, cortico-pontine, rubro-pontine, rubro-raphe, and rubro-spinal projections were enhanced in all lesioned animals compared to sham. *ngr1*$^{-/-}$ mice demonstrated significantly more dense projections between these nuclei in comparison to wild type mice. To dissect the impact of these *de novo* circuits on functional recovery after bPyX we used pharmaco-genetics to silence each circuit. Preliminary data shows that AAV-mediated overexpression of the inhibitory DREADD (Designer receptors exclusively activated by designer drugs) hM4Di receptor into the nucleus raphe magnus abrogates functional recovery in *ngr1*$^{-/-}$ mice after bPyX. Therefore, we hypothesize that a novel rubro-raphe circuit is capable of restoring function after complete axotomy of the CST and is thus a new anatomical substrate to target therapies to treat severe SCI.

Title: Identification of novel modulators of intrinsic CNS axon growth

Authors: *K. FINK, S. STRITTMATTER, W. CAFFERTY
Yale Univ., New Haven, CT

Abstract: Axons do not grow after spinal cord injury (SCI) because the central nervous system (CNS) is an inhibitory growth environment and adult CNS neurons have a diminished intrinsic growth capacity. Numerous studies have reported that relief of environmental inhibition by nullifying the effects of myelin associated inhibitors (NogoA, MAG and OMgp) and chondroitin sulfate proteoglycans (CSPGs), results in enhanced, yet clinically unsatisfactory, axon growth and functional recovery after SCI. Elevating the growth capacity of CNS neurons has been more challenging owing to a paucity of molecular targets. We sought to identify novel intrinsic modulators of axon growth by completing differential transcriptomic analysis between corticospinal tract neurons in an active or quiescent growth state after unilateral pyramidotomy (uPyX). Transgenic *crym-gfp ngr1*$^{+/+}$ (n=6) and *crym-gfp ngr1*$^{-/-}$ (n=6) mice received uPyX followed two weeks later by unilateral intraspinal injection of the retrograde tracer fast blue (FB) into the denervated cervical cord. Four weeks after lesion, mice were prepared for laser capture microdissection and RNA extraction. *Crym-gfp* mice express soluble GFP in CST neurons allowing us to identify this population at high density and fidelity. Neurons that had sprouted arbors into the denervated side of the spinal cord take up FB. Therefore, CST neurons were identified in cortex as sprouting (GFP+FB+) or non-sprouting (GFP+FB-) and isolated using laser capture microdissection. CST neurons were also collected from uninjured perinatal mice (P5) and adult mice (P28) to compare CST sprouting to active and quiescent growth states, respectively. Laser captured cells were prepared for RNA sequencing and sequenced to an average depth of 52 million reads per sample with an average of 66% mapping uniquely to genes. Transcriptional profiles were compared using TopHat and Cufflinks. 1174 genes were significantly differentially expressed between intact sprouting and non-sprouting neurons. Functional relevance of significantly differentially expressed genes was explored using Ingenuity Pathway Analysis. Functional analysis revealed 30 phosphatases that are differentially regulated in sprouting neurons. Of these phosphatases, 10 were knocked down in an *in vitro* cortical neuron scrape assay using shRNA to assess their effects on growth. The assay revealed that knockdown of 5 of the 10 candidate phosphatases significantly impaired growth of cortical neurons *in vitro*. Ongoing studies will reveal if these phosphatases can be targeted *in vivo* to enhance plasticity and regeneration after spinal cord injury.

Title: Targeting non-muscle myosin II to promote axon regeneration after optic nerve injury

Authors: *X. SAIJILAFU[1], Y. JIAN[2], Y. GUO[2], C. LIU[2], J. JIANG[2], M. ZHANG[2], F. ZHOU[2]

Abstract: Axon regeneration is essential for the restoration of neuronal connectivity and functional recovery after nerve injury. However, axons in the adult mammalian central nervous system (CNS) have very limited growth ability following injury, due to the inhibitory environment and diminishing intrinsic axon growth capacity. Our previous cell culture study has found that inhibition of nonmuscle myosin II (NMII) with either pharmacological inhibitor or siRNAs drastically increases axon growth of multiple neuronal types over either extracted CNS myelin or chondroitin sulfate proteoglycans (CSPGs), two major categories of inhibitory molecules in the CNS. However, it is unknown whether inhibition of nonmuscle myosin II have similar effects on axon regeneration *in vivo*. Herein, we showed that deletion of endogenous NMIIA/B in mouse retinal ganglion neurons significantly enhanced axon regeneration after the optic nerve crush injury without affecting the neuronal survial. Lens injury is well known to promote the axon regeneration of retinal ganglion neurons after optic nerve injury. We also found that lens injury and deletion of endogenous NMIIA/B act synergistically to promote enhanced axon regeneration. Thus, we believe that regulation of the local cytoskeletal machinery in the growth cone would provide an alternative and novel therapeutic treatments for peripheral and central nerve injuries.

Title: Inhibition of BMP and sFRP2 proteins in the adult mouse eye induces proliferation and expands the retinal stem cell population

Authors: *K. N. GRISE, L. BALENCI, D. VAN DER KOOY
Mol. Genet., Univ. of Toronto, Toronto, ON, Canada

Abstract: Adult retinal stem cells (RSCs) are a rare subset of cells that reside in the pigmented ciliary epithelium (CE) of the mammalian eye. Once dissociated from the CE, RSCs readily proliferate to form clonal, free floating spheres after 7 days, with the capacity to self-renew and differentiate into all of the cell types of the neural retina and retinal pigmented epithelium (RPE). Despite having the capacity to proliferate *in vitro*, RSCs do not proliferate or generate new retinal cells in adult mammals *in vivo*. Thus, we aimed to identify factors responsible for maintaining RSC quiescence and determine if those factors can be targeted *in vivo* to disinhibit RSC proliferation and induce retinal neurogenesis. To investigate if discrete tissue types in the eye contribute to the inhibitory RSC niche, we generated tissue-specific conditioned media (CM) from postnatal day 2 and adult mouse eyes and added it during the primary RSC clonal sphere formation. Only CM from the adult lens and cornea reduced the number of spheres formed. We considered two proteins known to be expressed in the adult eye as potentially mediating the lens and cornea CM inhibition: bone morphogenic proteins (BMPs) and secreted frizzled related protein 2 (sFRP2). We found that BMP and sFRP2 proteins could dose-dependently impede sphere formation. When noggin (BMP inhibitor) and α-sFRP2 antibody were added in combination to lens and cornea CM, sphere number returned to control levels. Thus, inhibiting BMP and sFRP2 signaling eliminated lens and cornea CM-induced quiescence of adult RSCs *in vitro*. Next, we investigated whether BMP and sFRP2 inhibition could disinhibit RSC quiescence *in vivo*. We injected noggin or α-sFRP2 intravitreally into the right eye 3 times; once every 24 hours. The left eye was injected with an equivalent volume of PBS as a control. All injections also included 0.5ug/uL of EdU. Seven days after the last injection, EdU-positive cells were detected in both noggin and α-sFRP2 treated eyes at a much higher frequency than control at all doses. Also, the number of EdU-positive cells in both conditions appeared to be dose-dependent. Further, by performing a clonal sphere assay 6 days after injection, we found that α-sFRP2 doubled the number of primary RSC spheres. These results establish that inhibition of BMP and sFRP2 signaling can cause proliferation within the adult mouse eye. Also, inhibiting sFRP2 appears to expand the retinal stem cell pool. Experiments are now underway to better characterize the cell types being induced to proliferate, the combinatorial effects of noggin and α-sFRP2 (together and with mitogens), as well as whether any new retinal neurogenesis ensues.

Title: DCLKs: New regulators of growth cone regeneration

Authors: *H. NAWABI[1], S. BELIN[1], R. CARTONI[1], C. WANG[1], A. LATREMOLIERE[1], X. WANG[1], C. WOOLF[1], C. V. GABEL[2], J. STEEN[1], Z. HE[1]

Abstract: Axon regeneration in the adult central nervous system is extremely limited and the underlying mechanisms are still poorly understood. Transforming the stump of an injured axon into a motile growth cone structure has been implicated as a key rate-limiting step in axon regeneration. Using a comparative proteomic approach on FACS-purified RGCs, we found that the abundance of DCLK1/2 (doublecortin like kinase 1/2) is dramatically reduced in injured retinal ganglion cells (RGCs). DCLK1/2 share structure similarities with DCX (doublecortin), which is involved in neuronal migration, but their functional roles in mature neurons are not defined. Our further studies suggest a critical role of DCLKs in the growth cone reformation during optic nerve axon regeneration. First, we verified that the expression of DCLK1/2 decreases dramatically after injury. Second, when overexpressed in WT animals, DCLK2 induced a limited yet significant regeneration. Yet, in a PTEN deleted background, DCLK2 expression resulted in dramatically increased axon regeneration, in particular at the initiation stage of optic nerve regeneration. Third, our time lapse imaging studies on retinal explants implicate DCLK2 as being crucial to growth cone regeneration. Our current studies involve analyzing the phenotypes of growth cone regeneration in mice with the DCLK1/2 double knockout. We are also dissecting the molecular mechanisms by which DCLK2 executes its effects on growth cone formation and other stages of axon regeneration. Together, our results may reveal the key molecular players in the growth cone regeneration, which should be important for designing therapeutic strategies of promoting axon regeneration after injury.

Abstract: Mammals lose the ability to regrow the injured optic nerve shortly before birth, whereas the South African-clawed frog Xenopus laevis retains this regenerative capacity throughout development. To study how Xenopus laevis accomplish this, we seek to generate a translational profile for the regrowth of retinal ganglion cell (RGC) axons following injury. As a means of isolating RGC mRNAs from a heterogeneous population of retinal cells, we generated transgenic Xenopus laevis frog lines that express enhanced green fluorescent protein (EGFP) in the ribosomes of only RGCs. We crushed the optic nerves of juvenile Xenopus using forceps, collected tissue samples 0, 1, 3, 7, and 11 days post-surgery, and used translating ribosome affinity purification (TRAP) to isolate mRNAs being actively translated by ribosomes expressing EGFP. Here we present initial results showing differential gene expression patterns for ~16,000 genes sequenced using RNA-Seq, as well as subsets of RGC-enriched genes. These data indicate unexpected broad temporal patterns of expression: primarily up-regulation by Day 3, followed by widespread down-regulation in Days 7 and 11. Using quantitative PCR (qPCR), we validated RNA-Seq results for a subset of 14 genes with distinct expression patterns. Finally, we present results of clustering analysis to determine novel gene subsets that likely play a role in the

regeneration process. Molecules or signaling pathways discovered to facilitate the regeneration process may have potential for translation into clinical practice.

Title: The krüppel-like factor gene targeting dusp14 regulates axon growth and regeneration

Authors: ***Y. WANG**[1], K. IWAO[2], A. APARA[2], D. L. MOORE[2], M. BLACKMORE[3], N. J. KUNZEVITZKY[1], J. L. GOLDBERG[1]

Abstract: Retinal ganglion cells (RGCs) and other central nervous system (CNS) neurons in adult mammals are unable to regenerate their axons after injury. Krüppel-like transcription factor (KLF) family members regulate intrinsic axon growth ability of CNS neurons during development, but downstream mechanisms have been elusive. By screening genes regulated by KLFs in RGCs, we identify Dual specificity phosphatase 14 (Dusp14) as a key player limiting axon growth and regenerative ability downstream of KLFs' ability to regulate axon growth in RCGs. We demonstrate Dusp14 expression increases in parallel to KLF9 during RGC development, and is induced by KLF9 in RGCs *in vitro*. The Dusp14 mediates neurite growth suppression *in vitro* in a phosphatase-dependent fashion, and the KLF9-Dusp14 pathway inhibits

activation of mitogen-activated protein kinases (MAPK), critical to neurotrophic signaling of RGC axon elongation. Decreasing Dusp14 expression or function in RGCs rescues KLF9-induced neurite outgrowth suppression *in vitro* and optic nerve regeneration after trauma *in vivo*. Thus, developing strategies to modulate this KLF-Dusp14 pathway to enhance MAPK signaling may further promote axon regeneration after CNS injury.

Title: Regeneration of serotonin axons in the neocortex of the adult mouse probed with *in vivo* two-photon imaging

Authors: Y. JIN, *D. J. LINDEN
Neurosci Dept, Johns Hopkins Univ. Sch. Med., BALTIMORE, MD

Abstract: Experiments using fixed tissue have suggested that the serotonin (5HT) neurons of the dorsal raphe have an unusual and atypical capacity for axonal regeneration. However, these fixed tissue experiments cannot capture the dynamics of axonal regeneration and cannot easily distinguish true regeneration from the compensatory sprouting of undamaged axons or transient serotonin depletion. To address these issues, we employed chronic *in vivo* two photon imaging of the somatosensory cortex in an Slc6A4 (serotonin transporter)-soluble EGFP BAC transgenic mouse in which the complete extent of the serotonin-containing neurons was labeled. Consistent with previous work using fixed rat tissue, we found that repeated systemic injection of p-chloro-amphetamine (PCA) produced immediate and profound degeneration of 5HT axons but no loss of the 5HT-poisitve cell bodies of origin in the dorsal raphe. In the weeks to follow, a slow recovery was observed that was dominated by axon regeneration. Most of regenerated axons became morphologically stable and survived till the final monitoring point (27 weeks). The regenerated serotonin axons entered the neocortex individually rather than bundles and did not follow blood vessels or spared axons. They appear to avoid the spared axons and each other to

fill the imaged cortical volume efficiently. The spared axons observed soon after PCA treatment almost entirely survived to the final monitoring point and exhibited only a small degree of sprouting. In contrast to PCA treatment, saline treatment didn't cause any degeneration, sprouting or rearrangement of 5HT axons over the ensuing 27 weeks. Based on these descriptive results, we believe that time-lapse imaging of regenerating 5HT axons in somatosensory cortex may provide an ideal test bed to develop therapeutic strategies to promote axon regeneration and hence the recovery of function following brain injury.

Title: The role of mitochondrial fission/fusion in CNS axon regeneration

Authors: *A. KREYMERMAN[1,2], Y. WANG[3], N. J. KUNZEVITZKY[4], M. B. STEKETEE[6], J. L. GOLDBERG[5]
[1]Shiley Eye Center, UCSD, La Jolla, CA; [2]Univ. of Miami Miller Sch. of Med., Miami, FL; [3]Shiley Eye Ctr., [5]Neurosci., [4]Univ. of California San Diego, San Diego, CA; [6]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Central nervous system (CNS) disease or injury is often accompanied by progressive axon degeneration, leading to lost sensory, motor, or cognitive abilities, with little to no regenerative response. In search of signaling factors to restore degenerated CNS axons, we identified a group of developmentally regulated transcription factors, the Krüppel-like transcription factors (KLFs), which differentially suppress or enhance hippocampal, corticospinal neuron, and retinal ganglion cell (RGC) axon growth. However, the downstream mechanisms by which KLFs regulate axon growth are unknown. Evidence suggests one downstream effector may be mitochondrial (Mt) fission/fusion dynamics. We recently showed that suppressing fission (increasing fusion) leads to a loss in axon growth inhibition by

chondroitin sulfate proteoglycans, supporting a hypothesis in which CNS axon growth and guidance is regulated by Mt fission-fusion dynamics. These data also suggest suppressing Mt fission is a potential therapeutic strategy for improving axon regeneration after CNS trauma or disease. To identify whether Mt fission/fusion mechanisms also underlie the axon suppressing/enhancing activity of KLFs, we are investigating the potential ability for KLFs to critically regulate Mt genes for axon growth. Pertinent to our previous findings, we found that axon growth-suppressing KLF9 increased and growth-promoting KLF7 decreased the genetic expression of mitochondrial fission process 1,18 kDa (MTP18), a positive regulator of Mt fission, supporting the hypothesis that increased fission is inhibitory for axon growth in CNS neurons. Furthermore, our recent data analyzing exome sequencing of familial axonopathies also pointed to a disease association with a number of mitochondrial proteins thought to act on fission/fusion dynamics, including MTP18. Therefore, we hypothesize that KLF7/9-mediated regulation of the mitochondrial fission enhancer MTP18 regulates intrinsic axon growth ability in CNS neurons. To address this hypothesis, we will express/knockdown MTP18 in combination with or independent of KLF7/9 expression/knockdown in RGCs both *in vitro* and *in vivo*, identifying the neuronal role of MTP18 in regulating Mt fission/fusion dynamics, CNS axon growth and guidance, and KLF7/9-mediated axon regeneration. The overall goal is to improve our understanding of how Mt fission/fusion regulates axon regeneration and identify strategies for restoring axon growth after CNS injury or disease.

Title: Elevation of chemorepulsive axon guidance receptors UNC5 and Neogenin are involved in the “bad-regenerating” RS neuron death after spinal cord injury

Authors: *J. CHEN, C. LARAMORE, J. S. SHAHOUD, M. SHIFMAN
Temple Univ. Sch. of Med., Shriners Hosp. Pediatric Res. Ctr., Philadelphia, PA

Abstract: After complete spinal cord injury (SCI) in mammals injured axons are unable to regenerate. Both intrinsic and extrinsic factors associated with myelin and glial scar play important roles in limiting axonal regeneration. Many documents evidenced that a number of axon guidance molecules (eg. Netrin and RGM) are expressed in the adult CNS and their expression altered following injury. Growing axons receives signals from a plethora of both attractive and repulsive guidance cues that recognized by multiple receptors. Recently published studies suggest that axonal guidance molecule and their receptors play very important role not only during development but also at adult stage. We hypotheses that the inability of severed axons to undergo regeneration in the adult CNS is, at least in part, attributable to the presence of the very same molecules that were so important during development in establishing the axonal connections. In order to test the hypothesis that combination of multiple repulsive guidance molecules contribute to regeneration failure after SCI, we developed new sequential chromogenic triple-labeling *in situ* hybridization method, and investigated the Co-expression of Netrin receptors DCC, UNC5 and RGM receptor Neogenin mRNA in reticulospinal neurons of the larval lamprey brainstem. We found that in control animals, DCC, UNC5 and Neogenin are Co-expressed in both “good regenerating” and “bad regenerating” RS neurons. After SCI, neither Neogenin nor DCC or UNC5 mRNAs is expressed in “good regenerating” neurons. On the contrary, in the “bad regenerating” neurons, the expression of chemoattractive receptor DCC decreased, while the expression of chemorepulsive receptors Neogenin and/or UNC5 prominently increased from 1 month till two month after spinal cord transection. Further, in combination with FLICA staining and Dextran-retrograde labeling methods, we found these RS neurons with elevated expression of Neogenin and/or UNC-5 are going to undergo apoptosis and hardly to regenerate afterwards. While after injection of Neogenin antisense Morpholino oligos, some type of “bad regenerating” RS neurons can survive through 4months after SCI. Our data indicated chemorepulsive effects of Netrins and RGM may inhibit regeneration in those neurons and we are proposing the hypothesis that selective inhibition of chemorepulsive receptors (e.g. Neogenin and UNC5) will change balance between repulsive and attractive signaling, enhancing regenerative potential “bad regenerating” neurons and converting them into “good regenerating” neurons.

Title: Temporal and spatial analysis of neuronal fiber subpopulations in the regenerating radial nerve cord of the sea cucumber Holothuria glaberrima

Authors: *C. I. LOPEZ, L. VÁZQUEZ-FIGUEROA, D. CRESPO-VÉLEZ, J. E. GARCÍA-ARRARÁS
Univ. of Puerto Rico, Rio Piedras Campus, San Juan, Puerto Rico

Abstract: Regeneration mechanisms within the central nervous system (CNS) have yet to be fully unraveled. To understand these mechanisms, our lab studies the regenerating process in the CNS of the sea cucumber Holothuria glaberrima. We have previously shown that three commercial antibodies (anti-Pax6, anti-Nurr1, and anti-Phosphohistone H3) identify distinct fiber subpopulations within H. glaberrima CNS. In this study, our objective was to characterize the temporal and spatial regeneration patterns of these distinct subpopulations following transection of the holothurian CNS. To do this, one of the five radial nerve cords (RNC) of the sea cucumber wastransected with a scalpel and left to recover. Animals were sacrificed at different days post-injury (dpi): 2, 6, 12, 21, and 28 dpi. Using immunohistochemistry, the fiber subpopulations were labeled with anti-Pax6, anti-Nurr1, and anti-PH3 and analyzed. At 2 dpi, anti-Pax6 showed high expression in the cut ends of the RNC at the injury site. Anti-PH3 expression showed little changes during the first two weeks of regeneration, but appeared to be more prominent at the injury site in 21 dpi animals. Anti-Nurr1 labeled a distinct fiber population in the RNC whose expression appears to decrease at 21 dpi. The results suggest that the fiber population differs in their regeneration profile. These results provide insight into the spatial and temporal patterns of CNS regeneration that might help understand the regenerative capacities of these organisms.

Abstract: MicroRNAs are key negatively epigenetic regulators of gene expression. But we know very little about the roles of MicroRNAs in axon growth and regeneration in the mammalian peripheral nervous system (PNS). Here we observed that MiR-26a regulates mammalian axon regeneration in the PNS. GSK3β is the functional target of miR-26a. The MiR-26a inhibitor decreases axon regeneration ability by directly increasing the endogenous expression level of GSK3β. Importantly, we provide the first evidence that MiR-26a and GSK3β modulate axon regeneration ability *in vivo*. Furthermore, we show that MiR-26a-GSK3β signal is conveyed by the induction of a transcription factor Smad1 and that overexpression of Smad1 rescues axon regeneration ability mediated by miR-26a inhibitor *in vitro*. Together, these results suggest MiR-26a-GSK3β-Smad1 signaling as a central module for controlling axon regeneration ability in the mammalian peripheral nervous system.

Abstract: Neurons in the adult mammalian central nervous system (CNS) decrease in intrinsic axon growth capacity during development in concert with changes in Krüppel-like transcription factors (KLFs), which regulate axon growth capacity in CNS neurons including retinal ganglion cells (RGCs). Here we find that knockdown of KLF9, an axon growth suppressor normally upregulated 250-fold in RGC development, promotes long-distance optic nerve regeneration *in vivo*. We identify a novel binding partner, MAPK10/JNK3 kinase, and find JNK3 is critical for KLF9's axon growth suppressive activity. Interfering with a JNK3-binding domain (JBD), or mutating two newly discovered serine phosphorylation acceptor sites, Ser106/Ser110, effectively abolished KLF9's neurite growth suppression *in vitro* and promoted axon regeneration *in vivo*. These findings demonstrate a novel, physiologic role for the interaction of KLF9 and JNK3 in regenerative failure in the optic nerve and suggest new therapeutic strategies to promote axon regeneration in the adult CNS.

Title: Evaluating the role and effect of specific neuron-intrinsic pathways that mediate collateral axonal sprouting after CNS injury

Authors: *D. LEE, X. LUO, B. YUNGHER, J. LEE, K. PARK
Univ. of Miami Miller School/ Miami Project, Miami, FL

Abstract: Following injury, axonal remodeling in the form of collateral sprouting of spared axons that compensate for lost circuits represents a key mechanism by which behavioral functions are recovered. For instance, in the case of spinal cord injury (SCI), clinical lesions are often functionally incomplete, and thus compensatory sprouting of uninjured axons represents an important mechanism for functional recovery. Such axonal re-growth is robust after injury in young postnatal animals but diminishes with ageing. Using conditional knockout mouse and RNA interference, here we perform loss of functions studies to define the role of mTOR, STAT3, Dicer and MEK1/2 in neonatal or young adult neurons in regulating spontaneous collateral sprouting of corticospinal tract (CST) axons after pyramidotomy. Our findings demonstrate that mTOR is dispensable for the robust spontaneous sprouting of CST axons in immature mice. In contrast, moderate spontaneous axonal sprouting or induced-sprouting seen under different conditions in adult mice (i.e. PTEN deletion or inactivation of chondroitin proteoglycans) are reduced upon mTOR inhibition. In addition, we find that co-inactivation of PTEN and CSPGs leads to striking increase in axonal sprouting, and enhances functional recovery compared to single treatments. We also present our primary findings on the effects of depleting STAT3, Dicer or MEK1/2 in triggering spontaneous axonal sprouting in immature or young adult mice.

Title: DRGs haploinsufficient for the mRNA binding protein IMP1 show increased regenerative properties and alterations in the PTEN/mTOR pathway

Authors: *A. L. HAWTHORNE[1], P. L. PRICE[1], J. L. TWISS[2], G. J. BASSELL[1]
[1]Dept of Cell Biol., Emory Univ., Atlanta, GA; [2]Biol. Sci., Univ. of SC, Columbia, SC

Abstract: Spinal cord injury (SCI) results in loss of function due to the failure of axon regeneration through an inhibitory environment in the CNS. Promoting axonal growth can be accomplished by relieving inhibition from the extracellular environment or through enhancing the neuron's intrinsic growth potential. Research from our lab and others has shown that local protein synthesis in axons plays a vital role in neuronal development and axon regeneration in the PNS. A major gap in our current understanding is that very little is known about the molecular mechanism and regulation of mRNA translation and local protein synthesis in adult CNS neurons following SCI. An increased understanding of how SCI effects local translation in regenerating axons is expected to lead to the identification of novel therapeutic strategies. Our recent work has shown that haploinsufficiency of the mRNA binding protein, IMP1/ZBP1/IGF2BP1, results in axon outgrowth impairments of adult naïve dorsal root ganglion (DRG) neurons in culture on a growth-promoting laminin substrate and in a peripheral nerve injury model *in vivo* (Donnelly *et al*., 2011). However, the role of IMP1 in axon growth in the more inhibitory environment of a CNS lesion is unclear. Here we have investigated the role of the IMP1 in axon regeneration *in vitro* on permissive and inhibitory substrates, as well as in response to a preconditioning lesion. When grown on more challenging substrates containing either low levels of laminin or an inhibitory aggrecan/laminin mix, the difference in axon outgrowth between WT and *Imp1*$^{+/-}$ DRGs was not significant. Conditioning did stimulate neurite outgrowth in both genotypes. However, when tested in an *in vitro* model of the inhibitory CNS lesion environment, the spot assay, unconditioned *Imp1*$^{+/-}$ DRGs surprisingly exhibited a marked increase in axon crossing comparable to conditioned WT DRGs. Conditioning did not further augment *Imp1*$^{+/-}$ axon crossing, as was observed with WT DRGs. We further observed that growth cones from *Imp1*$^{+/-}$ DRGs exhibited an increase in markers of translational activity, including phosphorylated ribosomal S6 protein, which is down stream in the PTEN/mTOR pathway. IMP1 associated with *β-actin* and *Pten* mRNA by co-immunoprecipitation. *Imp1*$^{+/-}$ DRGs have significantly less *Pten* and *β-actin* mRNAs than WT in axonal fractions as compared to γ-actin. We hypothesize that deficiency of IMP1 may impair axon growth in a permissive environment, yet allow for axon growth on an inhibitory substrate due to elevated mTOR

pathway activation. These results from *in vitro* paradigms will motivate *in vivo* experiments in spinal cord injured mice to possibly enhance axon outgrowth after injury.

Title: Translational analysis of retinal ganglion cells undergoing axon regeneration

Authors: ***E. BRAY**, K. LYAPICHEV, X. LUO, J. LEE, K. PARK
Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Neurons of the central nervous system fail to mount a strong regenerative response to axotomy. Although advances have been made in understanding how to overcome barriers to regeneration through modulation of cell intrinsic and extrinsic factors, the spatial and temporal domains of the induced regeneration remain limited. By utilizing a cell type specific RNA immunoprecipitation method coupled with RNA sequencing technology we wish to investigate the pool of RNA undergoing active translation in retinal ganglion cells (RGCs) induced to regenerate. Conventional methods for purifying a cell type from a complex tissue have multiple shortcomings. Fluorescence-activated cell sorting and immunopanning require tissue dissociation and hours of prep during which viable cells must be maintained, potentially resulting in major changes to the translational pool of RNA. Laser capture microdissection can be time intensive and presents difficulties in maintaining high quality RNA. Here we wish to utilize the Ribotag method to obtain cell type specific RNA in order to better understand the mechanisms by which RGCs regenerate. Viral delivery of Cre-recombinase to RGCs is used to induce expression of hemagglutinin tagged ribosomes for use as an IP target. The resulting mRNA pulled down by

this method will undergo RNA sequencing and computational analysis. Following optic nerve crush the RNA undergoing translation in untreated RGCs and those induced to regenerate will be compared. By utilizing this method we plan to establish a specific view of the *in vivo* translational network of RGCs in order to find new therapeutic targets that promote regeneration.

Title: Zinc is a critical regulator of optic nerve regeneration

Authors: ***Y. LI**[1,2], L. ANDEREGGEN[1], K. OMURA[1], B. ERDOGAN[1], M. S. ASDOURIAN[1], C. SHROCK[1], H.-Y. GILBERT[1], Y. YIN[1], U.-P. APFEL[3], S. J. LIPPARD[3], P. A. ROSENBERG[1], L. I. BENOWITZ[1]

Abstract: Like other pathways in the mature central nervous system (CNS), the optic nerve cannot regenerate if injured, resulting in lifelong losses in vision. Recent studies have achieved a moderate level of axon regeneration in the injured optic nerve by combining three treatments that synergistically activate the intrinsic growth state of retinal ganglion cells (RGCs), the projection neurons of the eye. Nonetheless, even under optimal conditions, more than 50% of RGCs die after optic nerve injury and most of the surviving RGCs fail to regenerate axons. These observations point to the existence of additional major suppressors of RGC survival and axon

regeneration. Using autometallography (AMG) or the fluorescent Zn2+ sensor ZinPyr1 (courtesy Robert Radford, MIT), we found that levels of free Zn2+ increased in the inner plexiform layer (IPL) of the retina within an hour of optic nerve injury, whereas levels within RGCs themselves increased more slowly. The IPL contains synaptic inputs onto the dendrites of RGCs from retinal interneurons (amacrine cells and bipolar cells). The Zn2+ transporter ZnT3 is highly expressed in the IPL, suggesting that Zn2+ becomes sequestered in presynaptic vesicles after injury. Chelating Zn2+ using either TPEN or the highly selective chelator ZX1 eliminated the Zn2+ signal in the IPL and led to enduring survival of RGCs as well as considerable axon regeneration. These effects were lost when the chelators were saturated with Zn2+, suggesting that the effects of the chelators are mediated through binding of free Zn2+. Combining Zn2+ chelation with other pro-regenerative treatments enabled some RGCs to regenerate axons the full length of the optic nerve in just 2 weeks. These studies indicate that Zn2+ is an endogenous suppressor of axon regeneration, and they suggest that Zn2+ chelators may be valuable in promoting recovery after various forms of traumatic or neurodegenerative CNS damage.

Title: Sustained neurogenesis-an instrument for a successful regeneration in adulthood

Authors: *J. NINKOVIC, J. BARBOSA, R. DI GIAIMO, M. IRMLER, D. TRÜMBACH, J. BECKERS, M. GÖTZ
Helmholtz Zentrum München, Neuherberg, Germany

Abstract: The regenerative capacity in the CNS differs greatly between different vertebrate species. Importantly, wide-spread, life-long neurogenesis is often associated with the remarkable regenerative potential. Indeed, the neural progenitors from the neurogenic zones of zebrafish telencephalon engage in the repair process without impairment of the constitutive neurogenesis. Therefore, we followed the response of a different type of progenitors to the brain injury at the single cell level *in vivo*. We first could show that only fast dividing progenitors, labelled with the

retroviral vectors, immediately react to the injury, leave the neurogenic zone and migrate towards the injury site. In contrast to fast dividing progenitors, the injury induced proliferation of neural stem cells, the radial glia-like cells, is delayed and coincident with the full tissue restoration. To assess the role of radial glia-like cells in the regeneration process, we continuously followed them for more than 1 month using the two-photon live imaging. Our data suggest the activation of previously quiescent radial glia-like cells in response to the injury, but with the different mode of division. The radial glia in the intact telencephalon show either asymmetric or self-renewing symmetric divisions, while the symmetric non-gliogenic division becomes the predominant type of symmetric division in response to injury. This change in the division mode leads to the depletion of some activated radial glia-like cells and production of the transit amplifying progenitor population that is used up in the neuronal regeneration process, but necessary for the constitutive neurogenesis. We could, further, identify the injury-induced activation of several pathways in progenitor cells. The activation of these pathways, using the small molecules, elicited both proliferation of progenitor cells and gene expression comparable to the injury. Moreover, the activation of these pathways in the injured mouse cortex increased the de-differentiation of the reactive astrocytes and increased their neurosphere-forming capacity. Taken together, our data describe for the first time the reaction of the endogenous progenitors to the injury at the single cell level and identify evolutionary conserved molecular pathways, involved in the initiation of the repair process by the endogenous progenitors in the vertebrate brain.

Title: Differential binding of receptor protein tyrosine phosphatase type iia family (rptpσ/rptpδ/lar) to glycosaminoglycans

Authors: *A. A. MORGAN[1], Y. KATAGIRI[2], P. YU[2], N. J. BANGAYAN[2], R. JUNKA[2], H. M. GELLER[2]
[2]Natl. Heart, Lung, and Blood Inst., [1]NIH, BETHESDA, MD

Abstract: Abstract Body: Type IIa Receptor protein tyrosine phosphatases (RPTPs) have been shown to modulate neural regeneration and development. All members of this family (RPTP, RPTP, and LAR) have a cell adhesion molecule-like extracellular domain that includes three N-terminal Ig domains and four to nine fibronectin type III (FNIII) domains, as well as tandem intracellular tyrosine phosphatase domains. Along with protein tyrosine kinases, protein tyrosine phosphatases are crucial to the regulation of cellular protein tyrosine phosphorylation. This family of leukocyte common antigen-related receptors has been shown to influence axonal outgrowth and guidance during neural development. Compelling evidence suggests that both heparan sulfate (HS) and chondroitin sulfate (CS) are the ligands for RPTP and LAR, and the Lys-loop located in the first Ig domain is responsible for the ligand binding. However, the functional outputs of HS and CS are promotion and inhibition of axonal growth, respectively. The opposite effects of HS and CS glycosaminoglycans (GAGs) on axonal growth were attributed to the differential oligomeric state of RPTP because binding to HS, but not to CS, induces clustering of the extracellular region of RPTP. Here we show that all RPTP type IIa members display high affinity binding for heparin. Both CS-E and dermatan sulfate (DS) have similar dissociation constants within the typical nanomolar range, however, there is considerable variation of binding sites on GAGs among RPTPs. We also demonstrate differential contribution of FNIII domains required for high affinity binding to GAGs. In particular, PTP binding to heparin was not completely abolished by the disruption of the Lys-loop. This along with a decrease in binding with deletion of the fourth FN domain leads us to hypothesize that there is a greater contribution of the FN domain in binding to glycosaminoglycans that previously believed. Preliminary data shows that the fourth fibronectin repeat is able to bind to heparin without contribution of the three Ig domains. Furthermore, only RPTP is clustered upon binding to both heparin and CS-E, but not DS. Despite 66% overall shared amino acid identity amongst RPTPs, we conclude there exist discrete binding sites on RPTPs that determine binding to GAGs. Our data indicate that clustering of the receptor may not explain the distinct biological functions of HS and CS.

Title: AKT regulates Id2 for axonal regeneration in CNS

Authors: *H. KO[1], J. CHO[2], K.-H. LEE[2], J.-Y. AHN[2]
[1]1Department of Mol. Cell Biol., [2]Dept. of Mol. Cell Biol., Sungkyunkwan Univ. Sch. of Med., Suwon, Korea, Republic of

Abstract: Id2 is a negative regulator of basic helix-loop-helix (bHLH) transcription factors. Id2 dimerizes and prevents bHLH from binding to E box DNA response elements that modulate neurogenetic transcription during development. Recent report showed that Id2 may be a novel target for enhancing sensory axonal regeneration following injuries to the adult spinal cord. However, how Id2 exerts axonal regeneration is unclear. In this study we demonstrate that Id2 interacts with AKT and is phosphorylated by Akt. Id2 phosphorylation is required for controlling Id2 protein levels and the interaction between Id2 and E3 ligase Cdh1. Moreover, AKT regulates the interaction of Id2 with transcription factors of E47. E47 belongs to the bHLH (basic helix-loop-helix) family of transcription factors and complex with NeuroD. NeuroD/E47 promotes the activation of myelin gene expression and inhibition of axon growth. Therefore, we suggest that regulation of Id2 by AKT has important role of axonal regeneration.

Title: H3k27 methylation balance regulates axon regeneration

Authors: ***C. LIU**[1,1], R.-Y. WANG[3], J.-J. JIANG[3], Z.-X. JIAO[1], S. XXX[1], B.-Y. ZHANG[1], S. ZHANG[1], M. ZHANG[1], Y.-W. HU[1], F. ZHOU[1,2]

Abstract: The devastating and permanent disabilities after spinal cord and other types of mammalian central nervous system (CNS) injury is caused by the failure of injured axons to regenerate and to re-build the functional circuits. Neurons in the mammalian CNS lose their intrinsic ability to support neural regeneration. Regulated gene expression is one of the intrinsic ability determinations of neurons to extend axons. Methylation (mono-, di-, and tri-methylation) on histone H3 lysine (K) 27 induces transcriptional repression, and thereby participates in controlling gene expression patterns. Methyltransferase EZH2/EZH1 and de-methyltransferase JMJD3/UTX play essential roles in the epigenetic maintenance of the H3K27me3 repressive chromatin mark, however, their roles in mammalian axon regeneration are not well explored. Here we report that H3K27me3 methylation balance mediated by EZH2/EZH1 and JMJD3/UTX is a novel modulator of axon regeneration. H3K27me3 expression level is increased after axotomy in DRG neurons, and the expression levels of EZH2, JMJD3/UTX are also changed. We provide the first evidence that EZH2 knockdown impaired and JMJD3 knockdown promoted mammalian axon regeneration *in vivo*. Moreover, we found that KLF4 acts as a transcriptional downstream target of H3K27me3 to mediate axon regeneration in adult sensory neurons in response to peripheral nerve injury. Therefore, H3K27 methylation balance mediated by EZH2/JMJD3/UTX provides a novel mechanism for controlling intrinsic axon regeneration ability in adult dorsal sensory neurons

Title: Celsr3 is required in hippocampal projection neurons for network wiring and spatial learning

Authors: *Y. HUANG, J. FENG, Y. DING, K.-F. SO, L. ZHOU, Y. QU
GHM Inst. of CNS Regeneration, Guangdong, China

Abstract: The atypical cadherin Celsr3, which belongs to the core planar cell polarity group, orchestrates axonal guidance and network wiring. Previous work using regional inactivation of Celsr3 in forebrain showed that Celsr3 is widely involved in hippocampal maturation and connectivity. However, inactivation in the whole forebrain does not provide sufficient specificity to address the function of Celsr3 in detail. Here, we studied the Celsr3|Emx1 mouse mutant model, in which Celsr3 is selectively inactivated in hippocampal projection neurons, but not in entorhinal cortex, basal ganglia and interneurons. In that mutant, the hippocampal cytoarchitecture was almost normal. Inactivation of Celsr3 in projection neurons perturbed intrinsic hippocampal wiring and efferent fiber projections, whereas afferent fibers from entorhinal cortex were unaffected. In addition, it resulted in incomplete maturation of pyramidal cell dendrites and synaptogenesis, and increased adult neurogenesis in the dentate gyrus. Consistent with these wiring defects, Celsr3|Emx1 mutant mice showed impaired learning and memory, and were less anxiety-prone than control mice. Thus, Celsr3|Emx1 mutant mice provide a simple way to study the consequences of defective hippocampal wiring in absence of drastic structural anomalies.

Title: Localization of BgNPY-like immunoreativity in the nervous system of Biomphalaria glabrata, an intermediate host for schistosomiasis

Authors: *S. ROLÓN-MARTÍNEZ[1,2], N. DELGADO-RIVERA[1,2], G. TORRES[1,2], L. O. VAASJO[1,2], E. RIVERA[1,2], M. W. MILLER[1,2]
[1]Inst. of Neurobio., San Juan, Puerto Rico; [2]Dept. of Anat. & Neurobio., Univ. of Puerto Rico, Med. Sci. Campus, San Juan, PR

Abstract: Over 200 million people worldwide live at risk of the parasitic disease schistosomiasis, or "snail fever". The digenetic trematode worm species *Schistosoma mansoni* that causes the most widespread form of intestinal schistosomiasis, employs the freshwater snail *Biomphalaria glabrata* as its primary intermediate host. Previous investigations in other schistosome-snail systems (*Trichobilharzia ocellata – Lymnaea stagnalis*) showed that neuropeptide Y (NPY) gene expression was increased during the "shedding" stage of snail infection, when a high production and release of parasites (cercariae) requires considerable redirection of host energy resources (Hoek et al. 1997; de Jong Brink et al. 1999). A recently submitted mRNA sequence was reported to encode a *B. glabrata* NPY prepropeptide (GenBank Accession No.: JX013957). For this investigation, affinity purified polyclonal antibodies (rabbit) were generated against part (20 amino acids) of the predicted NPY neuropeptide (BgNPY) deduced from the mRNA sequence. BgNPY-like immunoreactive neurons (20 – 30 um diameter) were present on the dorsal and ventral surfaces of most central ganglia; buccal ganglion (B. g.; dorsal: 9 ± 2, ventral: 3 ± 1), cerebral ganglion (Cer. g.; dorsal: 17 ± 2, ventral: 19 ± 7), pedal ganglia (Pd. g.; dorsal: 20 ± 6, ventral: 16 ± 8), and pleural ganglia (Pl. g.; dorsal: 4 ± 1, ventral: 2 ± 1). Larger (40 - 50 um diameter) BgNPY-li neurons in the left parietal ganglion (Pa. g.; dorsal: 14 ± 5, ventral: 7 ± 4), and visceral ganglion (V. g.; dorsal: 23 ± 3, ventral: 12 ± 6) had prominent axons oriented toward the parietal-visceral connective. Areas of the sheath surrounding the ganglia and specific nerves, such as the tentacular nerve and medial lip nerve, were rich in BgNPY-like fibers, suggesting that this peptide could be released in a neurohaemal fashion. BgNPY-like staining was also found in the statocysts. These results suggest that BgNPY could be involved in behaviors such as food intake and reproduction, and are consistent with a role of this neuropeptide in the redirection of energy resources during the stage of cercarial shedding in the *Schistosoma mansoni* - *Biomphalaria* host-parasite system.

Title: Genomic portrait of a synapse: Enormous variability and unexpected complexity in the molecular complement

Authors: *A. B. KOHN[1], L. L. MOROZ[2,3]
[1]Universtiy of Florida Whitney Lab., Saint Augustine, FL; [2]Neurosci. and McKnight Brain Inst., Univ. of Florida, Gainesville, FL; [3]The Whitney laboratory for Marine Biosci., St Augustine, FL

Abstract: Advances of single-neuron genomics allowed us to obtain an unbiased view of the genomic organization of both neurons and synapses within identified neural circuits. Here, we took advantage of the sequenced *Aplysia* genome and well-developed transcriptome profiling from various neurons to characterize the complement of genes associated to synaptic functions and excitability. Specifically we targeted several identified components of defensive feeding circuits. Our genomic analysis of the *Aplysia* glutamatergic synapse revealed a significantly greater complexity compared to recently reported hippocampal synapses in rodents and the vertebrate synapse in general. In part, we detected higher diversity of the *Aplysia* ionotropic glutamate receptors (iGluRs, 23 compared to the number of human iGluRs at 18). We also determined there are greater number of predicted secretory molecules in pre- and postsynaptic neurons including novel types of prohormones. The overall complement of ion channels in *Aplysia* (197) is comparable to the human complement at 237 ion channels. However, in *Aplysia* we identified, a number of subfamilies significantly expanded in the molluscan lineage compared to all other animals. Second, we also revealed an enormous diversity and differential recruitments of various components controlling excitability and synaptic efficiency (both across and within the same classes of neurons and synapses). We hypothesize that the observed redundancy and variability can be considered as adaptive mechanisms controlling synaptic homeostasis and robustness of synaptic functions. The obtained data together with comparative genomic analysis across basal metazoans allowed us to reconstruct the early origins and parallel evolution of synaptic functions in animals.

Title: Use of an internal FLAG epitope for biochemical characterization and localization of histidine decarboxylase (HDC) in tissues of *Drosophila* melanogaster

Authors: *M. G. BURG[1], M. MIANECKI[2], A. HAGE[3], D. BURG[3]
[1]Biomed. Sciences/Cell and Mol. Biol., Grand Valley State Univ., ALLENDALE, MI; [2]Cell and Mol. Biol., [3]Biomed. Sci., Grand Valley State Univ., Allendale, MI

Abstract: Histamine (HA) is synthesized by the enzyme histidine decarboxylase (HDC) that is encoded by the *Hdc* gene in *Drosophila*. The analysis of *Hdc* mutants defective in HA synthesis and regulation of *Hdc* expression has, in the past, relied solely upon HA immunohistochemistry to assess HDC activity. Determining the location of the *Drosophila* HDC protein in various tissues and isolating HDC for biochemical studies has been hampered due to the inability to detect HDC immunohistochemically. Efforts in the past to label the HDC protein, including N- or C-terminal labeling using an epitope tag such as 6XHIS or FLAG, have been unsuccessful. This failure to label HDC is likely due to the fact that, as in other species, the protein is post-translationally modified by the removal of both the N- and C-terminus (ref.1), preventing the use of conventional N- and C-terminal epitope-labeling techniques to label the HDC protein. Several internal sites for an epitope label within the *Drosophila Hdc* gene were identified, one of which could accept an insertion of a small epitope label (6XHIS) without disrupting the HDC protein's function (ref. 2). Using this same approach, a FLAG epitope was placed into the same internal site of the *Hdc* gene structure, resulting in a FLAG-*Hdc* transgene. The FLAG-*Hdc* transgene was placed into a plasmid vector and transformed into *Drosophila* using standard techniques. Linkage of the FLAG-*Hdc* transgene was determined for each transformant line generated and selected transformant-bearing flies were then crossed into a mutant Hdc^{JK910} background lacking endogenous HDC activity. These transgenic flies were analyzed for a functional HDC protein by immunostaining with HA antibodies in a number of developmental stages. A similar procedure was used to detect the epitope-labeled FLAG-HDC protein using the M2 FLAG antibody. Results for the FLAG-HDC epitope immunodetection yielded a staining pattern very similar to

the HA immunostaining in the wildtype fly. Co-localization experiments for HA and FLAG-HDC have been completed in both the larval and adult CNS, indicating that FLAG expression co-localizes with HA. Immunoprecipitation experiments using the M2 FLAG antibody have identified a 52 kD protein specific to the FLAG-*Hdc* transformant, which we propose to be the size of the HDC monomer in *Drosophila*. These epitope tagged FLAG-*Hdc* transgenic flies can now be used to further our understanding of HDC biochemistry and cell biology *in vivo*. (1) Fleming and Wang (2000) Molec. Cell Biol. 20: 4932-4947. (2) Fair et al. (2012) 53rd *Drosophila* Research Conference.

Title: A role for dopamine in peripheral sensory processing in the predatory sea-slug Pleurobranchaea

Authors: B. M. SCHAUB[1], B. L. KLUSAS[3], J. W. BROWN[4], D. I. VALLEJO[5], N. DELGADO[6], N. M. MADEIROS[6], S. R. MARTINEZ[6], E. BARRETO[6], M. W. MILLER[6], *R. GILLETTE[2]
[1]Sch. of Mol. and Cell. Biol., [2]Dept Physiol., Univ. Illinois, URBANA, IL; [4]Physiol., [3]Univ. of Illinois, Urbana, IL; [5]Med. Sci. Campus, [6]Univ. of Puerto Rico, San Juan, PR

Abstract: The peripheral nerve networks of the chemotactile oral veil-tentacle complex and rhinophores of the predatory sea-slug *Pleurobranchaea californica* show extensive tyrosine hydroxylase immunoreactivity (TH-IR), consistent with dopaminergic innervation. TH-IR is also marked in ciliated, epithelial putative primary chemoreceptor cells, as well as in downstream somata of the associated peripheral ganglia. Some of these TH-IR somata project into the sensory Large Oral Veil and Tentacle Nerves (LOVN, TN), which supply the CNS with information critical to cost-benefit decisions serving foraging, defense, and reproduction (Brown et al., in preparation). We tested a potential role for dopamine in both food-seeking behavior and the underlying peripheral sensory physiology with sulpiride, a dopamine D2/D3 receptor antagonist. Appetitive responses were observed to application of raw shrimp on both sides of the oral veil-tentacle complex before and after unilateral topical application of sulpiride. Sulpiride

significantly increased latency to orient to and bite at food stimuli applied to the treated side ($p < 0.001$, Wilcoxon matched pairs test), while latencies did not significantly vary on the control side before and after treatment. Recordings of sensory activity from LOVN and TN were consistent with the above observations. Unilateral sulpiride application significantly attenuated neural responses to tactile and appetitive chemotactile stimuli in decerebrated preparations. Thus, behavioral and physiological results are consistent with a pivotal role for peripheral dopaminergic pathways in sensory transduction and/or downstream peripheral integration.

Title: Identifying serotonergic neurons in the brain of the cockroach Rhyparobia maderae implicated in the regulation of carbohydrate self-selection feeding behavior

Authors: *L. DANIELS, JR, R. W. COHEN
Biol., California State University, Northridge, Northridge, CA

Abstract: Cockroaches like the madeira cockroach *Rhyparobia maderae* possess the ability to self-select a balanced diet based on nutritional need. Given a choice between a carbohydrate diet and a protein diet, an *R. maderae* nymph will feed 80% on the carbohydrate cube and only 20% on the protein cube. Previous work in our lab has shown that various neurotransmitters function to regulate this self-selection feeding behavior. For example, it appears that octopamine regulates hunger, while dopamine controls satiety. In contrast, serotonin is known to regulate specific nutrient self-selection in many animals, including *R. maderae* nymphs. Precisely, serotonin release in the cockroach brain is correlated with carbohydrate consumption: high levels cause reduced feeding while lower levels increase carbohydrate feeding. In the present study, immunohistochemistry was utilized to determine which regions of the *R. maderae* brain are involved in the regulation of carbohydrate self-selection behavior by serotonin. In determining

the pattern of serotonin release in the brain of actively feeding *R. maderae*, large nymphs (n=10 per treatment group) were randomly selected and divided into five treatment groups. Prior to treatment, nymphs were starved for seven days and allowed only water as sustenance. After seven days, nymphs were placed into individual glass petri dishes that were used as feeding arenas. Each arena contained a diet block and water *ad libitum*. The experimental treatment groups included one group feeding on carbohydrate (sucrose) diet cubes for 1 hour, a second group feeding on sucrose for 2 hours, a third group feeding on casein (protein) for 1 hour, and a fourth group feeding on casein for 2 hours. Unfed, control groups were used to compare to the other feeding treatment groups. After 1-2 hours of feeding, the *R. maderae* nymphs were anesthetized with CO_2, and their brains were dissected out. All brains were fixed by incubating in 30% sucrose in 4% paraformaldehyde solution for three days. Brains were then sectioned with a cryostat at 25µm thickness and prepped for immunohistochemistry. Briefly, brain sections were incubated in 1% primary antibody (serotonin), normal goat serum and PBS for 2 hours. The sections were then incubated in secondary antibody (anti-rabbit), normal goat serum and PBS for one hour. Our results show a very high localization of serotonin in and around the mushroom bodies of cockroach brain. This finding corroborates our hypothesis that the insect mushroom body is involved in carbohydrate self-selection behavior.

Abstract: Snails of the genus *Biomphalaria* are intermediate hosts for the digenetic trematode parasite *Schistosoma mansoni*, which infects people living in tropical regions of Africa and the Americas. It has been proposed that the development of *S. mansoni* from the free-living miracidium to the parasitic mother sporocyst stage depends upon uptake of biogenic amines from the snail host (see Boyle et al. 2003; El-Shehabi and Ribeiro 2010). Previous studies have demonstrated the presence of histamine in *Schistosoma* (Ribiero et al. 2005) but no data are available concerning possible sources of histamine in the tissues of *Biomphalaria*. This investigation examined the localization of histamine-like immunoreactive (HA-Lir) material in the central nervous system (CNS) and peripheral tissues of both *B. alexandrina* (the snail host in Egypt) and *B. glabrata* (the snail host in the American tropics). Evidence indicates that HA is plentiful throughout the nervous system of the snail. Within the CNS, clusters of HA-Lir neurons were observed in the buccal, cerebral, pedal, left parietal, and visceral ganglia, suggesting involvement in a variety of neural functions. Histamine was also found in the hair cells of the statocyst indicating involvement in graviception. Finally, numerous peripheral cell bodies in the cephalic sensory organs and anterior margin of the foot, together with the heavy labeling of nerves connecting these regions with the CNS indicates that populations of chemo- and/or mechanoreceptor afferent cells also use HA as their transmitter. The patterns of staining for both species of *Biomphalaria* were similar to each other and to the staining observed in other pulmonates examined to date. The results thus indicate that the snail hosts have abundant sources of HA that could be exploited by larval schistosomes and suggest numerous host-parasite interactions involving this aminergic transmitter.

Title: Establishing and maintenance of neuronal identity in *Aplysia*: Tracing the origins of serotonergic and dopaminergic neurons in bilaterians

Authors: *E. C. DABE[1], A. B. KOHN[2], L. L. MOROZ[2]
[1]Univ. of Florida Whitney Lab., Saint Augustine, FL; [2]Univ. of Florida, Gainesville, FL

Abstract: *Aplysia californica* neurons are some of the largest somatic cells in the animal kingdom and contain enough genetic material per cell to allow for in depth transcriptome analysis. In order to understand the logic of gene regulation and gene expression changes underlying complex neuronal phenotypes, we performed RNA-seq on freshly isolated individual *Aplysia* neurons. By using this specific single-cell transcriptome approach, we were able to identify a subset of gene candidates involved in the maintenance of unique phenotypes of serotonergic and dopaminergic neurons such as transcription factors in the *ETS*, *Hox* and *Pitx* subfamilies. *In situ* hybridization was then performed to map the expression pattern of these candidate regulators in the *Aplysia* nervous system to identify and define cells with specific neurotransmitter phenotypes Computational approaches then identified potential transcription factor binding sites in the promoter regions of the genes encoded dopamine and serotonin synthetic pathways respectively. Together, our data on the regulation of neurotransmitter expression suggest both serotonergic and dopaminergic neuronal cell lineages arose from a common bilaterian ancestor. Title: Brain transcriptomes from six sea slug species provide insights into neural circuit evolution

Authors: A. SENATORE, *P. S. KATZ
Neurosci. Inst., Georgia State Univ., ATLANTA, GA

Abstract: Neuronal circuits in the clade Nudipleura (Mollusca, Gastropoda, Heterobranchia) differ between species that swim using dorsal ventral (DV) or left-right (LR) whole body flexions, even when comparing analogous forms of swimming. To understand molecular elements underlying these differences, we performed deep mRNA sequencing of the central ganglia of six species with each form of swimming behavior, five nudibranchs: *Tritonia diomedea* (DV); *Melibe leonina* (LR); *Hermissenda crassicornis* (LR); *Flabellina iodinea* (LR); and *Dendronotus iris* (LR), and one outgroup *Pleurobranchaea californica* (DV). This effort generated full-length sequences of approximately 24,000 genes, which is similar to the size of the fully sequenced genome of another gastropod, *Lottia gigantea*. Analysis of these sequences is providing broad insights into the molecular elements underlying neuronal excitability, synaptic connectivity, and neuromodulation in these species. For example, we found a disproportionately large number of the most abundantly expressed genes to be secretory neuropeptides (e.g. Cerebral peptide 1, Pedal peptide 1 and Molluscan insulin-related peptide 3), suggesting that peptidergic signaling is a prominent form of neurotransmission in nudibranchs and perhaps all gastropods. Additional insights arise from phylogenetic comparisons: 1) The nudibranch FMRFamide gene possesses considerably fewer repeats of the FMRF peptide motif compared to other molluscs, whereas the *Aplysia* ortholog seems to have duplicated it many more times. 2) The *Melibe* Small Cardioactive Peptide (SCP) gene duplicated to produce a third putative SCP peptide (SCP_C) in addition to SCP_A and SCP_B. We are using the full transcriptome data to resolve ancestral phylogeny of the Nudipleura, to test the hypothesis that DV and LR swimming arose independently in distinct phylogenetic lineages of the Nudipleura. The availability of neuronal gene sequences is expanding research on traditionally electrophysiological preparations to allow a molecular understanding of the basis for species-typical behavior.

Title: Identification of novel serotonin receptors in six species of sea slugs

Authors: ***A. N. TAMVACAKIS**, A. SENATORE, P. S. KATZ
Georgia State Univ., Atlanta, GA

Abstract: Serotonin (5-HT) is important for many behaviors in both invertebrates and vertebrates. In sea slugs, 5-HT has been studied extensively with respect to neural control of learning, memory, and movement. To date, four molluscan 5-HT receptor families have been identified and shown to be expressed in neural tissue: 5-HT1, 5-HT2, 5-HT4, and 5-HT7 (Nagakura et al, 2010, J. Neurochem 115, 994-1006). In addition, a putative 5-HT6 receptor family orthologue was identified from *Aplysia* californica genomic DNA. No 5-HT receptors, however, had been identified in any species of Nudipleura sea slugs (Mollusca, Gastropoda, Heterobranchia), which are important models for studying serotonergic neuromodulation. We therefore sequenced the transcriptomes of six sea slug species: Tritonia diomedea, Pleurobranchaea californica, Hermissenda crassicornis, Dendronotus iris, Melibe leonina and Flabellina iodinea. 5-HT receptor homologues from each of the four previously identified molluscan 5-HT receptor families were identified in the transcriptomes of all species. In addition, we confirmed the existence of the 5-HT6 receptor subtype transcript. We also identified a previously uncharacterized 5-HT2 family receptor, 5-HT2b. ClustalX and BLAST alignments showed that 5-HT2b aligned closely with non-molluscan 5-HT2 family receptors, but was distinct from the previously published molluscan 5-HT2 receptor. All transcriptome sequences were consensus sequenced to verify sequence identity. Phylogenetic analyses of the receptor protein sequences showed that they aligned within the distinct molluscan 5-HT receptor families.

Within the receptor sequences, several insertions or deletions resulting in alternative gene sequences were identified in each species. 5-HT-mediated behaviors are likely controlled by multiple 5-HT receptor families; these receptor sequences can therefore be used to study the identity and expression levels of 5-HT receptors involved in many behaviors across multiple species of sea slugs.

Title: Evidence of nicotine-induced, d-tubocurarine-insensitive behavior in planarians

Authors: *O. R. PAGAN[1], E. MONTGOMERY[2], S. DEATS[2], D. BAKER[2], D. BACH[2]
[1]BIOLOGY, West Chester Univ., WEST CHESTER, PA; [2]West Chester Univ., West Chester, PA

Abstract: Planarians are rapidly developing into very useful research subjects in pharmacology and neuroscience research. These organisms possess many of the neurotransmitter systems used by vertebrates and are one of the most primitive example of cephalization in the animal kingdom, displaying a bona fide brain. Here we report that d-tubocurarine, a cholinergic antagonist, alleviates the nicotine-induced planarian seizure-like movements (pSLM) by 50 % up to equimolar concentrations of nicotine and d-tubocurarine (1 mM) while D-tubocurarine alone does not induce pSLM. The simplest interpretation of our data is that there are nicotine induced behaviors insensitive to d-tubocurarine in our experimental organism. To the best of our knowledge, this is the first report on d-tubocurarine-insensitive, nicotine-induced effects.

Title: Identified aminergic neurons in Biomphalaria glabrata, an intermediate host for human intestinal schistosomiasis

Authors: *L. VAASJO[1,2], N. DELGADO[2], S. ROLÓN-MARTÍNEZ[2], M. W. MILLER[2]
[1]Inst. of Neurobio., San Juan, PR; [2]Dept. of Anat. & Neurobio., Inst. of Neurobiology, Univ. of Puerto Rico Med. Sci. Campus, San Juan, Puerto Rico

Abstract: Schistosomiasis is a neglected tropical disease (NTD) that impacts over 200 million people throughout Asia, Africa and South America. The planorbid snail *Biomphalaria glabrata* serves as the major intermediate host for *Schistosoma mansoni*, the trematode parasite responsible for the most widespread form of human intestinal schistosomiasis. Our previous studies mapped the localization of serotonergic and catecholaminergic neurons in the nervous system of *B. glabrata* (Delgado et al. 2012; Vallejo et al., 2014). We reported the presence of a group of five serotonergic neurons (the CeSF cluster) on the dorsal surface of each cerebral hemiganglion and proposed that this cluster could correspond to a serotonergic system that has been highly conserved in other gastropod groups (see Katz et al. 2001). As these neurons have been intensively studied and found to participate in responses to noxious stimuli in a range of opisthobranch species (*Hermissenda*: CPT cells, *Tritonia:* DSI cells, *Melibe:* Si, *Aplysia*: CC3, *Pleurobranchaea*: As1-3), we explored the possibility that they could be similarly involved in responses to aversive stimuli, such as miracidia penetration, in the pulmonate snail *Biomphalaria*. An isolated "head-brain" preparation was developed to assess the receptive fields of the CeSF neurons to tactile (probe) and noxious (sharp electrode) stimuli designed to simulate penetration of the cephalic epithelium by *S. mansoni* miracidia. We found that neurons comprising the CeSF clusters are anatomically and physiologically heterogeneous. Neurobiotin fills demonstrated dissimilar projections, such as the designated Left Superior (LS CeSF) cell,

projecting contralaterally to the right parietal nerve, while its contralateral counterpart projected bilaterally to multiple peripheral nerves. Experiments demonstrated cells with variable receptive fields, such as the LS cell that was responsive to all areas tested and its contralateral counterpart that was excited only by lip stimulation. Dye fills of some CeSF neurons demonstrated projections to the region of the contralateral CeSF cluster and were indicative of dye coupling. Further experiments were performed to characterize the structure and synaptic relations between the two CeSF clusters and neurons in other ganglia that could support a role for these cells in the responses of *B. glabrata* to noxious or aversive stimuli.

Title: Identification of Neuropeptide-like Proteins (NLPs) in the motor neurons of Ascaris suum

Authors: *J. J. KNICKELBINE, C. J. KONOP, C. D. WRUCK, A. O. W. STRETTON
Univ. of Wisconsin-Madison, Madison, WI

Abstract: The parasitic nematode *Ascaris* affects both humans (*A. lumbricoides*) and livestock (*A. suum*), causing devastating effects on human health and global economy. Treatment involves administration of anthelmintic drugs, which often target classical neurotransmission in the motor nervous system. Detailed studies of cellular connectivity and classical transmitter expression have been completed on the motor nervous system of *Ascaris suum*; however, an adequate functional circuit has not yet been described for this relatively “simple” system. One missing piece of information is the neuropeptide content of the motor neurons themselves. Neuropeptides

are the largest class of neurotransmitter molecules, playing a variety of roles in the nervous systems of vertebrate and invertebrate animals. Neuropeptides are grouped into three categories based on their structure, with the largest and most diverse group being the neuropeptide-like proteins (NLPs). The objective of this study was to identify the neuropeptides produced by the inhibitory and excitatory motor neurons of female *A. suum*, and to examine their effects on classical neurotransmission and locomotory behavior of the worm. To accomplish this, we used single-cell mass spectrometry to determine the peptide content of 5 types of motor neurons. The results were confirmed with *in situ* hybridization. The effects of these peptides on acetylcholine (ACh)-induced muscle contraction were measured on strips of dorsal muscle, and effects on locomotory behavior were observed by injecting intact worms and monitoring their behavior in a tube with the same diameter as the porcine small intestine. We found that the GABAergic inhibitory motor neurons (DI, VI) express only one major peptide product (SLASGRWGLRPamide), which is a homolog to *Caenorhabditis elegans* peptide NLP-22. Pharmacological experiments show a dramatic decrease in ACh-induced muscle contraction of *Ascaris* dorsal muscle in the presence of As-NLP-22, with an IC_{50} of 10^{-8} M. Behavioral experiments in which intact worms were injected with this peptide exhibited flaccid paralysis in the anterior 1/3 of the worm, where locomotory behavior is most frequent. The cholinergic forward-projecting excitatory motor neurons (DE1, DE3, VE1), responsible for forward movement, express 6 peptides homologous to those on the *C. elegans nlp-21* transcript. Muscle exposed to these peptides showed no significant change in ACh-induced contraction compared to controls. Given the dramatic behavioral effects of As-NLP-22, it is crucial that we consider neuropeptides in developing a functional circuit for *Ascaris*, and also as novel targets for anthelmintic drug development.

Title: Cephalopod transcriptomes unravel details about centralized brain evolution across metazoans

Authors: *G. C. WINTERS[1], A. B. KOHN[1], B. HOCHNER[2], N. STERN[2], E. T. WALTERS[3], R. CROOK[3], Y. BOBKOVA[1], L. L. MOROZ[1]
[1]Neurosci., Univ. of Florida- Whitney Lab. for Marine Biosci., Saint Augustine, FL; [2]Hebrew Univ. of Jerusalem, Jerusalem, Israel; [3]Hlth. Sci. Ctr., Univ. of Texas, Houston, TX

Abstract: Cephalopod molluscs (e.g. *Nautilus, Loligo, Octopus*, *Sepia*) are powerful models for comparative biology and neuroscience. Their nervous systems range in complexity from simple cords (*Nautilus*) to one of the most intricate brains of the animal kingdom (*Octopus)*. These highly specialized nervous systems allow for an advanced capacity for learning and a rich behavioral repertoire. Of all cephalopod brain innovations, the most extraordinary structure appears to be the vertical lobe, where we find cell circuits modulating the most advanced learning and memory in all invertebrates. Although collaborative efforts have made progress in describing physiological properties of memory circuits, little is known about the implementation of signaling molecules in the vertical lobe. To examine this, we have sequenced neuronal transcriptomes from key model cephalopods and made comparisons to one another and to our sequenced genome and transcriptomes of the gastropod mollusc, *Aplysia californica*. This approach has allowed us to identify evolutionarily conserved neural signaling molecules and numerous innovations within molluscs. For example, we have identified in cephalopods approximately half of all known *Aplysia* neuropeptides, including putative markers for both sensory and motor neuron populations, as well as traditional neuromodulatory peptides. Of all identified cephalopod neuropeptides, we have cloned and localized expression of seventeen in *Octopus vulgaris*, and thirteen in the squid *Loligo pealei*. Of these neuropeptides, about twenty percent appear to localize to specific and distinct cell populations in the vertical lobe, indicating a greater level of complexity than has been previously described. Additionally, some neuropeptides involved in memory modulation in gastropods, such as FMRF-amide, do not localize to the vertical lobe in *Octopus* or *Loligo,* indicating either an alternate role for FMRFamide, or the presence of additional cephalopod memory circuits. Neuropeptide expression in cephalopod and gastropod neural tissues support a hypothesis that there has been expansion of potentially homologous neural cell populations across lineages. This comparative anatomical and genomic approach provides unique opportunities to reconstruct ancestral neuronal lineages, identify conserved cell types across species, and reveal trends in evolution within neural circuits.

Title: Localization of FMRFamide-like immunoreativity in the nervous system of Biomphalaria glabrata, an intermediate host for schistosomiasis

Authors: *R. A. PAGAN-ALEMAN[1,2], S. ROLÓN-MARTÍNEZ[1,2], N. DELGADO-RIVERA[1,2], M. W. MILLER[1,2]
[1]Inst. of Neurobio., Old San Juan, Puerto Rico; [2]Anat. & Neurobio., Univ. of Puerto Rico, Med. Sci. Campus, San Juan, Puerto Rico

Abstract: It is estimated that approximately 10% of people worldwide live at risk of the parasitic disease schistosomiasis, or “snail fever”. The digenetic trematode worm *Schistosoma mansoni* that causes the form of schistosomiasis found in the Western Hemisphere employs the freshwater snail *Biomphalaria glabrata* as its primary intermediate host. As infection of snail hosts by larval trematodes has been reported to alter the expression of genes that encode precursors of molluscan neuropeptides belonging the FMRFamide family (Hoek et al. 1997), this investigation examined the localization of FMRFamide-like immunoreactivity (FMRFa-li) in the central nervous system (CNS) and peripheral nervous system (PNS) of *B. glabrata*. Within the CNS, FMRFa-li neurons were mainly located in the cerebral ganglion (Cer. g.; 34 ± 7), pedal ganglia (Pd. g.; 36 ± 10), left parietal ganglion (L Pa. g.; 18 ± 11) and visceral ganglion (V g.; 13 ± 3). While no FMRFa-li neurons were observed in the buccal ganglion, the buccal neuropil contained branching fibers that originated from axons in the cerebral-buccal connective. In the periphery, structures associated with the male reproductive system (penis muscle and sheath) were richly innervated by FMRFa-li fibers. Double-labeling experiments (biocytin backfill x FMRFa-li) of the penis nerve demonstrated that the neurons projecting to male reproductive structures were

located in the ventral lobe (VL) of the Cer. g. It is suggested that parasite-induced changes in this peptidergic system could contribute to modifications of feeding and reproductive behaviors that have been reported in infected snails.

Abstract: Induced desensitization of neuronal nicotinic acetylcholine receptors holds promise as an effective treatment of tobacco addiction. Previously, we found that Sazetidine-A (Saz-A), which selectively desensitizes alpha4beta2 nicotinic receptors, significantly decreased IV nicotine self-administration (SA) in a rat with an effective dose of 3 mg/kg in acute and chronic studies. We then found that VMY-2-95, a Saz-A analog that we developed, also significantly decreased nicotine SA with the same effective dose. In continuing efforts, we have studied other Saz-A analogs to determine their efficacies in reducing nicotine SA in the rat model.. Young adult female Sprague-Dawley rats were fitted with IV catheters and were trained for nicotine SA (0.03 mg/kg/infusion) on a fixed ratio-1 schedule for ten sessions. Each drug treatment was administered SC in a separate set of rats ten minutes before the start of 45-minute sessions in a counterbalanced design including each dose and saline control twice. YL-2-203, like sazetidine-A and VMY-2-95, significantly reduced nicotine SA at 3 mg/kg. Follow-up investigation with YL-2-203 showed that with chronic administration of 3 mg/kg it was effective in reducing nicotine during two weeks of treatment and during a resumption period after a week-long period of enforced abstinence. VMY-2-109 at 3 mg/kg significantly reduced nicotine SA, but this effect

was restricted to rats with high pre-treatment baseline levels of nicotine SA with no effect discerned in rats with low baseline levels of nicotine SA. YL-1-127 did not have a monotonic dose-effect of reducing nicotine SA; it had some efficacy at a lower (0.3 mg/kg) but not higher (1-9 mg/kg) doses. YL-1-231 did not affect nicotine SA at doses up to 3 mg/kg. Triazetidine-O was not effective in reducing nicotine SA up to 18 mg/kg. These studies, together with our studies of Saz-A and VMY-2-95, revealed a spectrum of efficacies for these alpha4beta2 nicotinic receptor desensitizing agents and provide a path forward for the most effective compounds to be further developed as possible aids to smoking cessation.

Title: Role of nicotinic acetylcholine α4β2* receptors in alcohol intake: testing novel compounds in rats

Authors: *A. H. REZVANI[1], M. L. BROWN[2], Y. XIAO[2], Y. LIU[2], V. M. YENUGONDA[2], K. J. KELLAR[2], E. D. LEVIN[1]

Abstract: Neuronal nicotinic acetylcholine receptors (nAChRs) have been implicated in alcohol drinking behavior and manipulation of these receptors has been shown to influence alcohol consumption. The goal of the present study was to examine the effects of a series of novel compounds that desensitize α4β2* nAChRs on alcohol intake in alcohol preferring (P) rats. Sazetidine-A (Saz-A), VMY-2-95, YL-1-127 and YL-2-203 were tested. These compounds are strong desensitizers of α4β2 receptors and demonstrate only weak varying partial agonist effects. Alcohol preferring rats were given the choice of water or alcohol. Once stable baselines were established, the acute effects of Saz-A (0.1, 0.3, 1 and 3 mg/kg, s.c.) and its chronic effect (3 mg/kg for 10 days) as well as the effects of different doses of VMY-2-95 (0.33, 1 and 3 mg/kg), YL-1-127 (0.33, 1, 3, 6 and 9 mg/kg) and YL-2-203 (0.33, 1, 3 and 6 mg/kg) on alcohol intake and preference were assessed. In addition, the acute effects of Saz-A (3 mg/kg) and YL-1-203 (6 mg/kg) and VMY-2-95 (3 mg/kg) on alcohol intake after alcohol deprivation were evaluated. The saline vehicle was used as control. Alcohol intake and preference were recorded at 2, 4, 6 and 24 h after the treatments. Our results show that the lead compound Saz-A caused a dose-dependent reduction in alcohol intake and preference with an effective dose threshold at 1 mg/kg). Chronic Saz-A also effectively reduced alcohol intake. In the post-deprivation experiment, when the urge for drinking is enhanced, Saz-A significantly reduced alcohol intake and preference. YL-1-127 at 1 mg/kg reduced alcohol intake significantly over 24-h, and at 3 mg/kg the compound reduced alcohol intake at both the 6-h and 24-h. VMY-2-95 at all doses tested reduced alcohol intake at all-time points. VMY-2-95 at 3 mg/kg also significantly reduced alcohol intake after alcohol deprivation. YL-2-203 was not effective in reducing alcohol intake. In conclusion, these findings suggest an important role for α4β2 nAChRs in excessive drinking and indicate that compounds that desensitize these receptors may hold promise for the treatment of alcohol use disorders. Title: Cross tolerance between nicotine and ethanol is accompanied by increased ethanol self-administration and changes in striatal synaptic transmission

Abstract: Nicotine and ethanol (EtOH) are two of the most widely abused and co-abused drugs. A major risk factor for alcoholism is tolerance to intoxication as this may result in greater EtOH consumption and greater likelihood of addiction. In a number of animal studies, increased EtOH self-administration is correlated with tolerance to EtOH intoxication. Although nicotine EtOH cross-tolerance has been demonstrated in a number of studies, this has not been correlated with changes in levels of EtOH self-administration. In this study we demonstrate that intermittent nicotine pretreatment in Sprague-Dawley rats results in tolerance to nicotine induced motor impairment and cross tolerance to EtOH induced motor impairment, as assessed using the accelerating rotarod. This cross tolerance to EtOH is accompanied by persistently increased levels of EtOH self-administration using a 20% EtOH solution in a 2-bottle choice test. The dorsolateral striatum (DLS) has been implicated in both reward and motor control. Using electrophysiology, we assessed the effects of repeated nicotine on excitatory synaptic transmission in DLS medium spiny neurons (MSN's). Using the paired-pulse ratio as a measure of the release probability of glutamate, we found that repeated nicotine increased the paired-pulse ratio in DLS MSN's, indicating a decrease in the release probability of glutamate. Further studies will assess the role of nicotine induced changes in DLS excitatory synaptic transmission in both EtOH tolerance and reward.

Title: Interactions of hippocampal nAChR subtypes with beta amyloid and the kinase inhibitor gesistein

Authors: D. G. CLARK[1], *S. N. SUDWEEKS[2]
[1]Neurosci., [2]Brigham Young Univ., Provo, UT

Abstract: The exact mechanism and progression of Alzheimer's disease (AD) at present is not fully understood. Damage to the hippocampal region in AD is evidenced by the impairment of learning and memory. It is also known that a buildup of β-amyloid plaques occur in AD patients and that β-amyloid interacts with some subtypes of neuronal nicotinic acetylcholine receptors (neuronal nAChRs). The neuronal nAchRs are pentameric and can consist of several different subunit types. The most prevalent nAChR in the brain as a whole are homomeric α7 receptors and heteromeric receptors composed of α4 and β2 subunits. A broad variety of neuronal nAChR subunits are known to be expressed by interneurons within the hippocampus, a brain region strongly associated with learning and memory. It is hypothesized that memory formation can be impaired through the interaction of β-amyloid with these nAChRs. In this experiment we characterize the interactions of β-amyloid$_{42}$ with human nAChR subunit combinations expressed in *Xenopus laevis* oocytes. We observed a decrease in potentiation when the homomeric α7 receptors was exposed to β-amyloid42. We also observed genistein, a kinase inhibitor, modulates the effects of β-amyloid42 on the α7 receptors, indicating a possible therapeutic option to combat the neurodegeneration in AD.

Abstract: Nicotinic acetylcholine receptors (nAChRs) are recognized for playing a pivotal role in cognitive function. Signaling between cholinergic neurons has been shown to be compromised in many models of Alzheimer's disease. Stimulation of nAChRs with synthetic analogues of the natural neurotransmitter has been shown to reinvigorate cognitive function in such models. In order to identify new chemical entities to potentially aid in the treatment of Alzheimer's disease, a panel of myosmine analogues was prepared and screened with a high throughput method utilizing a series of acetylcholine binding proteins (AChBPs). Some of the compounds prepared had affinities for the AChBPs in the low nanomolar range. Select compounds were co-crystallized with the AChBPs and X-ray structures obtained help demonstrate essential molecular interactions within the binding pocket. The highest affinity compound from the set was studied for its toxicity and efficacy using multi-electrode electrophysiology of dissociated neuronal networks made with hippocampal neurons from c57bl6/J mice. The results of these assays show that the compound was not toxic to the neuronal network and it modified synaptic activity in a dose dependent manner. This data provides the necessary information to extend the testing of the potent compounds in networks mimicking Alzheimer's brain conditions.

Title: Developmental regulation of nicotinic receptor signaling in mouse hippocampal CA1 pyramidal neurons

Authors: B. Y. T. CHUNG[1], D. L. JACKLIN[2], W. BIGNELL[1], B. D. WINTERS[2], *C. D. BAILEY[1]

Abstract: The normal development and function of the hippocampus depends on afferent cholinergic neurotransmission mediated by nicotinic acetylcholine receptors (nAChRs). Nicotinic signaling during development has been implicated in shaping the long-term dendritic morphology of neurons in the central nervous system, and specifically within the hippocampus has been demonstrated to persistently influence the number of postsynaptic spine synapses on CA1 pyramidal output neurons. A major class of nAChR in the hippocampus is the α4β2* receptor. Although it is established that α4β2* nAChRs mediate nicotinic signaling in hippocampal GABAergic interneurons, their ability to mediate nicotinic signaling in glutamatergic CA1 pyramidal neurons is not well understood. Interestingly, expression of individual α4β2* receptor subunits within the rodent CA1 pyramidal cell layer is developmentally regulated and greatest during early postnatal life, suggesting that receptor function is greatest in these neurons at this time. We sought to determine whether functional α4β2* nAChRs are present on CA1 pyramidal neurons during the postnatal development of male CD1 strain mice. Whole-cell electrophysiological responses to acetylcholine (ACh) were recorded for visually-identified CA1 pyramidal neurons within acute brain slices, in the presence of both atropine (to block muscarinic acetylcholine receptors) and methyllycaconitine (MLA; to block α7 subunit-containing nAChRs). We found that ACh elicited postsynaptic inward currents and facilitated neuronal excitation, and that the magnitude for both of these nicotinic responses was greatest in CA1 pyramidal neurons during the first and second postnatal weeks of life compared with later developmental ages examined. Nicotinic responses were resistant to antagonists of synaptic transmission and were inhibited by dihydro-β-ethroidine, suggesting that they were mediated by α4β2* nAChRs located directly on recorded CA1 pyramidal neurons. These findings demonstrate that α4β2* nAChRs mediate nicotinic signaling in CA1 pyramidal

neurons during hippocampal development, and suggest a role for these receptors in the formation and maturation of hippocampal learning and memory networks.

Title: Facilitation of alpha 7 nachr current by picomolar concentration of amyloid beta peptide

Authors: *M. ISLAM, K. DEBOEUF, L. LAURIDSEN, J. BAE, J. FARLEY
Neurosci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: Alpha 7 (α7) nicotinic acetylcholine receptors (nAChRs) are widely distributed in brain particularly in those areas involved in motivation, learning and memory. Various interactions of α7 Rs with amyloid beta peptides (e.g., Aβ 42) have been proposed by several groups, with possible relevance for Alzheimer's disease (AD). The results have been variable and mixed, however, and no clear consensus has yet been reached concerning their interaction or functional significance. Early studies (Wang et al, 2000, J. Neurochem) showed that α7 nAChRs and Aβ 42 are co-localized in AD cortical regions including the hippocampus, and further that high-affinity receptor-peptide complexes could be co-immunoprecipitated (Wang et al., 2010, Biol Psychiatry). The high affinity interaction of Aβ 42 with α7 Rs may be unique to low-n oligomeric forms of Aβ, but the exact nature of the interaction is still largely unknown (Parri et al, 2011, Biochem. Pharmacol.). The apparent high affinity for the α7 R-Aβ 42 interaction suggests that the very low (pM) concentrations of Aβ 42 found in healthy brain under normal physiologic conditions (Kuo et al, 1996, J Biol Chem) might facilitate receptor activation by ACh. In support of this view, behavioral and synaptic plasticity studies in hippocampus found that pM Aβ 42 was essential for normal function of alpha 7 Rs (Puzzo et al, 2010, Ann Neurol). In contrast, high (nM - uM) concentration of Aβ 42 found in advanced AD patient brain (Kuo et al, 1996, J Biol Chem) might have an inhibitory effect on α7 nAChRs as suggested by some studies. To elucidate the functional consequences of Aβ 42 - α7 nAChR interactions, we tested the effects of Aβ 42 (1 pM, 10 pM, 1 uM applied acutely as well as for several hrs) on murine α7 nAChRs heterologously expressed in Xenopus oocytes. No concentration of Aβ 42 tested was

found to directly activate α7 Rs. Similarly, short term preexposure (10 sec) to Aβ 42 (10 sec) produced no effect on 500 uM ACh-evoked α7 currents (i.e., neither PAM- nor NAM-like effects observed). However, incubation with 10 pM Aβ for 2-4 hours produced a clear and significant ~ 3-fold facilitation of α7 currents (mean ± SEM) : Controls, 242±24 nA (n=36) vs. 10 pM, 742±190 nA (n=35). Lower or higher Aβ 42 concentrations had no significant effects: 1 pM, 219±39 nA (n=18); 1 uM, 245±29 nA (n=19). Thus, low Aβ 42 concentrations (similar to physiologic conc. in brain) facilitated α7 function. Additional studies examined the relative contribution of Type I PAM-like actions vs. intracellular signaling pathways to the facilitatory effects of 10 pM Aβ 42 on α7 currents.

Title: Association of alcohol preference with the low hypothalamic alpha7 nicotinic receptor level

Authors: S. NUUTINEN[1], *O. S. SALMINEN[2], P. PANULA[3]
[1]Fac. of Pharm. and Neurosci. Ctr., [2]Fac. Pharm., [3]Fac. of Medicine, Neurosci. Ctr., Univ. Helsinki, Helsinki, Finland

Abstract: Nicotine and alcohol are often used together. The effects of nicotine are mediated via neuronal nicotinic receptors in the brain. In addition, emerging evidence suggests that nicotinic receptors are involved in the mediation of the rewarding and reinforcing effects of alcohol. Here we studied the expression of α5, α6 and α7 nicotinic receptor subunits in alcohol preferring AA and alcohol non-preferring AA rats. *In situ* hybridization and receptor binding studies were conducted in drug-naïve animals. The brain areas to be studied were selected based on their high expression level of these nicotinic receptor subunits and if earlier association of behaviors linked to alcohol or nicotine dependence with these areas was suggested. We found that the mRNA level of α5 subunits in the medial habenula and hippocampus were similar in AA and ANA rats.

In addition, there was no difference in the expression of α6 subunit mRNA in the ventral tegmental area and substantia nigra. However, the level of α7 nicotinic receptor subunit mRNA was significantly lower in the hypothalamus of alcohol preferring AA rats than in alcohol avoiding ANA rats. Also the hypothalamic [125]I-α-bungarotoxin binding was lower in AA rats indicating lower levels of α7 nicotinic receptors. Hippocampal α7 subunit mRNA level and receptor binding for α7 nicotinic receptors were similar in AA and ANA rats. The α7 nicotinic receptors in the hypothalamus are located in histaminergic neurons suggesting that regulation of genetic preference or avoidance to alcohol or other addictive substances involves brain histaminergic system.

Title: Combinations of nicotine and ethanol enhance AMPA receptor function in VTA DA neurons through activation of α6β2* nAChRs

Authors: *S. E. ENGLE[1], J. M. MCINTOSH[2,3], R. M. DRENAN[1]
[1]Medicinal Chem. and Mol. Pharmacol., Purdue Univ., West Lafayette, IN; [2]Psychiatry and Biol., Univ. of Utah, Salt Lake City, UT; [3]George E. Wahlen Veterans Affairs Med. Ctr., Salt Lake City, UT

Abstract: Nicotine and alcohol are frequently co-abused, suggesting they may have common molecular targets mediating their rewarding effects. While nicotine can directly activate nicotinic

acetylcholine receptors (nAChRs) in the mesolimbic dopamine (DA) system, emerging evidence suggests that alcohol can modulate nAChR function. nAChRs containing the α6 subunit are highly and selectively expressed in midbrain DA neurons of the substantia nigra and ventral tegmental area (VTA). We previously reported that nicotine can act selectively through α6β2* nAChRs to enhance 2-amino-3-(3-hydroxy-5-methyl-isoxazol-4-yl) propanoic acid (AMPA) receptor (AMPAR) function on VTA DA neurons. This effect sensitizes the VTA to excitatory input and promotes drug seeking in animal models. Exposure to alcohol also enhances AMPAR function in VTA neurons. We therefore hypothesized that α6β2* nAChRs are also involved in the mechanism by which ethanol enhances AMPAR function on VTA DA neurons. Mice expressing hypersensitive α6 nAChRs (α6L9′S mice) were used in this study to determine if enhanced α6* nAChR activity can modulate the ability of ethanol to enhance AMPAR function in VTA DA neurons. We found that incubating naïve brain slices containing the VTA in a low concentration of ethanol (5 mM) for 60 min was sufficient to enhance AMPAR function in VTA DA neurons of α6L9′S mice. This concentration of ethanol was insufficient to enhance AMPAR function in non-transgenic littermate neurons, but 20 mM ethanol was sufficient to enhance AMPAR function in these control mice. To determine whether *in vivo* ethanol exposure produced effects similar to those seen in experiments utilizing slice incubation, α6L9′S and nonTg littermate mice were injected (i.p.) with ethanol and 60 min later brain slices were prepared. α6L9′S mice injected with 0.5 g/kg ethanol exhibited enhanced VTA DA neuron AMPAR function, but nonTg control mice required 2.0 g/kg ethanol to achieve the same effect. Because ethanol and nicotine both modulate AMPAR function in a manner involving α6* nAChRs, we tested the hypothesis that low concentrations of alcohol and nicotine combine to modulate AMPAR function in an additive manner. Co-incubation of α6L9′S or nonTg slices in concentrations of ethanol and nicotine that are sub-threshold when incubated alone resulted in robust enhancement of AMPAR function. Pre-incubation of slices in either α-conotoxin MII (α6β2* nAChR antagonist) or varenicline (a partial agonist of α4β2* and α6β2* nAChRs) attenuated the additive/synergistic enhancement of low concentrations of nicotine and alcohol. These data suggest that α6β2* nAChRs play an important role in alcohol+tobacco co-dependence.

Title: Individual differences in the modulation of rapid dopamine signals by presynaptic nicotinic acetylcholine receptors

Authors: *M. J. FERRIS, S. R. JONES
Wake Forest Sch. of Med., WINSTON SALEM, NC

Abstract: Variability in the rate in which animals will acquire self-administration of psychostimulants is a preclinical model for vulnerability to abuse drugs in humans. The variability in animals' acquisition rate can be predicted by individual differences in animals' locomotor response to a novel environment. Therefore, we investigated whether the propensity to explore a novel environment might also predict individual differences in the activity of receptors that have been shown to be critical for acquisition behavior. We focused on nicotinic acetylcholine receptors (nAChR) located on dopamine terminals in the core of the nucleus accumbens given their well-documented ability to modulate rapid dopamine signals that are critical for acquisition behavior. Moreover, activation of nAChRs is critical for amphetamine, cocaine, and nicotine sensitization, and nAChR blockade reduces psychostimulant self-administration. We assessed locomotor activity in an inescapable novel environment followed by measurements of dopamine release using voltammetry in brain slices from the same animals. We found no relationship between the animals' locomotor response to a novel environment and the magnitude of electrically-stimulated dopamine release in the nucleus accumbens. In fact, no relationship between these parameters was found when dopamine was elicited under single-pulse conditions and under multiple-pulse conditions across a range of frequencies (5 Hz - 100 Hz). Following assessment of dopamine release under drug-free conditions, the general nAChR antagonist mecamylamine, the β2-specific antagonist DHβE, and a desensitizing dose of nicotine was bath applied to different slices from the same animal. Animals with lower response to a novel environment (LR) showed greater inhibition in dopamine release to nAChR blockade or desensitization under single pulse and low frequency, multiple-pulse stimulations that reflect tonic firing of dopamine neurons. However, animals with a higher response to a novel environment (HR) showed greater facilitation of dopamine release to nAChR blockade or desensitization under multiple-pulse, high-frequency conditions that reflect phasic firing of dopamine neurons. Thus, LR animals are more sensitive to the dopamine inhibitory effects of nAChR blockade under tonic firing-like conditions while HR animals are more sensitive to the dopamine facilitative effect of nAChR blockade under phasic firing-like conditions. The increased sensitivity to nAChR induced facilitation of dopamine signals elicited by phasic-like stimulation parameters may be mechanistically linked to faster and more robust acquisition of drugs of abuse.

Title: Native α7-containing nicotinic acetylcholine receptors form heteromers with β2 subunits in the human cortex and have a distinct pharmacology: Evidence for an alternative drug target for schizophrenia and Alzheimer's Disease

Authors: *J. D. MIKKELSEN[1], R. ZWART[2], D. URSU[2], G. GILMOUR[2], M. M. JENSEN[1], L. PINBORG[1], J. WU[3], E. SHER[2], M. S. THOMSEN[1]

Abstract: In the brain, the α7 nicotinic acetylcholine receptor (nAChR) is composed as a penta-homomeric ligand gated ion channel. In addition, α7β2 nAChR heteromers have been demonstrated in heterologous expression systems. Since partial agonists currently used in clinical trials are selected from screening on the homomeric and not the heteromeric receptor, it is important to determine whether α7β2 nAChRs are present in the human brain, and whether such receptors are pharmacologically different from α7 nAChR homomers. In this study, we used α-bungarotoxin to affinity purify α7-containing nAChRs from surgically excised human temporal cortex, and determined the pharmacology and kinetics of human α7β2 nAChR heteromers in two cellular systems. Using α-bungarotoxin pull down from extracts of temporal neocortex resected under neurosurgical operations, it was revealed that β2 subunits co-purified in the eluent. The same data were replicated in three distinct human samples. In animal studies, the co-purification of β2 occurs in the cortical tissue from wild-type, but not α7 or β2 knock-out mice. These data strongly indicate that the α7β2 nAChR heteromer is indeed present in the human brain. Furthermore, the pharmacology and kinetics of human α7β2 nAChR heteromers differ significantly from that of α7 homomers in response to the nAChR ligands carbachol, choline, epibatidine and compound A when expressed in Xenopus oocytes and HEK293 cells. Notably, α7β2 heteromers expressed in HEK293 cells display markedly slower rise and decay phases in response to epibatidine and compound A. The present results demonstrate that part of the α7-containing nAChRs in the human brain are heteromers containing one or more β2 subunits, and

that human α7β2 nAChR heteromers respond to selective α7 nAChR agonists with unique pharmacology and kinetic profiles. The α7β2 nAChR heteromer thus represents an alternative mechanism through which the reported clinical efficacy of α7 nAChR ligands may occur, and may represent an alternative drug target for treatment of cognitive dysfunction.

Abstract: Neuronal nicotinic acetylcholine receptors (nAChRs) play a pivotal role in nicotine addiction. Heteromeric neuronal nAChRs are ligand-gated, pentameric, cation channels formed from combinations of 9 α and 3 β subunits, which allows for the possibility of a large number of receptor subtypes with different biophysical properties and pharmacological characteristics. The habenula is an important brain region that expresses several different nAChR subtypes (Grady et al., J Neurosci, 2009; Fonck et al., Neuropharmacology, 2009), some of which appear to be closely linked to withdrawal symptoms in nicotine-treated animals (Salas et al., J Neurosci, 2009) Many of the nAChRs in the habenula contain the α5 subunit, which appears to play an important role in nicotine addiction. The α5-containing receptors have significantly higher Ca++

conductance and faster rates of desensitization than their non α5-containing counterparts (Gerzanich et al., JPET, 1998). Additionally, the α5 subunit in the habenula may play a role in animals' sensitivity to high doses nicotine and their threshold for aversion (Fowler et al., Nature 2011). Although many nAChR subtypes are expressed in the rat habenula, the distribution of the a5 subunit in the different subtypes, e.g., α3β4 and α4β2 nAChRs, is still not certain. In this study, we investigated the associations of the α5 subunit in the rat habenula using the sequential immunoprecipitation method. This method allowed us to quantify the total α5 subunit expression in the habenula, as well as the extent to which α5 was associated with other subunits. Our study shows that the α5 subunit exists in about 20% of the nAChRs that are expressed in the rat habenula. Additionally, we show that in the rat habenula the α5 subunit is associated with both β2- and β4-containing receptors, providing the habenula with a diverse group of α5-containing nAChRs. This data provides important insight into how α5 can potentially mediate functions of the habenula by incorporating into multiple nAChR subtypes. By understanding the library nAChR subtypes in the habenula, it may be possible to understand how the actions of these nAChRs impact nicotine addiction. Therefore, this study will provide important insight into the role habenular nAChRs play in addiction.

Title: miRNome analysis of the mammalian neuronal nicotinic acetylcholine receptor gene family

Authors: A. P. CASSERLY[1], E. M. HOGAN[1], M. D. SCOFIELD[1], Z. MOU[1], R. ZHAO-SHEA[1], C. W. JOHNSON[1], A. R. TAPPER[1], *P. D. GARDNER[2]

Abstract: Nicotine binds to and activates a family of ligand-gated ion channels, neuronal nicotinic acetylcholine receptors (nAChRs). Chronic nicotine exposure alters the expression of various nAChR subtypes, which likely contributes to nicotine dependence; however, the underlying mechanisms regulating these changes remain unclear. A growing body of evidence indicates that microRNAs (miRNAs) may be involved in nAChR regulation. Using bioinformatics, miRNA library screening, site-directed mutagenesis and gene expression analysis, we have identified a limited number of miRNAs that functionally interact with the 3′-untranslated regions (3′-UTRs) of mammalian nAChR subunit genes. In silico analysis revealed specific, evolutionarily conserved sites within the 3′-UTRs through which the miRNAs regulate gene expression. Mutating these sites disrupted miRNA regulation confirming the in silico predictions. In addition, the miRNAs that target nAChR 3′-UTRs are expressed in mouse brain and are regulated by chronic nicotine exposure. Furthermore, we show that expression of one of these miRNAs, miR-542-3p, is modulated by nicotine within the mesocorticolimbic reward pathway. Importantly, over-expression of miR-542-3p led to a decrease in the protein levels of its target, the nAChR β2 subunit. Bioinformatic analysis suggests that a number of the miRNAs play a general role in regulating cholinergic signaling. Our results provide evidence for a novel mode of regulation of the mammalian nAChR gene family by nicotine.

Abstract: Ly6/neurotoxin 1 (Lynx1) is an important regulator of synaptic plasticity in the brain, and this is believed to be due to its regulation of nicotinic acetylcholine receptors (nAChRs). Heterologous expression studies have shown that Lynx1 binds directly with α7 and β2 nAChR subunits, but it is not known to which extent Lynx1 can bind to endogenous nAChRs in the brain or how this is affected by Alzheimer's disease pathology. Here, we apply affinity purification with recombinant soluble Lynx1 (Ws-Lynx1) to show that Ws-Lynx1 can co-purify α4, α5, α6, α7, β2, and β4 nAChR subunits from human cortical extracts as well as rat cortical, midbrain and olfactory bulb extracts. We further show that Ws-Lynx1 can decrease nicotine-mediated Extracellular-signal Regulated Kinase (ERK) phosphorylation in rat PC12 cells. This finding indicates that binding of Lynx1 is sufficient to inhibit signalling downstream of nAChRs. The effect of nicotine itself in this assay is sensitive to inhibition by mecamylamine, but not by methyllycaconitine or dihydro-β-erythroidine. This suggests that Lynx1 can affect the function of native non-α7, non-α4β2 nAChR subtypes. Finally, we show that oligomeric β-amyloid1-42 can inhibit the interaction between Ws-Lynx1 and several nAChR subunits, and that cortical Lynx1 levels are decreased in a transgenic mouse model with age-dependent β-amyloidosis and tau pathology. Our data suggest that Lynx1 is a promiscuous protein that can bind to and regulate multiple nAChR subtypes in the human brain, and implicates Lynx1 in the pathophysiology of Alzheimer's disease.

Title: Blockade of α6* nAChRs reduces L-dopa-induced dyskinesias; studies using parkinsonian α6* nAChR gain of function mice

Authors: *M. M. MCGREGOR[1], T. BORDIA[1], R. M. DRENAN[2], M. QUIK[1]

Abstract: L-Dopa-induced dyskinesias (LIDs) are a serious side effect of dopamine replacement therapy for Parkinson's disease for which there are a few treatment options. Accumulating preclinical studies using nicotinic agonists and nicotinic receptor (nAChR) null mutant mice suggest a role for various nAChRs in LIDs, including the α6β2* nAChR population. Deletion of the α6 nAChR subunit reduced L-dopa-induced abnormal involuntary movements (AIMs) compared to wild type (WT) mice, while nicotine treatment reduced AIMs in WT but not in α6 nAChR knockout mice. To understand the mechanism through which α6β2* nAChRs regulate L-dopa-induced AIMs, we used gain-of-function α6* nAChR (α6L9'S) mice. This mutation results in enhanced sensitivity to nicotine/acetylcholine and prolonged receptor-mediated activity. Male WT and α6L9'S mice were lesioned by unilateral injection of 6-hydroxydopamine (3 µg/ml) into the medial forebrain bundle. Three to 4 wk later, they were rendered dyskinetic by administration of L-dopa (3 mg/kg) plus benserazide (15 mg/kg) for 3 wk. L-dopa-induced AIMs were expressed to a similar extent in the α6L9'S mice and WT mice. Three week later, when AIMs had stably developed, α6L9'S mice and WT mice were administered nicotine. WT mice were given nicotine in the drinking water in gradually increasing doses to a maximum of 300 µg/ml. This dose led to a 40% decline in L-dopa-induced AIMs. The reduction in AIMs in WT mice was maintained with doses of nicotine as low as 20 µg/ml. Because of their exquisite sensitivity to nicotine, α6L9'S mice received 10 µg/ml in the drinking water; higher nicotine doses resulted in mortality. In contrast to WT mice, nicotine treatment did not reduce L-dopa-induced AIMs in α6L9'S mice. To determine whether this may be due to enhanced activity of hypersensitive α6L9'S nAChRs, we tested the effect of the general nAChR blocker mecamylamine that has previously been shown to reduce L-dopa-induced AIMs. Two-day administration of mecamylamine (1 mg/kg ip 30 min before L-dopa) similarly reduced L-dopa-induced AIMs in

α6L9'S mice and WT mice. The observation that a nAChR antagonist still reduced L-dopa-induced AIMs in α6L9'S mice suggests that nicotine decreases LIDs by a nAChR desensitization block. These results indicate that α6β2* nAChR antagonists may be useful for reducing L-dopa-induced dyskinesia.

Title: Role of nicotinic receptor subunits in spontaneous activity of prelimbic cortex

Authors: F. KOUKOULI[1], D. TZIOTIS[2], M. NILGES[2], D. DIGREGORIO[1], *U. MASKOS[3]
[1]Neurosci. CNRS UMR 3571, [2]Unité de Bio-Informatique Structurale, [3]Neurosci. CNRS URA 2182, Inst. Pasteur, Paris Cedex 15, France

Abstract: The Prefrontal Cortex (PFC) is important for many cognitive processes including attention, decision making, social behavior and emotion. The PFC receives significant cholinergic innervation in concert with numerous neurons in this brain region expressing nicotinic Acetylcholine Receptors (nAChRs). nAChRs are pentameric transmembrane proteins that exhibit divergent cationic permeabilities, agonist affinities and desensitization properties. In our study, we investigated *in vivo* the cholinergic modulation of PFC layer II/III neurons in order to better understand the impact of specific nAChR subunits on neuronal network activity. We performed two-photon Ca2+ imaging in lightly anesthetized, adult, wild type and subunit-specific knock-out (KO) mice (α7, β2, α7β2 and α5). In WT mice (6-8 months old) we categorized neuronal firing behavior according to the number of Ca2+ events per minute (EPM) as segregated with principal component analysis. Silent cells produced 1 or less EPM, whereas

moderately firing neurons produced between 1 to 34 EPM, and finally hyperactive neurons produced more than 34 EPM. The distribution of spontaneous activity was remarkably stable in WT mice, with 71 ± 3% having normal EPM and only 7 ± 3% showing hyperactive EPM. In all the various nAChR subunit KO mice, the distribution of firing types was altered as compared to WT. A common finding was a significant increase in the fraction of hyperactive neurons, with a notable three-fold increase in the a7 KO mice. Interestingly, we did not observe significant differences in the fraction of silent neurons between WT mice and β2 and α5 KO mice. In order to assess the effect of acute alterations in nAChR signaling on PFC activity, we subcutaneously administered nicotine and other subunit-specific cholinergic agonists while imaging. Our findings suggest that nicotine regulates PFC baseline neuronal activity and is dependent on the nAChR subunit composition.

Title: The α7 nicotinic receptor agonist ABT-107 protects against nigrostriatal damage in parkinsonian rats

Authors: *T. BORDIA[1], M. MCGREGOR[1], R. L. PAPKE[2], M. J. MCINTOSH[3], M. W. DECKER[4], M. QUIK[1]
[1]Ctr. for Hlth. Sci., SRI Intl., Menlo Park, CA; [2]Dept. of Pharmacol. and Therapeutics, Univ. of

Florida Col. of Med., Gainesville, FL; [3]George E. Wahlen Veterans Affairs Med. Ctr., Salt Lake City, UT; [4]AbbVie, Inc, 1 North Waukegan Road, North Chicago, IL

Abstract: The finding that smoking is inversely correlated with Parkinson's disease and that nicotine attenuates nigrostriatal damage in parkinsonian animals supports the idea that nicotine may be neuroprotective. Nicotine is thought to exert this effect by acting at nicotinic receptors (nAChRs), including the α7 nAChR subtype. The objective of this study was twofold; first, to test the neuroprotective potential of ABT-107, an agonist with high affinity and selectivity for α7 nAChRs and has low incidence of side effects in patients, and second, to investigate its mechanism of action. Rats were implanted with minipumps containing ABT-107 (0.25 mg/kg/d). In addition, we tested the effect of the α7 nAChR agonist DMXB (2 mg/kg/d) and nicotine (1 mg/kg/d), as positive controls. Two wk after minipump placement, the rats were lesioned by unilateral administration of 6-hydroxydopamine into the medial forebrain bundle. Lesioning alone decreased contralateral forelimb use and adjusted stepping, two measures of parkinsonism. ABT-107 and nicotine treatment significantly improved these behaviors at all wk tested, with variable improvements with DMXB. We next investigated the mechanism that may be involved. The striatal dopamine transporter (DAT), a marker of dopaminergic integrity, was reduced ~70% with lesioning. ABT-107, DMXB or nicotine treatment led to significantly higher DAT levels in lesioned striatum. The drugs did not alter DAT levels in intact striatum. ABT-107 and nicotine also significantly improved basal dopamine release from lesioned striatum, as well as nicotine-stimulated dopamine release mediated via α4β2* and α6β2* nAChRs. These data suggest that drugs targeting α7 nAChRs could be useful for neuroprotection in Parkinson's disease.

Title: Differential localization and function of nicotinic acetylcholine receptors in subdivisions of medial habenula

Authors: *P. SHIH[1], S. ENGLE[1], G. OH[1], P. DESHPANDE[2], N. PUSKAR[3], H. LESTER[2], R. DRENAN[1]
[1]Purdue Univ., West Lafayette, IN; [2]Div. of Biol. and Biol. Engin., [3]Div. of Chem. and Chem. Engin., Caltech, Pasadena, CA

Abstract: Neuronal nicotinic acetylcholine receptors (nAChRs) in the medial habenula (MHb) to interpeduncular nucleus (IPN) pathway are key mediators of nicotine's aversive properties. However, no previous work has systematically examined the anatomical localization and function of distinct nAChR subtypes in these two small brain regions. To address this issue, a new group of knock-in mice were created that each express a single nAChR subunit fused to green fluorescent protein (GFP), allowing high-resolution mapping. We find that α3 and β4 nAChR subunits levels are strong throughout the ventral MHb (MHbV). In contrast, α6, β2, β3, and α4 subunits are selectively found in some, but not all, areas of MHbV. All subunits were found in both choline acetyltransferase (ChAT)-positive and ChAT-negative cells in MHbV. Next, we examined functional properties of neurons in the lateral and central part of MHbV (MHbVL and MHbVC) using brain slice patch clamp recordings. MHbVL neurons were more excitable than MHbVC neurons, and they also responded more strongly to puffs of nicotine. In addition, our studies of firing responses in MHbV neurons showed that MHbVL neurons, but not MHbVC neurons, increased their firing substantially in response to a nicotine concentration (1 μM) achievable in smokers. This effect was eliminated in α4 subunit knockout mice. Bath application of SR16584, a selective antagonist for α3β4* nAChRs (the asterisk indicates the possible presence of additional subunits), also significantly blunted the ability of MHbVL neurons in response to 1 μM nicotine. These data highlight the role of α3β4* and α4* nAChRs in MHbVL neuron firing. Additionally, the increase in firing frequency by nicotine was significantly reduced in MHbVL neurons from mice that underwent withdrawal from chronic nicotine compared to mice withdrawn from chronic saline. Last, we characterized two electrophysiologically distinct neuronal populations in the dorsal part of the IPN, which receives input from MHbVL axons. Type II dorsal IPN neurons, compared to type I neurons, couple more strongly to cholinergic/glutamatergic afferents from MHbVL. Together, our data provide novel details regarding neurophysiology and nAChR localization and function in cells within the MHb-IPN tract. These results also highlight the importance of studying subregions of the MHbV to advancing our understanding of nicotine withdrawal.

Title: Interactions between NMDA and nicotinic receptor ligands in organotypic hippocampal slice cultures

Authors: *D. HAPP[1], D. S. MACDONALD[1], H.-P. DEIGNER[2], R. A. TASKER[1]
[1]Univ. of Prince Edward Island, Charlottetown, PE, Canada; [2]Hochschule Furtwangen Univ., Villingen-Schwenningen, Germany

Abstract: NMDA receptors have been extensively characterized for their involvement in hippocampal dependent learning and memory as well as excitotoxic cell death at higher concentrations. More recently there has been considerable interest in the role of the alpha7 nicotinic receptor (a7nAChR) in hippocampal and cortical processes underlying cognition and cognitive enhancement. Several recent publications have described formation of an NMDA-a7nAChR complex (Li et al. 2012, 2013), the functional significance of which is largely unknown. To investigate the interaction between NMDA and nicotinergic-based function *in vitro* we chose to use organotypic hippocampal slice cultures prepared from P5/6 day old SD rats and grown for 14 days on 0.4 um porous membrane inserts at 37°C. Viable slices were exposed for 24 hours to varying concentrations of NMDA and re-evaluated by propridium iodide exclusion to construct toxicity-response curves. Subsequent experiments are evaluating the effect of the cholinergic agonists choline and galantamine on NMDA receptor-mediated excitotoxicity, as well as the effect(s) of corresponding antagonists. Preliminary results to date support an interaction between NMDA and nicotinergic signaling systems *in vitro*.

Title: Activation of α7 nicotinic acetylcholine receptors increased intracellular cAMP levels in cultured hippocampal neurons

Authors: *Q. CHENG, J. L. YAKEL
Lab. of Neurobio., NIEHS, Durham, NC

Abstract: The activation of α7 nicotinic acetylcholine receptors (nAChRs) has been shown to improve hippocampal-dependent learning and memory. However, the molecular mechanism of α7 nAChRs' action remains elusive. We previously reported that activation of α7 nAChRs induced a prolonged enhancement of glutamatergic synaptic transmission in a protein kinase A (PKA)-dependent manner. Here, we investigated if there is a direct link between the activation of the α7 nAChR and cyclic adenosine monophosphate (cAMP) signaling in hippocampal neurons. To address this question, we employed a Förster- Resonance Energy Transfer (FRET)-based biosensor (mTurquoise-Epac(CD, ΔDEP)-^{cp173}Venus-Venus) to measure the intracellular cAMP levels directly via live cell imaging. We found that application of the α7 nAChR-selective agonist choline (2 mM; in the presence of the α7 nAChR positive allosteric modulator PNU-120596 (5 μM)) induced a significant change in the YFP/CFP ratio, which indicated an increase in intracellular cAMP levels. This choline-induced increase was abolished by the α7 nAChR antagonist MLA (40 nM) and the calcium chelator BAPTA (10 mM), suggesting that the cAMP increase depends on the α7 nAChR activation and subsequent intracellular calcium rise. The soluble adenylyl cyclase (AC) inhibitor KH7 (25 μM) also blocked the choline-induced cAMP increase, suggesting that calcium dependent ACs are required for choline's action. To determine the involvement of AC1, we tested the effect of siRNA against AC1. We found that this treatment reduced significantly the choline-induced FRET ratio change. This suggested that AC1 is the main mediator for the choline-induced cAMP rise. Our findings provide the first direct evidence to link activation of α7 nAChRs to a cAMP rise, which defines a new signaling pathway employed by α7 nAChRs. Our study sheds light into the molecular mechanisms of the positive cognitive actions of α7 nAChR agonists and development of therapeutic treatments for cognitive impairments.

Title: Nicotinic receptors regulate inflammatory and apoptotic signaling through nonconductive states

Authors: *T. M. GOULD[1], C. W. KINTER[2], N. A. HORENSTEIN[1], R. L. PAPKE[2]
[1]Chem., [2]Pharmacol. & Therapeut., Univ. of Florida, Gainesville, FL

Abstract: Nicotinic acetylcholine receptors (nAChRs) are present in the blood and epithelium. Paradoxically, leukocyte nAChRs remain to be proven as having conductive ion channels, yet these nAChRs regulate inflammatory and immune-mediated signaling responses to various pathogens and stimuli. Therefore, we hypothesize that nAChRs impact intracellular inflammatory signaling in leukocytes through nonconductive conformational states. We found that in the absence of detectable ion currents, nAChRs regulate inflammatory signal transduction events in three types of leukocytes: lymphocytes, monocytes and macrophages. Moreover, we confirmed that the most effective attenuators of inflammatory signaling are not prototypical ion channel agonists such as nicotine or acetylcholine, but rather ligands that stabilize non-conducting or desensitized states. As previously reported for microglia, the partial α7 nAChR agonist GTS-21 and silent agonist NS6740 significantly attenuate stimulus-induced NF-κB inflammatory signaling in both Jurkat T lymphocytes and THP-1 monocytes; these ligands are also effective suppressors of TNFα levels in LPS-stimulated RAW 264.7 macrophages. The inhibition of inflammatory signals in leukocytes by GTS-21 and NS6740 are coincident with decreased cell viability (mitochondrial respiration) as evidenced by reduced NADH dependent dehydrogenase activity. The reduction of TNFα levels in LPS-stimulated macrophages by GTS-21 also correlates with increased caspase activity. Interestingly, NS6740 potentiates LPS-stimulated NF-κB activation in monocytes while suppressing TNFα levels in LPS-stimulated macrophages. This suggests NS6740 has the ability to induce multiple nonconductive signaling modes, and that nAChRS may regulate intracellular signaling mechanisms at both the transcriptional and post-transcriptional level. NF-κB plays a crucial role in cell viability, regulating inflammatory, proliferative and apoptotic signals. Consistent with these findings, it is possible that nAChRs may induce apoptosis by inhibiting NF-κB in the attenuation of inflammation. Alternatively, diminished NF-κB signaling may be a consequence of induced

apoptosis. Our data support the hypothesis that ionotropically silent nAChRs may be metabotropically active and can regulate signaling and transcription. Our studies signify why the putatively nonconductive leukocyte nAChRs represent a major therapeutic target for the pharmacological control of inflammation and the regulation of aberrant NF-κB signaling in immune-mediated diseases and cancer, and recommend the further development of silent agonists for these indications.

Title: Nicotine increases GABAergic input to 5-HT dorsal raphe neurons by stimulation of presynaptic α7 nicotinic acetylcholine receptors

Authors: F. HERNANDEZ VAZQUEZ[1], K. CHAVARRIA[2], J. GARDUÑO[2], S. HERNANDEZ LOPEZ[2], *S. P. MIHAILESCU[2]
[1]Physiol., Univ. Nacional Autónoma de Mexico, Mexico, Mexico; [2]Physiol., Fac. of Medicine, UNAM, Mexico City, Mexico

Abstract: The dorsal raphe nucleus (DRN) contains the largest populations of serotonergic (5-HT) neurons. Excitatory and inhibitory afferents from many brain areas regulates 5-HT activity. 5-HT DRN neurons express functional nicotinic acetylcholine receptors (nAChRs) and stimulation of these receptors by nicotine causes and increase in 5-HT release and 5-HT DRN neuron discharge rate. Serotonergic neurons are also excited by nicotine through increases in glutamate and noradrenaline release. However, the role of nicotine on the GABAergic input to 5-HT DRN neurons was not investigated in detail. Therefore, the aim of this work was to determine the effect of nicotine on GABAergic spontaneous inhibitory postsynaptic currents (sIPSCs) of 5-HT DRN neurons and the subtype of nAChR(s) involved in this response. Experiments were performed in coronal slices obtained from young Wistar rats. GABAergic sIPSCs were recorded in 5-HT DRN neurons using the whole-cell voltage patch clamp technique. Immunohistochemistry identification of 5-HT neurons was made after recording. The administration of nicotine (1 μM) increased sIPSCs frequency in 72% 5-HT DRN neurons. This effect was not reproduced by the α4β2 nAChR agonist RJR-2403 and was not influenced by TTX (1 μM). It was, however, mimicked by the selective agonist for α7 nAChR, PNU-282987, and exacerbated by the positive allosteric modulator of the same receptor, PNU-120596. The nicotine-induced increase in sIPSCs frequency was independent on voltage-gated calcium channels but dependent on Ca2+-induced Ca2+ release (CICR). These results demonstrate that nicotine increases the GABAergic input to most 5-HT DRN neurons, by activating presynaptic α7 nAChRs and producing CICR in DRN GABAergic terminals.

Title: The effect of AT-1001, a selective α3β4 nAChR functional antagonist, on nicotine withdrawal and stress+cue induced reinstatement in rats

Authors: *M. YUAN[1], A. M. MALAGON[1], D. YASUDA[2], J. D. BELLUZZI[1], F. M. LESLIE[1], N. T. ZAVERI[2]
[1]Pharmacol., Univ. of California - Irvine, Irvine, CA; [2]Astraea Therapeut., Mountain View, CA

Abstract: Tobacco is the leading cause of preventable death worldwide. Relapse is common during initial onset of withdrawal. Stress and smoking-related cues are also key factors potentiating relapse. Therefore, management of withdrawal and craving is critical for smoking cessation. Currently, the most effective smoking cessation aid, varenicline, only has a 23% abstinence rate after one year. Varenicline is a partial agonist at α4β2 nicotinic acetylcholine receptors (nAChR), the subtype considered predominantly responsible for smoking addiction. However, the α3β4 nAChR has recently been implicated in tobacco dependence. In addition, AT-1001, a potent and selective α3β4 nAChR functional antagonist, reduces nicotine self-administration in rats (Toll et al., 2012; Costello et al., 2014). The β4 subunit is necessary for withdrawal since mecamylamine-precipitated nicotine withdrawal is diminished in β4, but not β2, null mice. The present study tests the effect of AT-1001 on (1) precipitated nicotine withdrawal and (2) stress+cue induced reinstatement of nicotine self-administration in rats. To evaluate withdrawal, adult male Sprague-Dawley rats were exposed to chronic nicotine via subcutaneous minipumps (3.15 mg/kg/day nicotine free-base). After 7 days, rats were administered either AT-1001 (3 mg/kg, s.c.), mecamylamine (1mg/kg, s.c.), or vehicle, and nicotine abstinence signs were scored for 30 minutes. A second group was pretreated with AT-1001 or vehicle prior to mecamylamine-precipitated withdrawal, and nicotine abstinence signs were scored for 30 minutes. To examine stress+cue induced reinstatement, rats were trained to lever press for food and then allowed to self-administer nicotine (30 μg/kg/inj) at FR5. After reaching stable baseline, responding was extinguished until extinction criteria were met. Rats were then primed to reinstate nicotine-seeking behavior with yohimbine (2.5 mg/kg, i.p), a pharmacological stressor, and cues. Prior to reinstatement, one group of rats was pretreated with 0, 0.75, 1.5 or 3 mg/kg (s.c.) AT-1001 in a randomized within-subjects design. A second group was pretreated with 0, 0.5, 1, or 2 mg/kg (s.c.) mecamylamine. AT-1001 dose-dependently attenuated reinstatement of nicotine self-administration, similar to mecamylamine. However, mecamylamine produced significantly more severe withdrawal symptoms compared to AT-1001. AT-1001 pretreatment had no significant effect on mecamylamine-precipitated withdrawal. Our results suggest that AT-1001 specifically attenuates nicotine-seeking behavior, does not exacerbate nicotine withdrawal, and may be a promising pharmacotherapy for tobacco dependence.

Title: Upregulation of nicotinic acetylcholine receptors containing the alpha4 subunit in VTA GABAergic neurons underlies reward sensitization

Authors: *J. NGOLAB, L. LIU, P. D. GARDNER, A. R. TAPPER
Brudnick Neuropsychiatric Res. Institute, Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Nicotine is the psychoactive component in tobacco and an agonist for nicotinic acetylcholine receptors (nAChR), ligand-gated cation channels normally activated by the endogenous neurotransmitter, acetylcholine. Unlike other drugs of abuse, chronic nicotine use leads to increased expression ("upregulation") of nAChRs in the mesocorticolimbic reward pathway in addition to other brain regions. While upregulation of nAChRs is a hallmark of chronic nicotine exposure, and was first identified over 20 years ago, the behavioral consequence of this phenomenon and how it relates to nicotine dependence is unknown. Furthermore, functional upregulation of nAChRs containing the [[Unsupported Character - Symbol Font ]]4 subunit ([[Unsupported Character - Symbol Font ]]4* nAChRs) in the mesolimbic pathway has been shown to be restricted to GABAergic neurons within the VTA. However, how functional upregulation of [[Unsupported Character - Symbol Font ]]4* nAChRs affects the micro-circuitry of the VTA and nicotine dependence-related behaviors is unknown. To address this question, we engineered a Cre recombinase-dependent gene expression system to selectively express [[Unsupported Character - Symbol Font ]]4 nAChR subunits harboring a "gain of function" mutation (a leucine mutated to a serine residue at the 9' position: L9'S), that renders nAChR containing the subunit hypersensitive to nicotine, in VTA GABAergic neurons of adult male mice, essentially mimicking functional upregulation. In mice expressing L9'S [[Unsupported Character - Symbol Font ]]4 nAChR subunits in VTA GABAergic neurons ($Gad2^{VTA}$:L9'S mice), an acute subcutaneous injection of 0.09 mg/kg nicotine was sufficient to activate VTA GABAergic neurons; whereas control mice required a much higher nicotine dose, 0.5 mg/kg, to activate GABAergic neurons. To test the hypothesis that functional upregulation of [[Unsupported Character - Symbol Font ]]4* nAChRs

in VTA GABAergic neurons modulated nicotine reward sensitivity, we measured nicotine reward in $Gad2^{VTA}$:L9'S and control animals using the conditioned place preference assay. Interestingly, the sub-reward threshold dose of 0.09 mg/kg nicotine conditioned a significant place preference in $Gad2^{VTA}$: L9'S mice but not in control animals. Together, these data indicate that upregulation of [[Unsupported Character - Symbol Font ]]4* nAChRs in VTA GABAergic neurons mediate reward sensitization, a neuroadaptation that could facilitate relapse in abstinent smokers.

Title: Dose-dependent effects of domoic acid on expression of alpha 7 nicotinic receptors in organotypic hippocampal slice cultures

Authors: *J. R. HAWKINS, D. S. MACDONALD, R. A. TASKER
Univ. of Prince Edward Island, Charlottetown, PE, Canada

Abstract: Recently the alpha7 nicotinic receptor (a7nAChR) has been shown to be involved in various forms of cognition and is a promising target for cognition enhancing drugs. At high concentrations, the marine toxin, domoic acid (DOM), is known to produce hippocampal cellular toxicity primarily by an AMPA-kainate receptor-dependent mechanism (Verdoorn et al. 2004; Tasker et al. 2006). However, at sub-toxic concentrations DOM induces both acute (Tasker et al. 2005) and persistent (Gill et al. 2012) deficits in cognition when administered to neonatal rats. To determine if DOM-induced deficits in cognition might be attributable, at least in part, to an effect on a7nAChRs we investigated the dose-dependent effects of DOM on cell-specific viability (propridium iodide exclusion) and a7nAChR expression (Western blot) *in vitro* using organotypic hippocampal slice cultures (OHSCs). Cultures were prepared from P5/6 day old SD rats and grown for 14 days on 0.4 um porous membrane inserts at 37°C. Viable slices were

exposed for 24 hours to varying concentrations of DOM and re-evaluated by propridium iodide exclusion to construct toxicity-response curves. The effects of sub-toxic concentrations of DOM on the expression of a7nAChRs was measured using Western blot analysis of pooled slice cultures normalized against total protein concentration. Preliminary results indicate that DOM reduces a7nAChR expression in a dose-dependent manner in OHSCs.

Abstract: Flavonoids are a group of small molecules derived from plant-based compounds. They have received considerable attention for their therapeutic use against cancer, heart disease and other pathological conditions. Apigenin (4,5,7-trihydroxyflavone) is one of the most widely studied dietery flavonoid found in different plants. Extracts of apigenin have been shown to have sedative, anxiolytic, and antidepressant actions. However, molecular and cellular mechanisms of apigenin actions in the central nervous system currently remain unknown. In the present study, effects of apigenin on the function of the cloned α7 subunit of human nAChR expressed in Xenopus oocytes were investigated using the two-electrode voltage-clamp technique. Apigenin, in the concentrations of 10 and 30 μM potentiated of nAChR-mediated currents (induced by 100 μM ACh) to 40 % and 60 % of controls, respectively. Potentiation by apigenin was reversible and concentration dependent. In conclusion, the results indicate that apigenin potentiates the function of human α7-nAChRs.

Title: Inhibition of nicotinic acetylcholine receptors by philanthotoxins is strongly influenced by subunit composition

Authors: ***H. KACHEL**[1], H. FRANZYK[2], K. STRØMGAARD[2], D. TIKHONOV[3], I. MELLOR[1]
[1]Univ. of Nottingham, NOTTINGHAM, United Kingdom; [2]Dept. of Mol. Drug Res., Univ. of Copenhagen, Copenhagen, Denmark; [3]Sechenov Inst. of Evolutionary Physiol. and Biochem., Russian Acad. of Sci., St. Petersburg, Russian Federation

Abstract: Abstract Philanthotoxin-433 (PhTX-433) is active component of the Egyptian solitary digger wasp, *Philanthus triangulum*, venom which non-selectively inhibits several excitatory ion channels. To improve selectivity two synthetic analogues, Philanthotoxin-343 (PhTX-343) and Philanthotoxin-12 (PhTX-12), were developed. Previous work by Brier et al. (2003) showed a 22-fold better selectivity for PhTX-12 on embryonic muscle-type nicotinic acetylcholine receptors (M-nAChR) naturally expressed in the TE671 cell line in comparison to PhTX-343. In this study, we investigated the pharmacological action of both analogues on mammalian hetero- and homooligomeric neuronal nicotinic acetylcholine receptor (N-nAChR) subunit combinations expressed in Xenopus oocytes. Whole-cell currents in response to application of acetylcholine alone or co-applied with PhTX-analogue were studied electrophysiologically using two-electrode voltage-clamp at three different membrane holding potentials (V_H = -60 mV, -80 mV and -100 mV). Concentration-inhibition curves were constructed and IC_{50} values estimated for each holding potential. The IC_{50} values for PhTX-343 inhibition of α3β4, α3β2, α4β2, α4β4 and α7 peak currents at -100 mV were 0.077 μM (n=9), 3.20 μM (n=8), 0.170 μM (n=7), 0.28 μM (n=6) and 8.7 μM (n =9) respectively; for PhTX-12 they were 2.03 μM (n=8), 36.0 μM (n=10), 0.430 μM (n=7), 2.7 μM (n=8) and 12.1 μM (n =10) respectively; i.e. in contrast to M-nAChR, PhTX-343 was more potent than PhTX-12 in all cases. The variation in potency is most likely due to a single amino acid change in the β2/4 subunit pore lining region. For inhibition of heteromeric N-

nAChRs, the potency of PhTX-343 was strongly augmented by holding the cell at more negative V_H while this was not the case for PhTX-12 where only weak voltage-dependence was observed. The inhibition of homomeric α7 receptors by both toxins was voltage-independent. Therefore, we conclude that PhTX-343 works as a potent open channel blocker of the mammalian heteromeric N-nAChR and has binding site deep in the channel while the PhTX-12 site is near to the outside of channel. In contrast, inhibition of homomeric α7 receptors may be through interaction at an alternative site outside the channel pore. Brier, T.J., Mellor, I.R., Tikhonov, D.B., Neagoe, I., Shao, Z., Brierley, M.J., Stromgaard, K., Jaroszewski, J.W., Krogsgaard-Larsen, P., Usherwood, P.N., 2003. Title: Effects of Phantasmidine on neuronal nicotinic ACh and serotonin 5-HT3 receptors

Authors: *A. A. PANDYA[1], J. YAKEL[2]
[1]Univ. of Alaska Fairbanks, KOTZEBUE, AK; [2]Lab. of Neurobio., Natl. Inst. of Envrn. Hlth. Sciences, Natl. Inst. of Hlth., Research Triangle Park, NC

Abstract: Phantasmidine is a condensed tetracyclic alkaloid obtained from the Ecuadorian poison frog Epipedobates anthonyi. We tested the functional effects of synthetic phantasmidine on various subtypes of neuronal nicotinic ACh receptors (nAChRs; α7, α4β2 and α3β2) and the serotonin 5-HT3 receptors (5-HT3ARs) that had been expressed in Xenopus oocytes using two-electrode voltage-clamp techniques. We found that phantasmidine is a full agonist for the α7 receptors (with EC50 values of 9.89 + 0.90 μM), and a partial agonist for the α3β2 and α4β2 nAChRs (with an EC50 value of 19.0 + 13 μM and 3.06 + 0.19 nM, respectively). The relative peak amplitudes of responses induced by phantasmidine (compared to 1 mM ACh) is 1.08 + 0.04, 0.32 + 0.04, and 0.25 + 0.08 for α7, α4β2 and α3β2 nAChRs, respectively. For the 5-HT3ARs, phantasmidine has a lower potency than that seen with any of the nAChRs (an EC50

value of 29.1 + 1.7 μM with a relative peak amplitude of 0.79 + 0.05 compared to 10 μM mCPBG). The phantasmidine-induced currents for the α7 and α4β2 subtype of nAChRs, as well as the 5-HT3ARs, were completely blocked by methyllycaconitine (30 nM), dihydro-β-erythroidine (10 nM), and tropisetron (30 nM), respectively. This shows that the functional effects of phantasmidine are due to its binding to the agonist site on these receptors since competitive antagonists are able to inhibit it's actions. In summary, phantasmidine is an agonist for α7, α4β2 and α3β2 nAChRs and the 5-HT3ARs with the potential for clinical applications.

Title: Cytoskeletal motility and structural growth in developing neural cells is driven by α7-nicotinic acetylcholine receptor association with G proteins

Authors: J. R. KING[1], J. C. NORDMAN[1], S. P. BRIDGES[1], S. BLACK[1], D. P. VELTRI[1], M. LIN[1], A. SHEHU[1], *N. KABBANI[2]
[1]George Mason Univ., Fairfax, VA; [2]Mol. Neurosci, Krasnow Inst., FAIRFAX, VA

Abstract: Several heterotrimeric G proteins are enriched at sites of cellular growth and can regulate the cytoskeleton during development and structural plasticity. We have recently shown a role for the α7 nicotinic acetylcholine receptor (α7 nAChR) in the regulation of axon growth in hippocampal neurons via the binding of a G protein signaling complex. Here we have generated a series of α7 nAChR mutants and characterized their ability to bind and signal via G proteins in developing neural cells. Immunoprecipitation studies suggest that a series of basic amino acid residues within the M3-M4 loop of the nAChR enable G protein coupling. Interactions between α7 nAChRs and G proteins were examined in the adult and developing rodent brain, and within synaptic and non-synaptic compartments. Cellular imaging studies reveal that activation of the α7 nAChR/G protein pathway directs cytoskeletal motility in neurites and growth cones.

Interaction with G proteins thus appears to contribute to changes in cholinergic modulation of axon growth and branching during brain development. Based on these findings we propose the existence of a G protein binding site within nAChRs. This domain appears to have evolved to augment the signaling and regulatory properties of this ligand gated ion channel in cells.

Title: Varenicline attenuates ventromedial prefrontal cortex activity, modulates reward circuitry for alcohol in heavy drinkers

Authors: *J. L. GOWIN, V. VATSALYA, R. MOMENAN, V. A. RAMCHANDANI
LCTS, Natl. Inst. On Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: Nearly 4% of deaths worldwide are attributed to alcohol, making it a major public health burden. Recent clinical trials have shown that varenicline, a α4β2 nicotinic partial agonist used for smoking cessation, can reduce heavy drinking among alcoholics. It remains unclear, however, what neural and cognitive mechanisms are affected by varenicline to reduce drinking. Previous studies have shown that the striatum and ventromedial prefrontal cortex (vmPFC) contribute to evaluation of outcomes. Striatal activation may indicate the value of a reward, and the vmPFC may integrate value and cost. Evaluation may involve a circuit beginning in the ventral striatum, then moving to the dorsal striatum before signaling the vmPFC. No study has examined how varenicline may affect this reward circuit in heavy drinkers. Here, we studied heavy drinkers given either varenicline (2mg/day) or placebo for 2 weeks prior to a functional MRI scan. During the scan, participants completed an incentive task where they had the opportunity to earn food, alcohol or neutral (no gain or loss) rewards. They saw cues for the rewards and then had to press a button during a brief response window. A button press within the response window resulted in earning points for the reward, while a response outside the window resulted in a missed reward. 30 heavy drinkers (5 female) were scanned. The placebo group

(N=13) showed increased vmPFC activation when missing a drink reward relative to a neutral or food reward, while the varenicline group (N=17) showed roughly equivalent activation when missing drink, food and neutral points. Direct contrast of treatment groups indicated that the varenicline group showed significantly decreased vmPFC activation relative to the placebo group when missing a drink reward. Functional connectivity analysis across the entire time series focusing on a vmPFC seed indicated significant connectivity with the dorsal striatum in the placebo group, with no significant effects in the varenicline group. Strength of connectivity between vmPFC and striatum showed a trend toward a positive relationship with vmPFC activation when missing drink points, where individuals with higher connectivity had higher activation. These results indicate that varenicline may decrease the value of alcohol rewards in the vmPFC, and this decrease may be related to disrupted functional circuitry with the striatum in heavy drinkers.

Title: Synapsin Ia, a synaptic vesicle protein, regulates the dynamics of dense-core vesicle exocytosis

Authors: *H.-J. YANG, Y.-C. CHANG, C.-T. WANG
Inst. of Mol. and Cell. Biol., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Neurotransmitters are packaged into two distinct classes of vesicles, synaptic vesicles (SVs) and dense-core vesicles (DCVs). Although the release from both vesicle classes shares a common mechanism of Ca2+-dependent exocytosis, a particular phosphoprotein, synapsin (Syn), localizes to SVs exclusively. The Syn protein family consists of ten homologous proteins, of which Syn Ia is the best studied. Upon phosphorylation by various protein kinases, Syn Ia can recruit SVs to plasma membrane, thereby increasing the dynamics of SV exocytosis. However, it remains unknown whether SV recruitment to plasma membrane may also facilitate the dynamics

of DCV exocytosis. Our preliminary results showed that in the rat hypothalamic-neurohypophysial system (HNS), Syn Ia increased oxytocin release by phosphorylation at the serine 62 site (Ser-62), suggesting that that Syn Ia phosphorylation may facilitate the release from DCVs. To further determine the Syn Ia's regulation of DCV exocytosis at the single-vesicle level, we directly measured norepinephrine release from DCVs by performing single-vesicle amperometry in PC12 cells. The foot signal preceding amperometric spikes (prespike foot, PSF) has been shown to represent the fusion pore dynamics. Secretory events were triggered by direct application of high extracellular KCl onto the cells. We found that Syn Ia significantly increased the secretion rate by phosphorylation at multiple serine sites (Ser-9, Ser-566, and Ser-603). These results suggested that Syn Ia may facilitate the secretion rate of DCVs by CaMK phosphorylation. In contrast, Syn Ia significantly increased the PSF lifetime by phosphorylation at Ser-62, suggesting that Syn Ia may stabilize fusion pores by MAPK phosphorylation. Immunostainings confirmed that Syn Ia did not localize to the DCVs in PC12 cells. Thus, our results suggest that the SV-specific protein Syn Ia may play an important role in regulating the dynamics of DCV exocytosis.

Title: Anesthetic effects on the calcium sensitivity of synaptic vesicle exocytosis in hippocampal neurons

Authors: *J. P. BAUMGART[1,3], Z. ZHOU[1], M. HARA[1], M. B. HOPPA[2,4], T. A. RYAN[2], H. C. HEMMINGS[1]
[1]Anesthesiol., [2]Biochem., Cornell Univ. Weill Med. Col., New York, NY; [3]Natl. Inst. of Hlth., Bethesda, MD; [4]Biol., Dartmouth Col., Hanover, NH

Abstract: The molecular and cellular mechanisms of anesthetic-induced amnesia, unconsciousness and immobilization are poorly understood. Identification of presynaptic mechanisms is critical to understanding the effects of anesthetics on synaptic transmission. Here we used quantitative imaging methods to show that the prototypical volatile anesthetic isoflurane inhibits synaptic vesicle exocytosis in cultured rat hippocampal neurons proportional to reductions in presynaptic [Ca^{2+}]. This finding indicates that isoflurane reduces [Ca^{2+}]$_i$ without altering the Ca^{2+} sensitivity of synaptic vesicle exocytosis. Greater inhibition by isoflurane of exocytosis in glutamatergic compared to GABAergic neurons can be explained by larger reduction in intracellular [Ca^{2+}], which correlated with inhibition of exocytosis. These data suggest that volatile anesthetic inhibition of neurotransmitter release from small synaptic vesicles involves primarily targets that reduce Ca^{2+} entry without significant direct effects on the synaptic vesicle fusion machinery.

Title: Nanodomain coupling between Ca2+ channels and release sensors explains the apparent Ca2+ independence of transmitter release time course at a GABAergic synapse

Authors: I. ARAI, *P. JONAS
IST Austria, Klosterneuburg, Austria

Abstract: A highly puzzling property of synaptic transmission is that the time course of transmitter release is independent of extracellular Ca^{2+} concentration ([Ca^{2+}]$_o$), whereas the rate of release is highly [Ca^{2+}]$_o$-dependent. However, it is unclear whether this apparent discrepancy, originally observed at the neuromuscular junction, also applies to central synapses. Furthermore, the underlying mechanistic explanation remains elusive. To address these questions, we measured the time course of release at GABAergic synapses between basket cells (BCs) and Purkinje cells (PCs), using paired whole-cell recordings from synaptically connected neurons in

mouse cerebellar slices at ~22°C. The release time course was obtained by deconvolution. When $[Ca^{2+}]_o$ was changed from 2 mM to either 1 mM or 4 mM, peak transmitter release rate was markedly altered. In contrast, the release time course was only minimally affected (half-duration at 2 mM: 0.45 ± 0.02 ms; 1 mM: 0.39 ± 0.03 ms; 4 mM: 0.46 ± 0.02 ms; mean ± SEM; 4–9 pairs). Thus, the time course of release at BC-PC synapses is largely $[Ca^{2+}]_o$-independent. We next examined the possible reasons for this apparent $[Ca^{2+}]_o$ independence. Recent results suggested that cerebellar BC-PC synapses show tight coupling between Ca^{2+} channels and release sensors (Christie et al., Nat. Neurosci. 14:62–68, 2011), raising the possibility that tight coupling may underlie $[Ca^{2+}]_o$ independence. To test this hypothesis, we probed the coupling distance by loading Ca^{2+} chelators with different Ca^{2+}-binding rates into the presynaptic neurons. BAPTA, a fast Ca^{2+} chelator, suppressed evoked IPSCs at submillimolar concentrations (IC_{50}: 0.6 mM, 14 pairs). In contrast, EGTA, a slow Ca^{2+} chelator, was much less effective (IC_{50}: 16.0 mM, 11 pairs). Describing the experimental data with a simple model of buffered diffusion revealed a coupling distance of ~20 nm. To further test whether tight coupling was sufficient to explain the $[Ca^{2+}]_o$ independence of release time course, we simulated release at different $[Ca^{2+}]_o$ using a realistic coupling model and a previously established release sensor model (Lou et al., Nature 435:497–501, 2005). Interestingly, models with tight coupling produced smaller Ca^{2+} dependence of release time course than those with loose coupling. Thus, tight coupling between Ca^{2+} channels and release sensors may explain the apparent Ca^{2+} independence of release time course. Constancy of time course of release might be particularly relevant at cerebellar GABAergic BC-PC synapses, helping to provide fast and precise feedforward inhibition during temporally fluctuating extracellular Ca^{2+} concentrations.

Title: Syntaxin1B deficiency affects Ca^{2+} sensitivity of vesicle fusogenicity and short term plasticity at the Calyx of Held

Authors: Q. GUO, J. GUO, X. WANG, *J. SUN
Chinese Acad. of Sci., Beijing, China

Abstract: Syntaxin1 (STX1), including Syntaxin1A (STX1A) and Syntaxin1B (STX1B), is the t-SNARE protein at presynaptic membrane and considered to be a key component in vesicle release. To determine whether /how STX1B functions in synaptic transmission as well as short term plasticity, a STX1B hypomorph mouse line with~5% expression of STX1B was analyzed at the calyx of Held synatpse. We found that mostly removal of STX1B significantly reduced basal synaptic transmission and enhanced synaptic depression; the deficiency of STX1B also significantly decreased readily releasable pool(RRP) size and largely slowed the vesicle priming process while Ca^{2+} channel activity was kept unchanged. Moreover, this STX1B hypomorph mutation was found to tighten, instead of weaken, the Ca^{2+} channel-vesicle spatial coupling. By flash photolysis uncaging Ca^{2+} and postsynaptic EPSC recording, we further studied the dependence of vesicle release and found that STX1B deficiency caused significant reduction of apparent Ca^{2+} sensitivity of vesicle release. Our biophysical modelling justified that reduction in the apparent Ca^{2+}-affinity of fusogenicity be due to the decrease in the number of assembled SNARE complexes per vesicle during fusion. In summary, our study shows that STX1B protein is a critical determinant in synaptic transmission and plasticity; in spite of Ca^{2+} sensor proteins, the number of assembled SNARE-complexes per vesicle plays a pivotal role in determining the intrinsic Ca^{2+} sensitivity and thus to regulate vesicle release probability as well as short term plasticity.

Title: The N-terminal peptide of syntaxin-1 differentially contributes to neurosecretion depending on the conformational state of the protein

Authors: *S. PARK[1,2], S.-Y. KANG[1], T.-C. CHOU[1], L. PARSAUD[1,2], S. SUGITA[1,2]
[1]Krembil Discovery Tower, Toronto, ON, Canada; [2]Univ. of Toronto, Toronto, ON, Canada

Abstract: As neurons communicate via neurotransmitters, the release of these chemicals is a key process. During the process, fusion of chemical-storing vesicles with the plasma membrane is

believed to be executed by a complex of three SNARE (the soluble N-ethylmaleimide sensitive factor attachment protein receptor) proteins: SNAP-25, VAMP2, and syntaxin-1. Of the SNAREs, syntaxin-1 is regulated through two conformations: open and closed. When the protein adopts the open conformation, it can assemble into a complex with the other SNAREs. In the closed conformation, the protein folds in half and binds with another protein: Munc18-1. As a result of this property, the latter conformation inhibits the SNARE assembly. For the past few years, several studies have demonstrated that the association of syntaxin-1 and Munc18-1 is not limited to forming the closed conformation; the N-terminal peptide of syntaxin-1 is essential for Munc18-1 to interact with the SNARE complex and accelerate SNARE-mediated fusion. However, we hypothesized that the N-terminal peptide is critical for securing the binary interaction of syntaxin-1 and Munc18-1. To test this hypothesis, we utilized both *in vitro* and *in vivo* systems. Introduction of mutations into the N-peptide of syntaxin-1 did not affect secretion from PC12 cells, although the localization of the mutants was perturbed to some degree when visualized using confocal microscopy. By contrast, introduction of the same mutations into a syntaxin-1A mutant form favoring open conformation severely impaired secretion and localization. Since different results were yielded depending on the conformational state of syntaxin-1, we investigated by employing a GST-pulldown technique to determine whether N-terminal mutations affect the strength of the binary interaction between syntaxin-1 and Munc18-1. We found that an N-terminal mutation alone slightly weakened the binary interaction, but the same mutation additionally introduced in the open mutant strongly disrupted it. Furthermore, we tested the hypothesis using C.elegans. Unc-64 (syntaxin-1 homolog) null mutant worms that exhibit a lethal phenotype were largely rescued with mammalian syntaxin-1A wild-type, the open mutant, or some of the N-terminal mutant forms tested in the *in vitro* system. However, the double mutant that exhibited strongly disrupted binding to Munc18-1 in the GST-pulldown experiment poorly rescued the lethal phenotype. Based on the results obtained from both model systems, we conclude that the N-peptide is not essential in exocytosis despite its role in securing the binary interaction between syntaxin-1 and Munc18-1.

Title: Synaptophysin regulates fusion pores and the mode of Ca2+-triggered exocytosis of dense-core vesicles in chromaffin cells

Authors: *C.-W. CHANG[1], M. B. JACKSON[2]
[1]Physioloy Grad. Training Program, [2]Neurosci. Dept., Univ. of Wisconsin-Madison, Madison, WI

Abstract: Synaptophysin (syp) is one of the most abundant proteins in synaptic vesicles (SVs), with ~32 copies per vesicle and accounting for ~10% of total SV protein mass. Syp has four transmembrane segments and is homologous in structure to two other proteins, synaptogyrin and synaptoporin. Syp may have a role in SV endocytosis and the retrieval of the v-SNARE protein, synaptobrevin 2. Although syp is considered SV specific and is widely used as a synaptic terminal marker, some evidence indicates its presence on large dense core vesicles (LDCVs), but at a lower density than SVs. To examine the role of syp in LDCV exocytosis, we used amperometry to record the release of catecholamine in chromaffin cells. In a comparison between cells from wild-type (WT) and syp knockout (KO) mice, the secretion rate was reduced by 30% in syp KO cells but most of the characteristics of single-LDCV full fusion events remained unchanged. The quantal size, rise time, decay time, and spike half-width of full fusion events of syp KO cells were the same as in WT. However, pre-spike feet (PSF) had shorter durations and the fraction of kiss-and-run events was higher in syp KO cells. Thus, syp may control fusion pore stability and influence the choice of LDCVs between full fusion and kiss-and-run. Transfection of syp KO cells with syp-mCherry fusion protein rescued the reduction of PSF duration and reversed the increase in kiss-and-run, but did not rescue the low secretion rate. Furthermore, syp-mCherry overexpression increased the quantal size and half-width of full fusion events. In both WT cells transfected with syp-mCherry and syp KO cells transfected with syp-mCherry we saw similar secretion, with no significant differences between PSF duration, fraction of kiss-and-run, quantal size, and half-width of full fusion events. Thus, while fusion pore stability and fate are sensitive to the absence of syp, overexpression has a greater impact on exocytosis after fusion pores start to dilate, influencing later steps of exocytosis that control quantal size and spike half-width. This implies roles for syp both on nascent fusion pores early in exocytosis and later in exocytosis during fusion pore dilation. The relatively low copy numbers of syp on LDCVs may account for the different results between KO and overexpression, and some of these results may reflect some replacement of function by synaptogyrin and synaptoporin. In summary, these results suggest that syp functions in LDCV exocytosis in chromaffin cells, controlling fusion pore stability, fate, and dilation.

Title: Synaptotagmin III modulates the kinetics of regulated exocytosis by Ca2+ binding to the C2AB domains

Authors: *Y.-T. HUANG, Y.-T. HSIAO, S.-Y. KAO, Y.-C. CHEN, C.-T. WANG
Inst. of Mol. and Cell. Biol., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Synaptotagmin (Syt) protein family consists of at least seventeen isoforms, and most of them serve as the Ca2+ sensor during regulated exocytosis. During the critical period of visual circuit development (postnatal day P6 in rats), we found that Syt III, but not Syt I, is transiently expressed in the retinal output neurons (retinal ganglion cells) and optic nerves. Previous studies showed that Syt I can modulate the kinetics of Ca2+-regulated exocytosis. However, it remains unclear whether Syt III may modulate the kinetics of Ca2+-regulated exocytosis. In this study, we investigated whether Syt III modulates regulated exocytosis and if this modulation involves Ca2+ binding to its C2AB domains. By combining molecular perturbation and single-event amperometry, the real-time exocytosis of single vesicles was detected in PC12 cells overexpressing control vector, wild-type Syt III (Syt III), or the Syt III mutant with the abolished Ca2+-binding sites at the C2AB domains (D386,520N, designated Syt III-C2AB*). We found that the secretion rate was reduced to a half in the cells overexpressing Syt III-C2AB* compared to control or Syt III. Therefore, through Ca2+ binding to the C2AB domains, Syt III may have a great capacity to modulate the kinetics of regulated exocytosis.

Title: Optogenetic-mediated glutamate release from the rat amygdala

Authors: *G. LONART, L. L. WELLMAN, M. MACHIDA, M. F. FITZPATRICK, L. D. SANFORD
Eastern Virginia Med. Sch., Norfolk, VA

Abstract: Optogenetics allows detecting and controlling intact neural pathways with high spatio-temporal resolution, both during and after the performance of complex behaviors (Deisseroth, 2014). Recording of electrical activity is commonly used to monitor the influence of optogenetic manipulations at the cellular level. A complementary approach, measuring neurochemical release, may be especially useful when the identity of the neurotransmitter is unknown or when a rapid or post-experiment assay is desired. To explore the compatibility of optogenetic and neurochemical approaches, we infected the basolateral nucleus of the amygdala (BLA) of rats with AAV-CaMKIIa-eNpHR3.0-eYFP (eNpHR3.0) and AAV5-CaMKIIa-hChR2(H134R)-eYFP (hChR2) vectors (University of North Carolina Vector Core, Chapel Hill, NC), where expression is under the control of a calcium-calmodulin dependent kinase IIa (CaMKIIa) promoter, allowing selective targeting of a subpopulation of glutamatergic neurons. Afterwards, the transduced cells express opsins that mediate either chloride (eNpHR3.0) or cation (hChR2) influx upon activation by light, allowing hyperpolarization (inhibition) or depolarization (activation), respectively. The vectors are fused to yellow fluorescence protein to enable localization in target neurons. Channel activation was produced using blue (473 nm) or green (532 nm) light from fiber coupled lasers (Laser Century) with ~10 mW output at the fiber tip to activate cation (hChR2) or chloride (eNpHR3.0) channels, respectively. We assessed light-evoked glutamate release *in vitro* using a slice preparation labeled with 14C-glutamate. As shown in Fig. 1, stimulation with blue light produced a release of glutamate in BLA that was blunted by concurrent stimulation with green light.These findings demonstrate the compatibility of optogenetic and neurochemical methods, which may be a valuable approach for identifying neurotransmitters of neuronal circuits.*Reference: Deisseroth K (2014) Circuit dynamics of adaptive and maladaptive behaviour. Abstract: We recently demonstrated, in *Drosophila* melanogaster, that the substitution of R in position 206 of SNAP25, or D in position 253 of Syx, with residues carrying an opposite charge,

prevents the assembly of SNARE complexes in a rosette-like supercomplex arounf the point of contact between neurotrasmitter vesicle membrane and presynaptic membrane. The formation of SNARE supercomplex plays a fundamental role in regulating neurotransmitter vesicle fusion and we have demonstrated that in our mutants evoked and spontaneous neurotrasmitter realease is impaired even if not blocked. Schizophrenia (SZ) was described since the beginning as a "sejuncto psichose", i.e. a mental disease due to a "disconnection" between different brain regions. Until now, few and contradictory signs of neuronal damage were found in patients soffering from this disease, leading to the hypothesis that the core of SZ physiopathological changes coulsd reside in a dysfunction of synapse. Among the various synaptic proteins which can be involved in the above mentioned changes, they were also considered the SNAREs. Some genetic data seem to indicate that SNAP25 levels are altered in SZ patients. Considering these hypotheses, we carried on various behavioral analyses using our mutant lines, which showed a variable and differential phenotype in each type of analysed behaviors . These data seem to indicate that the reduced synaptic strenght, observed with electrophysiological techniques, is able to induce a variety of functional impairments at the level of the complex neuronal circuits regulating different behavioral responses. These results could give support to the idea that also minor changes in synaptic function, if translated to complex neuronal circuits, could alter the flux of informations and their integration, leading to the changes in behavior and cognitive processes typical of some mental diseases lacking any clear pathological mark.

Title: Functional imaging of presynaptic calcium modulation mediated by metabotropic GABAB receptors

Authors: J. A. MARTINEZ-LOPEZ, F. MAVILLARD, L. GOMEZ-SANCHEZ, *R. FERNANDEZ-CHACON
IBIS, HUVR/CSIC/Universidad de Sevilla & CIBERNED, Sevilla, Spain

Abstract: Genetically-encoded fluorescent calcium sensors are very useful tools to image neural activity. Here we have used the calcium sensor GCaMP3 fused to the synaptic vesicle synaptophysin (syGCaMP3, Li et al., Front. Mol. Neurosci. 4:34, 2011) to study cytosolic calcium dynamics at the presynaptic terminals in mouse hippocampal cultures. Neurons were infected with a lentiviral vector to drive the expression of syGCaMP3 under the human synapsin promoter (Gascon et al., J Neurosci Methods 168: 104, 2008). Using epifluorescence microscopy, we have detected prominent calcium signals upon depolarization by electrical field stimulation (10 s, 20 Hz). Interestingly, attending to the duration of calcium transients we observed two clearly different types of responses: (1) long duration responses (LDR) characterized by a persistent elevation of calcium levels concomitant with the stimulus application and (2) short duration responses (SDR) characterized by a transient elevation of calcium levels of similar amplitude to LDR but with, however, shorter duration (4.94±1.35 s, mean±sem, 134 ROIs, 4 coverslips, 2 cultures; size of manually selected ROIs 1.66 squared microns). We have used correlation analysis based on the time course of responses to get spatial separation of two synaptic populations displaying either LDR or SDR (Junek et al., Biophys. J. 96:3801, 2009). The majority of synapses presented LDRs. In order to investigate the synaptic modulation underlying LDR and SDR we blocked GABAergic synaptic transmission. Incubation with the non-competitive GABAA-receptor antagonist picrotoxin did not change either the frequency of occurrence or the characteristics of LDR and SDR. In contrast, in the presence of the GABAB-receptor antagonist CGP-55845, the LDR dwell times were unchanged, while in the case of SDR, CGP-55845 extended the dwell time to coincide with the stimulus duration. Next, we combined calcium imaging with synaptic vesicle imaging. We used fluorescently-labeled antibodies against the luminal domain of the vesicular GABA transporter for the selective labeling of active GABAergic synapses (Martens et. al., J. Neurosci. 28:13125, 2008). We found that none of the synapses expressing syGCaMP3 were active GABAergic synapses, likely because the lentiviral vector preferentially labeled excitatory synapses (Nathason et al., Neuroscience 161:441, 2009). Our observations suggest that the SDR likely reflect presynaptic inhibition of glutamatergic synapses mediated by GABAB receptors. In addition, calcium imaging with syGCaMP3 opens new possibilities to study molecular mechanisms of presynaptic modulation mediated by metabotropic GABAB receptors.

Title: Molecular insights into the regulation of synaptic transmission by protein ubiquitination

Authors: *A. CAPUTO[1], K. M. MYERS[1], A. A. VASHISHT[2], J. A. WOHLSCHLEGEL[2], F. E. SCHWEIZER[1]
[1]Neurobio., [2]Biol. Chem., David Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: Protein ubiquitination regulates a variety of cellular events by targeting proteins to proteasomal degradation and/or by modifying the activity, localization and interactions of the modified protein. Neuronal and synaptic physiology depend on the Ubiquitin Proteasome System (UPS). Similarly, alterations of the UPS can be detected in aging, neurological and neurodegenerative diseases. However the role played by protein ubiquitination in synaptic and neuronal function has not been fully elucidated. We have previously reported that in primary neurons both acute pharmacological inhibition of the proteasome and of protein ubiquitination rapidly increase the frequency but not the amplitude of miniature events (minis). These findings lead us to propose that in addition to proteasomal degradation dynamic ubiquitination is critically involved in tuning synaptic activity (Rinetti and Schweizer, 2010). Here, we further investigate this hypothesis. Whole cell patch voltage clamp recording and imaging of vGlut1-pHluorin in primary cortical neurons reveal that acute pharmacological inhibition of protein ubiquitination or protein deubiquitination strongly increases mini frequency but concomitantly reduces action potential triggered responses. These data further suggest that dynamically ubiquitinated proteins orchestrate synaptic activity and indicate that protein ubiquitination can differentially impact on spontaneous and evoked neurotransmission. To uncover the molecular mechanisms underlying such complex regulation we have used a quantitative proteomic approach and identified synaptic proteins whose ubiquitination levels change upon acute UPS inhibition. The results of this study shed light on how protein ubiquitination modulates synaptic function and possibly point to new pathways and targets for the treatment of brain disorders.

Title: Compartmentalization of voltage-gated Ca2+ channels in the membrane of rat anterior pituitary cells

Authors: *I. NUSSINOVITCH, E. SOSIAL, A. TZOUR
Dept Anat. & Cell Biol., Hebrew Univ., Jerusalem, Israel

Abstract: Voltage-gated Ca^{2+} influx (VGCI) through Ca^{2+} channels plays a key role in the secretion of pituitary hormones. It is well established that L-type Ca^{2+} channels are involved in this VGCI. Whether non-L-type Ca^{2+} channels contribute to this VGCI is unknown. In this study we examined: 1. whether non-L-type Ca^{2+}channels exist in the membrane of pituitary cells. 2. Whether Ca^{2+} channels are segregated among different membrane compartments in the membrane of pituitary cells. Whole-cell recordings and the use of specific Ca^{2+} channel toxin blockers revealed a fraction of non-L-type VGCI that might reach ~46%. Western blotting identified immunblots for; α_{1C}, α_{1D}, α_{1A}, α_{1B} and α_{1E} subunits, corresponding to $Ca_v1.2$, $Ca_v1.3$, $Ca_v2.1$, $Ca_v2.2$, and $Ca_v2.3$ channels. Additionally, RT-PCR identified transcripts for α_{1C}, α_{1D}, α_{1A} and α_{1B} subunits. Transcripts for α_{1E} were non-specific and transcripts for α_{1S} were not detected at all. Taken together these results clearly demonstrate the co-existence of L-type ($Ca_v1.2$ and $Ca_v1.3$) and non L-type ($Ca_v2.1$, $Ca_v2.2$ and $Ca_v2.3$) Ca^{2+} channels in the membrane of anterior pituitary cells. Whether these channels are segregated among different membrane compartments was further investigated in flotation assays using Nycodenz gradients. Western blotting of gradient fractions revealed that $Ca_v1.2$ and $Ca_v1.3$ channels were distributed among light and heavy gradients fractions, i.e., among raft and non raft membrane domains. $Ca_v2.1$ channels were mostly localized in light gradient fractions, i.e., in raft membrane domains whereas $Ca_v2.2$ and $Ca_v2.3$ channels were mostly localized in heavy gradient fractions, i.e., in nonraft membrane domains. In summary, our results demonstrate multiple pathways for VGCI through L-type and non-L-type Ca^{2+} channels in the membrane of native anterior pituitary cells. Compartmentalization of these channels among raft and nonraft membrane domains may underlie their differential regulation by different signalling pathways, under different physiological conditions.

Title: Complexin regulates short-term plasticity of synchronous, asynchronous and delayed quantal release

Authors: ***R. A. JORQUERA**[1,2], E. A. QUIROZ[1]
[1]Neurosci., UCC, Bayamon, PR; [2]Physiol. and Biophysics, Univ. de Chile, Santiago, Chile

Abstract: The timing of neural communication depends on the number of contacts which synchronize the quantal release with the presynaptic action potential. In several chemical synapses the action potential evokes two major forms of release distinguishable by their decay kinetics, the fast synchronous and the slow asynchronous. A different slower form of release known as delayed is induced during high-frequency trains of action potentials decaying after the stimulation cease. Delayed release is thought to be a form of spontaneous release promoted by the resting calcium at the terminals and has been reported as asynchronous release as well. Nevertheless, how all those forms of release are regulated is still under investigation. Complexin binds the SNARE complex fusion machinery, clamps the spontaneous release and promotes the synchronous/asynchronous release. However, the regulatory function of Complexin in the evoked release during the high-frequency nerve-stimulation is not clear. Here we investigate the effects of Complexin in the quantal release kinetics during and after high-frequency nerve stimulation episodes at the *Drosophila* glutamatergic synapses. Complexin null and over-expressions were compared with controls. Quantal release rates were obtained by deconvolution of the evoked-currents recorded by two-electrode voltage-clamp. Our work reveals that the low frequency nerve-stimulation evoked two kinetics of release in Complexin null, control and overexpression, consistent with synchronous and asynchronous release. The synchronous and the asynchronous release at Complexin genotypes display the similar apparent kinetics but different magnitudes, suggesting that the synchronous and the asynchronous release act independently. High-frequency trains of nerve-stimulation evoked three kinetics of release: synchronous, asynchronous and the delayed release. Release rate analysis during the stimulation train indicates

that the synchronous and the asynchronous evoked release display different profile of short-term plasticity. In addition, synchronous and asynchronous short-term plasticity depend on the level of Complexin. The delayed release in Complexin null is earlier activated during the stimulation and decay slower after the stimulation ceases, in turn; Complexin overexpression suppresses this form of release. Our data during high-frequency bursts of nerve activity is consistent with the idea of three form of evoked release with different rates of replenishment and modulated by Complexin.

Abstract: Complexins (Cplx) are soluble synaptic proteins that exist in four isoforms in mammals. While Cplx1 and 2 are widely expressed in conventional synapses of the brain, the only isoform found at the rod bipolar cell (RBP) to amacrine AII cell ribbon synapse in the retina is Cplx3. All isoforms bind to and stabilize SNARE complexes, and their deletion leads to disturbances in vesicle release. While studies regarding the exact function of Cplx1/2 in conventional synapses have caused some controversy, the function of Cplx3 in mammalian ribbon synapses has not been described. To assess the role of Cplx3 in ribbon synapses, we performed paired recordings from RBP and AII cells in acute retinal slices from Cplx3 genetic deletion mutants. We found that loss of Cpx3 reduced synchronous release while spontaneous release appeared unchanged in Cplx3 KO cells. We simulated a more natural stimulus and determined a reduced release probability, however, multivesicular release is still present despite

the overall desynchronization of vesicle release. Furthermore, short-term depression was reduced at interpulse intervals shorter than 50ms. Taken together, our results suggest that Cplx3 plays an important role in coordinating vesicle release at the retinal bipolar cell - amacrine AII cell synapse.

Title: Spontaneous Ca2+ transients in the nerve terminal of neocortical excitatory neurons

Authors: *V. TRAN[1], C. STRICKER[1,2]
[1]Eccles Inst. of Neurosci., [2]Med. Sch., The Australian Natl. Univ., Canberra, Australia

Abstract: Within the last 15 years, it has become clear that a significant fraction of spontaneous transmitter release can arise from the release of Ca^{2+} from presynaptic stores. However, direct evidence for the role of intracellular Ca^{2+} stores in spontaneous synaptic transmission is still lacking. **Objective:** We hypothesise that, if Ca^{2+} release from stores can trigger transmitter release, then we might be able to detect it as spontaneous increases in cytoplasmic Ca^{2+}. Thus, we image cytoplasmic Ca^{2+} in presynaptic terminals of neocortical pyramidal neurons to investigate whether spontaneous Ca^{2+} transients can be observed. **Methods:** Ca^{2+} imaging is done at 35 ± 1 °C, using a Zeiss LSM 510 laser-scanning confocal microscope. Superficial layer II or layer V pyramidal neurons in the somatosensory cortex of male Wistar rats (P15–19) are filled through the patch pipette with Alexa 568 (50 μM) and Oregon Green 488 BAPTA-1 (OGB-1, 80 μM) for at least 30 min. Synaptic boutons, identified along 1^{st}–3^{rd} order axon collaterals using Alexa 568 fluorescence, are imaged and verified to be release sites based on the presence of a transient increase in OGB-1 fluorescence in response to an evoked AP. OGB-1 fluorescence across the diameter of the bouton is then monitored by line scanning at 10–20 Hz for ~15 min. **Results:** Spontaneous Ca^{2+} transients are observed at a low frequency in both layer II and layer V pyramidal neurons (2 ± 1 and 3 ± 1 mHz, n = 11 and 10 boutons, respectively; p = 0.8). Addition of tetrodotoxin (TTX, 1 μM) to block spontaneous firing does not affect their occurrence (5 ± 2 mHz for layer V pyramids, n = 13; p = 0.3). The average inter-event interval is

12 ± 2 s, with no difference between transients detected in control superfusate and those in TTX (p = 0.3), or between layer II and layer V neurons (p = 0.4). About ½ of all transients occur within 5 s of each other, with some summating to produce a large and extended rise in cytoplasmic Ca^{2+}. The amplitude and decay kinetics of the Ca^{2+} transients are similar between layer II and layer V pyramids ($\Delta F/F = 0.45 \pm 0.05$ *vs.* 0.40 ± 0.05, $\tau_{decay} = 560 \pm 90$ *vs.* 610 ± 100 ms; p = 0.5–0.7), and unaffected by TTX ($\Delta F/F = 0.47 \pm 0.05$, $\tau_{decay} = 680 \pm 70$ ms for layer V neurons; p = 0.4–0.6). However, the amplitude of these spontaneous transients is smaller and their decay time constant longer than those of AP-evoked Ca^{2+} transients ($\Delta F/F = 1.68 \pm 0.05$, $\tau_{decay} = 195 \pm 8$ ms for layer II neurons; $\Delta F/F = 1.19 \pm 0.05$, $\tau_{decay} = 173 \pm 7$ ms for layer V neurons; $p < 10^{-4}$). **Conclusion:** We have detected spontaneously occurring Ca^{2+} transients in nerve terminals of neocortical excitatory neurons. Although to be verified, these transients are likely a result of Ca^{2+} release from presynaptic Ca^{2+} stores.

Title: Differential transmitter and peptide release modulated by RNA editing of Ca2+-dependent activator protein for secretion (CAPS1)

Authors: *R. ULBRICHT[1], R. LAZARENKO[2], Q. ZHANG[2], R. B. EMESON[3]
[2]Dept. of Pharmacol., [3]Dept. of Pharmacol. and Vanderbilt Brain Inst., [1]Vanderbilt Univ. Sch. of Med., Nashville, TN

Abstract: Ca^{2+}-dependent activator protein for secretion (CAPS1) is required for regulated release from dense core vesicles (DCV) in pheochromocytoma PC-12 cells and promotes DCV exocytosis in chromaffin cells, pancreatic [[Unsupported Character - Symbol Font β]]-cells and neurons. Moreover, the loss of CAPS1 negatively affects synaptic transmission in the mammalian brain. Transcript encoding CAPS1 are subject to adenosine-to-inosine (A-to-I) RNA

editing in which a genomically-encoded adenosine is selectively deaminated to inosine at the level of the pre-messenger RNA. Since inosine base pairs with cytosine, it is recognized as guanosine by cellular machinery to alter a single amino acid within the functionally essential C-terminal domain of CAPS1 from a genomically-encoded glutamine (GAG) to glycine (GIG) codon. Our studies have focused upon defining the role of RNA editing in regulating CAPS1-mediated release. Analyses of RNA from several species showed that RNA editing-mediated changes to CAPS1 coding potential are conserved in vertebrate nervous systems. Quantitative analysis of CAPS1 editing from dissected mouse tissues revealed differential levels of editing ranging from 2% - 25% in peripheral endocrine tissues and selected brain regions. To determine the *cis*- and *trans*-active factors required for A-to-I conversion in CAPS1 transcripts, we used a variety of CAPS1 minigene constructs expressed in heterologous cell culture systems co-expressing one of two mammalian enzymes known to catalyze A-to-I editing (ADARs). Results from our analysis revealed that CAPS1 editing requires intramolecular base pairing of the region surrounding the editing site with a downstream intronic element. This double-stranded RNA duplex is sufficient for editing catalyzed by adenosine deaminase acting on RNA I (ADAR1). Importantly, our work to define the functional implications of CAPS1 editing in primary hippocampal neurons through FM dye loading and unloading as well as mini EPSC recordings suggests that neurotransmission is differentially affected by the expression of edited or non-edited CAPS1 both pre- and post-synaptically. This work provides the first detailed analysis of CAPS1 editing patterns across species and tissues, defines the molecular mechanism underlying this RNA processing event, and indicates its evolutionary significance. Most importantly, these studies provide critical insights into the role that RNA editing plays in the modulation of CAPS1-dependent exocytosis and how dysfunction of this process may contribute to disorders where alterations in hormone/neurotransmitter release have been implicated.

Title: Characterization of voltage-gated Ca2+ channels at individual presynaptic terminals of lamprey reticulospinal axons

Authors: *S. RAMACHANDRAN[1], S. ALFORD[2]
[1]Univ. Illinois, Chicago, CHICAGO, IL; [2]Biol. Sci., Univ. of Illinois at Chicago, Chicago, IL

Abstract: Stimulus-evoked Ca^{2+} influx through voltage-gated Ca^{2+} channels, localized to the presynaptic release face membrane, evokes neurotransmitter release. Differing spatio-temporal Ca^{2+} requirements for release have been proposed in different presynaptic terminals, either gated by Ca^{2+} influx through a large number of open channels or through very few channels, with varying structural relationships to the release machinery. Enumeration of Ca^{2+} channels at a terminal and more importantly the number that open in response to a stimulus is critical to determining the Ca^{2+} requirement for release. Recording Ca^{2+} currents at the release face membrane is thus crucial and recording access to the release face membrane at individual presynaptic terminals an absolute necessity. This has has not been impossible in most presynaptic terminals, including the lamprey reticulospinal synapses. Such recordings have only successfully been achieved in two calyceal presynaptic terminals, which while ideal for recording, represents a rather specialized structure. An acute dissociation of the lamprey spinal cord was developed to obtain viable isolated reticulospinal axons, with functional presynaptic terminals devoid of apposing postsynaptic projections. This presents a significant breakthrough at central synapses, permitting direct recording from the release face membrane of individual terminals. Utilizing the the resultant unrestricted access to the release face membrane afforded by this preparation, Ca^{2+} channels were characterized at individual terminals by immunohistochemistry and low- noise single channel electrophysiological recordings. Multiple subtypes of Ca^{2+} channels, N-, P/Q-, R- and L-type, were found to be present in these terminals. Single channel conductance (10 mM $[Ca^{2+}]_{external}$) was 2.97 ± 0.62 (N), 1.82 ± 0.36 (P/Q), 1.94 ± 0.41 (R), 2.4 ± 0.75 (L) pS. Single channel open probability at 0 mV was 0.26 ± 0.03 (N), 0.29 ± 0.03 (P/Q), 0.22 ± 0.02 (R), 0.24 ± 0.02 (L). Number of channels at a terminal was determined for each of the subtypes; N-type (4-10; mean 6), P/Q-type (3-9; mean 6), R-type (4-32; mean 12) and L-type (3-17; mean 10). A small number of Ca^{2+} channels (up to 68, mean 33) were found to be present at a terminal. Furthermore, a very small number (3-6, mean 4) of Ca^{2+} channels opened in response towith a stimulus, suggesting that Ca^{2+} influx through few open channels may gate release in these terminals. This result, which is the first determination of Ca^{2+} channel activity at single active zone central synapses, has profound implications for the reliability and function of evoked neurotransmitter release in the central nervous system.

Title: Paired presynaptic and postsynaptic patch clamp recordings to study the effects of action potential kinetics and afterpotentials on synaptic transmission

Authors: *K. G. PARADISO, S. G. CLARKE, A. KISNER
Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ

Abstract: We performed simultaneous presynaptic and postsynaptic recordings to determine how calcium entry produced by various action potential waveforms affects the timing and amplitude of the postsynaptic response in the calyx of Held synapse. Our results indicate that an action potential waveform with physiological kinetics of 0.3 msec depolarization and 0.7 msec repolarization is a close to optimal stimulus to minimize the delay and maximize the amplitude of the postsynaptic response. In separate experiments, we determined the relationship between the action potential repolarization phase and calcium channel response by using voltage jumps to +60 mV at various times during and after the repolarization. This indicated that calcium influx continues for a short duration after the action potential has returned to baseline. We therefore tested if afterpotentials that immediately follow a stimulus can affect calcium channel activity. We tested a box stimulus having an instant repolarization and compared that to an action potential-like waveform having a physiologically relevant 0.7 msec ramped repolarization. For both stimuli, the repolarization ended at baseline or ended in a -20 mV or +20 mV afterpotential. As expected, based on electrical driving force, instant current jumps show a difference in calcium channel response to both hyperpolarizing and depolarizing afterpotentials. Compared to traces without an afterpotential, a 20 mV afterhyperpolarization acts to slightly increase the peak calcium current and slightly shorten the decay phase of the calcium channel response, while a 20 mV depolarizing afterpotential does the opposite. Paired pre- and postsynaptic recordings with instant jumps demonstrated that depolarizing afterpotentials produced a larger postsynaptic response than hyperpolarizing afterpotentials. Consistent with this, the integral of the calcium channel response to an instant repolarization is larger in the presence of an afterdepolarization compared to the response in the presence of an afterhyperpolarization. In contrast, the ramped 0.7 msec repolarization did not appear to show a difference in calcium channel activity in the presence or absence of an afterpotential. In addition, paired recordings using a 0.7 msec ramp repolarization do not appear to show a statistically significant difference in the postsynaptic response when the presynaptic waveform ends in a hyperpolarized or depolarized afterpotential. This indicates that the physiological repolarization rate acts to prolong the response, and this acts

to reduce or prevent afterpotentials from affecting the calcium channel response and subsequent synaptic transmission.

Title: Reverse operation of NCX mediates presynaptic Ca2+ transient and spontaneous glutamate release during *in vitro* ischemia

Authors: *S. LEE, J. KIM
Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: An early cellular consequence of brain ischemia is an increase in vesicular glutamate release from presynaptic terminals in the central nervous system (CNS). However, the underlying mechanisms of increased vesicular glutamate release at presynaptic terminals during the early stage of ischemia are still controversial. Here we studied presynaptic responses and mechanisms of increased glutamate release during ischemia, using pre- and postsynaptic whole-cell recordings and presynaptic Ca2+ imaging at the calyx of Held synapse in rat brainstem slices. *In vitro* ischemia, induced by oxygen glucose deprivation and addition of 2 mM iodoacetic acid (IAA, an inhibitor of glycolysis), significantly increased the frequency of spontaneous excitatory postsynaptic currents (sEPSCs) without changing in the amplitude of sEPSCs, indicating that ischemia enhances vesicular glutamate release from the calyx of Held terminal. We found that the ischemia-induced vesicular glutamate release was dependent on an increase in presynaptic intracellular Ca2+ ([Ca2+]i), resulting from extracellular Ca2+ influx. During ischemia, increased Ca2+ influx to the presynaptic terminal is associated with the reverse operation of Na+/ Ca2+ exchanger (NCX) rather than presynaptic depolarization or voltage-activated Ca2+ currents. KB-R7943, an inhibitor of NCX, prevented the increase of presynaptic [Ca2+]i and vesicular glutamate release during *in vitro* ischemia. In addition, presynaptic Na+

accumulation using monensine (50 μM) facilitated reverse operation of NCX and consequently increased the frequency of sEPSCs that were inhibited by KB-R7943. These results suggest that the disruption of Na+ and Ca2+ dynamics causes a rise in presynaptic [Ca2+]i and an increase in vesicular glutamate release during the early phase of brain ischemia.

Title: Requirement of membrane cholesterol in vesicle endocytosis at a mammalian central synapse

Authors: H.-Y. YUE, *J. XU
Inst. of Mol. Med. and Genet., Georgia Regents Univ., Augusta, GA

Abstract: Membrane cholesterol has been indicated important in constitutive endocytosis and receptor-mediated clathrin-dependent endocytosis of non-neuronal cells, but its role in synaptic vesicle endocytosis remains unclear. We investigated this issue at the rat calyx of Held synapse by monitoring endocytosis with the whole-cell membrane capacitance measurement. Depleting cholesterol with methyl-β-cyclodextrin (MβCD) dialysis via the patch-clamp pipette led to significant inhibition of both rapid and slow endocytosis. Bath application of MβCD similarly inhibited endocytosis. Such inhibition of endocytosis could take place without any changes in the voltage-gated calcium channel current or exocytosis. Together, these results provide direct evidence that membrane cholesterol regulates vesicle endocytosis at the mammalian central synapse, probably downstream of Ca2+ entry and vesicle exocytosis.

Title: Synaptic vesicle phluorins differentially report distinct endocytic routes

Authors: *J. C. NICHOLSON-FISH[1], K. J. SMILLIE[1], M. A. COUSIN[2]
[1]Ctr. for Integrative Physiol., [2]Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: Upon depolarisation of a presynaptic terminal synaptic vesicles (SVs) fuse with the neuronal plasma membrane, thereby releasing their contents into the synaptic cleft in a process called exocytosis. Endocytosis is tightly coupled to exocytosis to ensure retrieval of SV membrane and to recycle deposited SV proteins. Endocytosis has two main modes: clathrin-mediated endocytosis (CME), which forms single SVs via the action of AP-2 and a clathrin coat and activity-dependent bulk endocytosis (ADBE), which invaginates a larger area of plasma membrane to form an endosome which later generates SVs. The kinetics of CME can be monitored by expressing exogenous SV proteins fused to pH-sensitive variants of green fluorescent protein (pHluorins). This enables the visualisation of the traffic of specific SV cargo as a proxy of the rate and extent of exo- and endocytosis. These pHluorin reporters are routinely employed to monitor CME, however little is known regarding how (and if) they report ADBE. We appraised the ability of widely used pHluorin reporters to monitor ADBE in primary neuronal cultures. To discriminate between CME and ADBE we employed a series of pharmacological inhibitors and genetic manipulations which arrested each endocytosis mode. We revealed that inhibition of ADBE has little effect on the response of a range of widely used pHluorin reporters, whereas manipulation of CME produced dramatic effects. Intriguingly we have identified one SV cargo that does report ADBE when fused to pHluorin, but does not report CME. Thus we have revealed preferential trafficking of specific SV proteins through different endocytic modes, and in turn we have identified a novel genetic reporter of ADBE.

Abstract: The presynaptic active zone (AZ) of cochlear inner hair cells (IHCs) sustains vesicle release at hundreds per second. This requires the function of otoferlin, a C2 domain protein defective in human deafness. Here we show that the endocytic adapter protein 2 (AP-2) directly associates with otoferlin and is required for vesicle replenishment and hearing. We demonstrate that conditional deletion of the Ap-2μ gene in mouse IHCs causes a use-dependent synaptic hearing impairment. Membrane capacitance measurements in IHCs and extracellular recordings from single spiral ganglion neurons (SGNs)show that AP-2μ-deficient IHCs are unable to sustain exocytosis already at 20 ms of stimulation. This phenotype reflects defective replenishment of the readily releasable pool of vesicles (RRP) despite unaltered membrane retrieval and a normal number of membrane-proximal vesicles at the AZ. It qualitatively resembles that of pachanga otoferlin mutants. This similarity and the fast onset lead us to suggest that AP-2 binding to otoferlin helps to clear newly exocytosed material from the release sites for the new coming vesicles to become fusion-competent (AZ clearance). Moreover, electron and super-resolution microscopy revealed an accumulation of endosome-like vacuoles (ELVs), impaired vesicle regeneration from ELVs and a concomitant depletion of ribbon-associated synaptic vesicles during long lasting stimulation of AP-2μ–deficient IHCs. We conclude that indefatigable sound coding at IHC ribbon synapses depends on clearance of newly exocytosed material from release sites to the perisynaptic endocytic zone via AP-2/ otoferlin and AP-2 dependent vesicle regeneration from ELVs.

Title: pH regulation by carbonic anhydrase modulates synaptic vesicle release mode at the mouse levator auris longus neuromuscular junction

Authors: *O. D. UCHITEL, A. I. GROISMAN
FBMC, IFIBYNE UBA CONICET, Buenos Aires 1428, Argentina

Abstract: Acetazolamide (AZ) is known to inhibit the action of carbonic anhydrase (CA), an enzyme responsible for regulating the extra- and intracellular pH. AZ is used to treat certain types of epilepsy and ataxia but its mechanism of action is still unknown. Our objective is to better understand the AZ mechanism of action on synaptic transmission vesicle recycling. Electrophysiological recordings performed on *ex vivo* levator auris longus neuromuscular junctions (NMJs) treated with AZ (100 uM in bicarbonate solution) showed reduced amplitude and increased frequency of spontaneous end plate potentials. Evoked end plate potential amplitude was also reduced but quantal content (m) measured at low, high frequency and during burst stimulation showed no differences between treated and control NMJs. To get further insight into the role of CA in transmitter release the above experiments were repeated in a Hepes buffer solution (10mM, pH 7.4). In those conditions m was not affected by AZ. The dynamics of vesicle exocytosis/endocytosis were studied in bicarbonate buffer solution loading the synaptic vesicle with fluorescence FM 2-10 dye incubated before and after 10 min nerve stimulation (20Hz) and unloading with a 50 Hz continuous stimulation after dye washed. The amount of dye loaded in the presence of AZ was reduced to 48±9% of control. After loading the nerve terminal in control conditions, muscles were treated with AZ and unloaded in the presence of the drug. Different kinetics of dye release were observed with a fluorescence retention of 68±6% vs. 24±4% in treated vs. control NMJs. Unloading experiments were repeated in a Hepes buffer (10mM, pH 7.4) and no effect of AZ was observed (26±4% at treated NMJs vs 23±2% of control). These results suggest that alterations in the buffer capacity of the nerve terminal by inhibition of CA affect vesicle recycling. Furthermore, the fact that in similar conditions AZ reduces dye release without affecting m suggests that intracellular pH changes may affect the mode of synaptic vesicle exocytosis.

Title: Regulation of vesicle cycling by myosin light chain kinase at hippocampal boutons

Authors: L. LI, H.-Y. YUE, *Y.-C. ZHU, J. XU
Georgia Regents Univ., Augusta, GA

Abstract: Synaptic transmission during repetitive activity is maintained by vesicle cycling via endocytosis at nerve terminals. Vesicle cycling depends on Ca2+/calmodulin, and, their downstream myosin light chain kinase (MLCK) according to our recent study at the calyx of Held synapse. Whether MLCK regulates endocytosis and vesicle cycling in small conventional synapses remains unclear. To address this question, we study effects of MLCK inhibition on vesicle exocytosis and endocytosis at cultured hippocampal boutons by imaging the dynamics of pHluorin-tagged synaptobrevin or synaptophysin. MLCK inhibitors, ML-7 and wortmannin, slowed the kinetics of endocytosis following electrical stimulation. Because MLCK inhibitors may have non-specific inhibition on calcium channel current, we are now studying effects of reducing MLCK expression by RNA interference-mediated gene silencing. Our results will help to further elucidate the presynaptic functions of MLCK in neurotransmission.

Title: Synaptic vesicle recycling is enhanced in complexin deficient *Drosophila* neuromuscular junctions

Authors: *N. SABEVA, A. GONZALEZ, M. BYKHOVSKAIA
Univercidad Central Del Caribe, Bayamon, Puerto Rico

Abstract: Complexin (Cpx) is a small cytosolic protein that interacts with the SNARE complex and regulates the final stages of exocytosis. Cpx null mutation in *Drosophila* produces drastic enhancement in spontaneous synaptic activity, suggesting that Cpx prevents spontaneous exocytosis. To understand how synaptic vesicle recycling can compensate for this increased activity in Cpx null mutants, we combined activity dependent loading of the fluorescent marker FM1-43 with electron microscopy analysis. First, we tested whether evoked and spontaneous release components in cpx(-) neuromuscular junctions (NMJs) are associated with different recycling pools of vesicles. The NMJs were loaded with the dye either in the absence of stimulation (passive staining) or during electrical stimulation at a 5 Hz frequency (active staining) and unloaded in the absence of stimulation (passive destaining). We found that the recycling pool of vesicles was significantly increased in cpx(-) NMJs and that the fluorescence loss during passive destaining was similar at the terminals loaded actively or passively. This result suggests the recycling pool is increased in cpx(-) terminals to compensate for the enhanced spontaneous release and that the recycling pools of vesicles participating in the evoked and spontaneous release components are intermixed. To test this hypothesis further, we employed photoconversion of FM1-43 loaded passively at different times ranging from 10 s to 10 min. We found that the number of FM1-43 loaded synaptic vesicles in cpx(-) NMJs was significantly increased at every time point and that the recycling and resting vesicles were spatially intermixed. These results suggest that the vesicle pools involved in evoked and spontaneous recycling pathways are mixed in the *Drosophila* NMJs and that cpx(-) synaptic boutons have an increased recycling pool to enable elevated spontaneous fusion.

Title: Enhanced synaptic vesicle recycling in cultured striatal neurons of DYT1 dystonia mouse model

Authors: *N. C. HARATA, S. IWABUCHI, J.-Y. KOH
Dept Mol Physiol & Biophys, Univ. Iowa Col. Med., IOWA CITY, IA

Abstract: Dystonia is a hyperkinetic movement disorder and is characterized by sustained or intermittent muscle contractions that cause abnormal and often repetitive movements, postures, or both. Patients with dystonia are subject to abnormal neuronal function in the brain, in the absence of neurodegeneration. Thus, one of the main pathophysiological causes is thought to be abnormal synaptic transmission, e.g. in the striatum, a region of the mammalian brain that plays an important role in motor control. However, whether this abnormality arises pre- or postsynaptically remains unclear. Here we have tested the striatal neurons of a mouse model of dystonia for abnormalities in presynaptic signaling. Specifically, we prepared primary cultures of striatal neurons from a knock-in model of DYT1 dystonia, the most common form of inherited dystonia. We evaluated the recycling of synaptic vesicles in the nerve terminals by live-cell imaging of the recycling marker FM1-43. Compared to wild-type controls, the mutant neurons showed an enhancement of both the amount of dye that was loaded in response to a stimulus, and the rate at which the dye was released from the loaded nerve terminals. Moreover, the amount of dye released from the mutant nerve terminals was higher even during miniature synaptic activity when action potentials were blocked with the Na+ channel blocker tetrodotoxin. Our results demonstrate that synaptic vesicle recycling is enhanced during both evoked and miniature synaptic activity in the mutant striatal neurons. In addition, they indicate that, at a minimum, a presynaptic factor is affected in DYT1 dystonia.

Title: A novel membrane-binding probe for the morphological and molecular characterization of synaptic vesicle recycling pathways

Authors: *N. H. REVELO, S. TRUCKENBRODT, S. O. RIZZOLI
STED Microscopy of Synaptic Function, European Neurosci. Inst., Goettingen, Germany

Abstract: The molecular composition of organelles involved in membrane recycling has been difficult to study due to the lack of suitable labeling tools. Electron microscopy approaches, such as those combining immunogold labeling and endocytosis tracers, have several drawbacks, including laborious sample preparation, low immunolabeling density, and low throughput. Fluorescence microscopy studies have tracked endocytosis by using amphiphatic dyes, rendered fixable by the addition of one amine group. We have found that these probes largely detach from membranes after permeabilization procedures, thus not allowing the use of immunofluorescence labeling to characterize endocytotic organelles. To circumvent these difficulties we have developed a novel probe, named mCLING (membrane-binding fluorophore-Cysteine-Lysine-Palmitoyl Group), which contains seven amine groups for better aldehyde fixation, a lipidic tail that binds to the plasma membrane, and a fluorophore suitable for high-resolution microscopy. mCLING is not toxic and is efficiently taken up during endocytosis. Moreover, mCLING remains attached to membranes after fixation and permeabilization, and can therefore be used in combination with immunolabeling. mCLING was tested in mammalian cultured cells, yeast and the *Drosophila* larval neuromuscular junction, finding efficient membrane labeling and uptake. We then applied mCLING to cultured hippocampal neurons in order to answer open questions about synaptic vesicle recycling and protein organization: 1) are the same synaptic vesicles responsible for active and spontaneous release? We found that actively and spontaneously-released synaptic vesicles are different in protein composition, the latter being more related to constitutive endosomal traffic. 2) What is the fraction of synaptic vesicle proteins that remains stranded on the plasma membrane, possibly as a readily retrievable pool of vesicles? Surface labeling with mCLING combined with immunolabeling of endogenous synaptic proteins allowed us to establish that ~12 to 22% of them remain on the plasma membrane. 3) What is the organization of SNAP-25 and syntaxin 1 on intracellular organelles? So far clusters of these proteins have only been studied on the plasma membrane. Using mCLING as a surface marker, it was possible to establish that SNAP-25 forms clusters of similar size on the plasma membrane and in intracellular organelles. In contrast, Syntaxin 1 forms larger clusters on the plasma membrane. We conclude that mCLING enables the investigation of trafficking membranes in a broad range of preparations.

Title: Hsp70 generates force to dissociate clathrin coats by an osmotic-pressure mechanism that is amplified by Hsp70 self-association

Authors: ***E. M. LAFER**, S. JIN, R. SOUSA
Dept Biochem, Univ. Texas Hlth. Sci. Ctr., SAN ANTONIO, TX

Abstract: Hsp70 molecular chaperones carry out a wide array of protein processing reactions in cells including protein translocation into the ER and mitochondrion, disaggregation of heterogeneous aggregates and disassociation of protein complexes. The mechanism by which Hsp70s generate force to execute these mechanical processes remains unclear, but is especially amenable to study in a reaction that is central to synaptic function: the Hsc70-mediated uncoating of the clathrin coated vesicles formed upon endocytosis at nerve terminals. Unlike heterogeneous aggregates, clathrin coats are homogeneous particles with defined Hsc70-binding sites presented with unique geometry inside the coat structure. We have taken advantage of these features to alter the geometry of these binding sites and to swap them with binding sites for other proteins so as to allow explicit testing of different models for Hsp70 force generation in protein complex dissociation. Our results allow us to reject models in which the Hsp70 needs to undergo a conformational 'power stroke' to generate force, and they also argue against simple 'thermal fluctuation capture' (Brownian ratchet) models. Instead, our results indicate that forces of up to tens to hundreds of piconewtons are generated by a mechanism analogous to that which generates osmotic pressure, and which provides for momentum exchange between the clathrin structural wall and Hsp70s tethered to flexible polypeptide segments adjacent to this wall. We also find that this force is amplified by Hsp70 self-association to allow dissociation of exceptionally stable clathrin coats, suggesting a biological function for the self-associating properties of these ubiquitous chaperones. In the broadest perspective, our data address how information processing in the brain is vastly more energy efficient than in human engineered

information processing machines by highlighting how biological machines, rather than expending energy in suppressing noise and fluctuations, exploit them.

Title: Trafficking of the vesicular glutamate transporter, VGLUT2

Authors: ***H. LI**, M. SANTOS, K. PARK, S. M. VOGLMAIER
Univ. California, San Francisco, San Francisco, CA

Abstract: The two principal vesicular glutamate transporter isoforms, VGLUT1 and 2, are essential for filling synaptic vesicles with the major excitatory neurotransmitter glutamate and have been suggested to confer distinct physiological properties of glutamate release in synapses where these isoforms are complementarily expressed. We investigated isoform-specific recycling to understand how differences in recycling of the two VGLUT isoforms might account for differences in exocytosis. We initially observed that VGLUT2 responds differently to high frequency stimulation than VGLUT1. To further explore trafficking differences of VGLUT2 from its closely related VGLUT1 isoform, we utilize a pHluorin-based reporter, VGLUT2-pH. VGLUT2-pH exhibits different recycling dynamics than VGLUT1-pH, even in response to moderate stimulation, reflected by slower rates of exocytosis and endocytosis. We explore how these differences are related to synaptic vesicle pools with differing probabilities of release. In addition, we characterize the crucial role of a C-terminal dileucine-like motif for VGLUT2 trafficking. Disruption of this motif abolishes the synaptic targeting of VGLUT2 and essentially eliminates the endocytosis of the transporter protein. Mutational and biochemical analysis demonstrates that clathrin adaptor proteins interact at the C-terminal dileucine-like motif of VGLUT2. This motif is crucial for the interaction of VGLUT2 with AP-2, a well-studied adaptor

protein required for clathrin mediated endocytosis. However, VGLUT2 also specifically interacts with AP-1 and -3 at the dileucine-like sorting signal. VGLUT2-pH relies on distinct recycling mechanisms from VGLUT1 under conditions of high frequency or sustained stimulation. Abrogation of these differences by pharmacological and molecular inhibition reveals that these mechanisms are dependent on the adaptor proteins AP-1 and AP-3. Further, shRNA-mediated knockdown demonstrates individual roles for AP-1 and AP-3 in VGLUT2 recycling.

Title: Parallel operation of slow and fast releasing readily releasable pools at calyx of Held synapses

Authors: K. MAHFOOZ[1], R. RENDEN[2], *J. F. WESSELING[1]
[1]Univ. Navarra/CIMA, Pamplona, Spain; [2]Sch. of Med., Univ. of Nevada at Reno, Reno, NV

Abstract: The readily releasable pool (RRP) of vesicles is a key concept in many studies of presynaptic function. The motivating idea is that readily releasable vesicles can participate in neurotransmission on demand. However, fast and slowly releasing subdivisions within the RRP have been identified, and it has been suggested that slow vesicles may be biochemically upstream of the immediately releasable state owing to incomplete priming. Nevertheless, here we use abrupt jumps in presynaptic action potential firing frequency from 100 to 300 Hz to show that slow vesicles are immediately available for synchronous release at intact calyces of Held from 2-3 week old mice and rats, albeit at lower probability of release compared to fast vesicles. In addition, other operating principles were more similar to standard excitatory synapses than expected: when slow vesicles were included, the RRP had a fixed capacity that did not depend on extracellular Ca2+ levels; and activity-dependent acceleration of recruitment of new vesicles reached a maximum quickly. Key differences were confirmed, including order-of-magnitude

more acceleration at calyces and the absence of a powerful short-term enhancement mechanism termed augmentation. Overall, the results support the simplifying concept that the RRP consists of a collection of independent release sites operating in parallel, with a range of release probabilities.

Title: SNAP-25 phosphorylation modulates the exocytotic kinetics in secretory cells and the large-scale network activity in the developing rat retina

Authors: *Y.-T. HSIAO, C.-C. YANG, Y.-T. HUANG, C.-T. WANG
Inst. of Mol. and Cell. Biol., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: SNARE complex mediates vesicle fusion. Among three SNARE proteins, SN25 can be phosphorylated by protein kinase A (PKA) at the residue of T138. Previous studies showed that SN25 phosphorylation by PKA can regulate secretion via recruiting vesicles. However, it remains unclear (1) how SN25 phosphorylation regulates the kinetics of exocytosis and (2) whether this regulation can cause a significant effect on the large-scale network activity. To address the first question, we performed single-event amperometry in PC12 cells to study the effects of SN25 phosphorylation on the exocytotic kinetics, with a special focus on the dynamics of fusion pore, reflected by foot signals preceding amperometry spikes (prespike foot, PSF). Two different secretogogues were applied to trigger calcium-dependent exocytosis, including KCl alone and KCl with forskolin. KCl alone did not change the secretion rate in cells overexpressing SN25 compared to control, but KCl with forskolin reduced the secretion rate in cells overexpressing SN25 compared to control, suggesting that SN25 may down-regulate calcium-dependent exocytosis via PKA phosphorylation. Furthermore, the secretion rate was increased in cells overexpressing the SN25 phosphodeficient mutant (SN25-T138A, designated SN25-PKA*) compared to SN25, confirming that SN25 down-regulates the secretion rate via the PKA phosphorylation site. Moreover, KCl with forskolin reduced PSF lifetime in cells overexpressing

SN25-PKA* compared to SN25, suggesting that SN25 phosphorylation stabilizes fusion pore. Thus, SN25 phosphorylation may regulate the kinetics of exocytosis in secretory cells. To address whether SN25 phosphorylation can cause a significant effect on the large-scale network activity, the spontaneous, correlated patterned activity (termed retinal waves) was detected in the developing rat retina where the PKA activity remains high. Live calcium imaging was subsequently performed to monitor the wave-associated calcium transients after overexpressing SN25 or SN25-PKA* in presynaptic neurons. The frequency of retinal waves was reduced by overexpressing SN25 in presynaptic neurons, whereas SN25-PKA* did not change the wave frequency, suggesting that SN25 phosphorylation by PKA may down-regulate the wave activity. Together, our results suggest that post-translation modification at a single residue of SN25 may serve as a molecular regulator to modulate neurotransmitter release and the large-scale network activity.

Title: Increased glutamate release in the CA3 correlates with memory deficits in mice expressing P301L tau

Authors: ***H. C. HUNSBERGER**, C. C. RUDY, D. S. WEITZNER, M. N. REED*
Psychology, West Virginia Univ., Morgantown, WV

Abstract: Individuals at risk for developing Alzheimer’s disease (AD) often exhibit neuronal network hyperexcitability, particularly in the CA3 region of the hippocampus, in the years preceding AD diagnosis. Recently, the microtubule-binding protein tau has been implicated in this hyperexcitability. The exact mechanism by which tau produces hyperexcitability remains to be determined, but recent work suggests tau may mediate glutamatergic signaling. We show that rTg(TauP301L)4510 mice, a commonly used tau mouse model of AD, exhibit a 65% increase in

hippocampal vesicular glutamate transporter (VGLUT) expression. Because VGLUTs impact the amount of glutamate released into the synapse and increased VGLUT expression causes excitotoxic neuro-degeneration, we hypothesized that the neurodegeneration observed in our AD model is due in part to an increase in extracellular glutamate levels. To examine glutamate regulation *in vivo* in TauP301L mice, we used an amperometry coupled to ceramic-based microelectrode arrays (MEAs), which allows for measurement of glutamate levels. Glutamate regulation was measured separately in the dentate gyrus (DG), CA3 and CA1 regions of the hippocampus and correlated with memory performance in the hippocampus-dependent Barnes maze. To control for the overexpression of human tau, we also examined glutamate regulation in mice expressing wild-type human tau (TauWT) at levels equivalent to that of mice expressing P301L tau (TauP301L). TauP301L mice exhibited memory deficits in the Barnes maze. P301L tau expression did not affect tonic extracellular glutamate levels or clearance from the synapse in any region examined. Similarly, amplitudes of potassium-evoked glutamate release in the DG and CA1 were similar among TauP301L, TauWT, and transgene negative littermates. However, memory-impaired TauP301L mice exhibited a 7-fold increase in glutamate release in the CA3 region of the hippocampus, and spatial reference memory errors correlated with potassium-evoked glutamate release in the CA3. In addition, the glutamate clearance peak area, area under the curve, was significantly greater for TauP301L mice in the DG and CA3 regions of the hippocampus. These data suggest a possible novel mechanism, increased presynaptic glutamate release, by which tau may mediate hyperexcitability. Findings of increased CA3 glutamate release in our mouse model corroborate findings of CA3 hyperexcitability in memory-impaired aged humans and patients with mild cognitive impairment (MCI). We are currently examining whether decreasing glutamate release can attenuate memory deficits and AD-related pathology in the TauP301L mouse model of AD.

Title: Readily releasable vesicles recycle at the active zone of hippocampal synapses

Authors: *T. A. SCHIKORSKI
Neurosci., Univ. Central Del Caribe, Bayamon, PR

Abstract: During the synaptic vesicle cycle, synaptic vesicles fuse with the plasma membrane and recycle for repeated exo/endocytic events. By using activity-dependent FM1-43 dye uptake combined with fast (<1s) microwave-assisted fixation followed by photoconversion and ultrastructural 3D-analysis, we tracked endocytic vesicles over time, “frame-by-frame”. The first retrieved synaptic vesicles appear 4s after stimulation and these endocytic vesicles are located just above the active zone. Second, the retrieved vesicles did not show any sign of a protein coat and coated pits were not detected. Between 10s and 30s, large labeled vesicles appeared that had up to 5 times the size of an individual synaptic vesicle. Starting at around 20s these large labeled vesicles decreased in number in favor of labeled synaptic vesicles and after 30s labeled vesicles re-dock at the active zone. The data suggest that readily releasable vesicles are retrieved as non-coated vesicles at the active zone.

Title: Monte Carlo simulation of transmitter release and receptor activation at CA1 glutamatergic synapses supports modified fusion dynamics as a mechanism of 5-HT1BR inhibition

Authors: *E. C. CHURCH[1], E. HAMID[1,3], S. ALFORD[2]
[1]Grad. Program in Neurosci., [2]Biol. Sci., Univ. of Illinois At Chicago, Chicago, IL; [3]NIH, Washington, DC

Abstract: Both 5-HT_{1B} receptors and $GABA_B$ receptors cause presynaptic inhibition and are colocalized at CA1-subicular pyramidal cell synapses. This $G_{i/o}$-mediated presynaptic inhibition is widely believed to require a reduction of release probability (P_r) following inhibition of evoked Ca^{2+} entry. However, GPCRs may inhibit neurotransmission independently of Ca^{2+} channel effects. Indeed, whereas presynaptic $GABA_B$ receptors inhibit presynaptic Ca^{2+} entry, 5-HT_{1B} receptors similarly inhibit neurotransmission from CA1 neurons but this action is mediated by a direct targeting of G[[Unsupported Character - Symbol Font ]][[Unsupported Character - Symbol Font ]] to the presynaptic release machinery (Hamid et al. 2014). We demonstrate that $GABA_B$ receptors alter P_r, whereas 5-HT_{1B} receptor activation leaves P_r unaltered, but reduces peak evoked cleft glutamate concentration. This modulation of cleft glutamate concentration allows a dynamic modulation of postsynaptic glutamate receptors, such that 5-HT_{1B} receptors are much less effective at inhibiting NMDA receptor-mediated synaptic responses than those mediated by AMPA receptors. Changes in peak glutamate cleft concentrations cannot be caused by a reduction of P_r spread over a number of synapses that exhibit univesicular release, but may be caused either by a reduction of P_r of multivesicular release sites or by a restriction of glutamate release from a fusion pore. A three dimensional simplified model of a synaptic cleft was thus created to run simulations in mcell (Stiles et al. 1998) of the effect of release of glutamate from a single vesicle in which fusion was arrested at pore sizes ranging from 0.4 nm to full fusion, or in which release was modelled from between 1 to 3 vesicles into a single synaptic cleft (modeled as a 300 nm disc). At 300 nm synaptic clefts, a restricted fusion pore model was substantially more accurate and reliable in predicting inhibition of AMPA currents modeled on activation of a 4 ligand kinetic model (Robert and Howe 2003) and a failure to inhibit a 2 ligand binding site of the NMDA receptor (Banke and Traynelis 2003), suggesting a likely mechanism of action for 5-HT_{1B}R-mediated synapic inhibition.

Title: Early developmental exposure to lead chronically inhibits vesicular release and alters presynaptic ultrastructure at excitatory synapses in the adult rat hippocampus

Authors: *P. K. STANTON[1], X.-L. ZHANG[1], S. R. GUARIGLIA[2], K. H. STANSFIELD[2], J. L. MCGLOTHAN[2], T. R. GUILARTE[2]
[1]New York Med. Col., Valhalla, NY; [2]Columbia Univ., New York, NY

Abstract: Lead exposure during brain development inhibits neurotransmitter release and this effect is likely to contribute to impaired synapse formation, plasticity and learning deficits. However, the mechanism(s) by which lead impairs neurotransmitter release have not been fully elucidated. In primary hippocampal neurons *in vitro*, lead exposure inhibits vesicular release and reduces the number of fast-releasing sites, an effect mediated by NMDAR inhibition. We wanted to determine if similar effects were also present in animals exposed to lead *in vivo*. In the present study, we examined the effects of chronic lead exposure on presynaptic transmitter release using two-photon laser scanning microscopy of FM1-43 vesicular release in Schaffer collateral-CA1 synapses in *in vitro* hippocampal slices. We found that chronic lead exposure significantly enhanced paired-pulse facilitation (Control PPF = 1.7 versus Lead PPF = 3.0 at 30msec inter-pulse interval), an indirect measure of reduced release probability. Mean-variance analysis of evoked synaptic potentials at Schaffer collateral-CA1 synapses directly confirmed that chronic lead treatment persistently reduced transmitter release probability (Control Pr = 0.46; Pb Pr = 0.25 at 2mM [Ca2+]o). Using FM1-43 2-photon imaging of release from CA1 Schaffer collateral terminals, we found that this reduced probability was associated with reduced release of glutamate from vesicles in the rapidly-recycling vesicle pool loaded by hypertonic shock. Furthermore, using transmission electron microscopy, we found that Schaffer collateral-CA1 terminals had fewer vesicles in the rapidly-recycling vesicle pool, decreased docked vesicle density at the presynaptic active zone and a reduced number of presynaptic terminals with multiple mitochondria. Similarly, in mossy fiber-CA3 synapses, we observed fewer vesicles in the rapidly-recycling pool, a decreased docked vesicle density and a shortened postsynaptic density length. These studies extend our previous finding in primary hippocampal neurons that lead produces profound impairments in vesicular release that are likely to contribute to deficits in synaptic plasticity necessary for cognitive function.

Title: Neurophysiological responses of recovery in pediatric mice compared to adult mice with transient focal cerebral ischemia

Authors: *J. E. ORFILA, H. GREWAL, T. SHIMIZU, R. T. TRAYSTMAN, P. S. HERSON
Univ. of Colorado, Anschutz Med. Campus, Aurora, CO

Abstract: Ischemic stroke is the fourth leading cause of death in the United States and is increasingly being recognized as a disease that strikes people of all ages, not just the elderly. Studies suggest that the immature developing brain may have a greater degree of plasticity compared to the adult, thereby enhancing functional recovery to a greater extent during development. However, this logical hypothesis has not been systematically investigated. Therefore, we took advantage of our novel model of pediatric ischemic stroke to directly compare plasticity and repair following stroke in the juvenile and adult mouse. Extracellular field recordings of CA1 neurons were performed in acute hippocampal slices prepared at 24 hrs, 7 or30 days after recovery from middle cerebral artery occlusion (MCAO) and compared to sham control mice. Our data shows that in adult mice, hippocampal long-term potentiation (LTP) is impaired as early as 24 hrs after stroke induced by the MCAO and remains impaired for at least 30 days in both the ipsilateral and contralateral, non-injured hemisphere. However, in pediatric mice, LTP is impaired as early as 24 hrs after MCAO and remained impaired in the ipsilateral side 7 days after MCAO, but recovered in the contralateral side at 7 days after MCAO. At 30 day, pediatric mice display a full recovery of synaptic function in both hemispheres. Furthermore, significant experimental data is emerging demonstrating an imbalance between inhibitory and excitatory cortical pathways after ischemic stroke, suggesting that reducing GABAergic inhibitory transmission enhances recovery. To test this, hippocampal slices were incubated in aCSF+L655,708 (100nM), an inverse agonist selective for α5 subunit-containing GABAA receptors, throughout the duration of the experiment. Our data shows that synaptic plasticity was rescued in pediatric mice 7 days following MCAO and 30 days in adult mice. Overall, the present study demonstrates that transient focal ischemia causes functional impairment in the hippocampus at various time points after MCAO and that excessive GABA activity may contribute to impaired synaptic function following ischemic injury, thus inhibition of specific GABA activity may provide a new therapeutic approach to improve functional recovery after stroke.

Title: Long lasting changes in metabolic efficiency occur during long term potentiation in hippocampal neurons

Authors: **C. M. PEQUIGNOT**, S. SACCHETTI, H.-A. PARK, C. WEISS, P. LICZNERSKI, *E. A. JONAS
Yale Univ. Sch. Med., New Haven, CT

Abstract: Long-term potentiation (LTP) and depression (LTD) are the mechanisms by which neurons modulate their inherent plasticity and provide for the storage and recovery of memories in mammalian brain. Although extensive research has been done regarding the changes in AMPA receptor trafficking that occur in neurons undergoing LTP, less is known about any underlying metabolic changes that may be required. Previous work has indicated that synaptic plasticity is correlated with changes in metabolic efficiency, and that the mitochondrial ion channel protein Bcl-xL may instigate that change due to its association with F1FoATP synthase. Here, we demonstrate that Bcl-xL is responsible for the elevation in ATP levels at synapse-specific sites in hippocampal neurons over the long term after high frequency stimulation in isolated hippocampal neurons. Utilizing FRET imaging techniques, we found that ATP levels remain elevated for up to 45 minutes at synapses after brief glycine stimulation. We found that ATP elevation was dependent on Bcl-xL because it was inhibited by a small molecule Bcl-xL inhibitor, the anti-cancer drug ABT-737. Studies with ABT-737 revealed neurons with ATP levels globally lower than control neurons and not limited to synapse specific sites. In future directions, we will test if Bcl-xL is responsible for driving the change in metabolic efficiency underlying LTP by its long term binding to the F1FoATP synthase after the stimulus has taken place. Our study also suggests that while only certain synaptic sites may undergo LTP in normal physiological conditions, inhibition of Bcl-xL leads to significantly lower ATP in the whole neuron, implicating Bcl-xL as not only essential to synapses experiencing LTP but also the

maintenance of synapses against LTD. Our study places Bcl-xL at the center of metabolism and synaptic plasticity.

Title: CBB68 protects against Aβ oligomer-induced deficits in synaptic function

Authors: R. JEGGO[1], J.-S. WALCZAK[2], A. D. WHYMENT[1], I. VEREYKEN[3], A. TEPPER[3], G. SCHEEFHALS[3], *D. SPANSWICK[1,4,5]

Abstract: The transformation of beta-amyloid (Aβ) into soluble, synaptotoxic, prefibrillar oligomers is a major pathogenic event underlying the neuropathology of Alzheimer's disease. Preventing the toxic effects of Aβ assemblies is therapeutically attractive because these events are believed to be exclusively pathogenic. We have investigated the effects of CBB68, a proprietary compound of Crossbeta Biosciences, on deficits in long-term potentiation (LTP) induced by intracerebroventricular (ICV) administration of stabilized oligomers of Aβ. The stabilization is a unique and proprietary technology of Crossbeta Biosciences. Male Sprague-Dawley rats were anaesthetized with urethane and cannulae inserted into the femoral artery and vein for monitoring blood pressure and administering substances (IV), respectively. A craniotomoy was performed and a cannula descended to the left lateral ventricle for ICV administration of Aβ oligomers. Stimulating and recording electrodes were descended to the *stratum radiatum* and *stratum pyramidale* of the CA1 region of the ipsilateral hippocampus for the identification, optimization and monitoring of population spike (PS) activity superimposed on field excitatory postsynaptic potentials. Animals were treated IV with either vehicle or CBB68 before ICV administration of Aβ or Aβ vehicle, followed 60 min later by the induction of LTP using theta-burst stimulation (TBS). PS activity was monitored for a further 90 min. LTP magnitude was derived from the change in PS amplitude pre- and post-TBS and compared

between treatment cohorts. In vehicle treated animals, ICV administration of stabilized oligomeric Aβ induced a significant deficit in LTP compared to those animals injected ICV with Aβ vehicle, with control LTP amounting to 211.5 ± 5.0% of baseline versus 144.6 ± 2.5% after Aβ, 90 min post-TBS. In CBB68 treated animals receiving vehicle ICV, there was a trend for slightly enhanced LTP of 217.9 ± 4.9% of baseline at 90 min, but this did not reach significance compared to control animals. However, CBB68 treatment did partially and significantly prevent the deficits induced by ICV administration of stabilized oligomeric Aβ with 90 min LTP of 182.4 ± 7.8% of baseline, compared to IV vehicle treated animals injected with Aβ (144.6 ± 2.5%). The present data demonstrate the *in vivo* functionality of these stabilized Aβ oligomers in inducing deficits in LTP in the anaesthetized rat hippocampus. They also demonstrate that the novel Crossbeta Biosciences compound CBB68 is centrally penetrant and protects against this Aβ-induced neurotoxicity in an electrophysiological model of learning and memory that is relevant to Alzheimer's disease.

Title: Enzymatic removal of chondroitin sulfates modulates neuronal excitability and synaptic plasticity in the hippocampal CA1 region

Authors: ***Y. DEMBITSKAYA**[1], I. SONG[2], M. DORONIN[1], A. DITYATEV[2], A. SEMYANOV[1]

[1]Univ. of Nizhny Novgorod, Nizhny Novgorod, Russian Federation; [2]Mol. Neuroplasticity Group, German Ctr. for Neurodegenerative Dis. (DZNE), Magdeburg, Germany

Abstract: Extracellular matrix (ECM) molecules occupy the space between neurons and glia in the brain and form conspicuous perineuronal nets. Chondroitin sulfate proteoglycans are major components of the ECM involved in synaptic plasticity: however, precise mechanisms of such involvement remain unclear. Using whole-cell recordings in hippocampal slices from male mice (P28-35), we found that acute enzymatic removal of chondroitin sulfates by chondroitinase ABC (ChABC) produced no significant effects on the basal efficiency of either inhibitory or excitatory synaptic transmission, but decreased the number of action potentials (APs) during theta-burst stimulation and impaired theta-burst induced LTP in CA3-CA1 synapses. Consistent with decreased cell excitability ChABC treatment decreased the number of APs in response to somatic current injections. Similar changes were detected in brevican deficient mice, suggesting that brevican is one of the carriers of chondroitin sulfates modulating neuronal excitability. In addition, ChABC treatment increased afterburst hyperpolarization in CA1 pyramidal neurons. Both the decrease in cell excitability and the increase in aftreburst hyperpolarization were prevented by 100 nM apamin, a blocker of the SK family of Ca^{2+} activated K^{+} channels, suggesting up-regulation of SK channel activity in ChABC treated slices. Notably, LTP recorded in the presence of apamin after ChABC treatment was enhanced as compared to slices, which were not treated with ChABC. However, the number of APs during theta-burst stimulation in the presence of apamin was not different between control and ChABC treated slices. This enhancement of LTP was suppressed by 10 μM Y-27632, a ROCK kinase inhibitor, suggesting modulation of RhoA signaling pathway by ChABC treatment. Our findings demonstrate that removal of chondroitin sulfates has a complex effect on synaptic plasticity in the CA1 region: the enhancement of LTP through the RhoA signaling pathway is masked by upregulation of SK channel activity. The later can serve as a protective mechanism that prevents overexcitation of neuronal network due to enhanced LTP.

Title: Post-synaptic long-term potentiation of gaba synapses in the oval bed nucleus stria terminalis

Authors: *E. HAWKEN, E. C. DUMONT
Queen's Univ., Kingston, ON, Canada

Abstract: Neural circuits consist of highly dynamic networks of excitatory and inhibitory neurons. While synaptic plasticity at excitatory synapses throughout the brain is well-established, synaptic plasticity of inhibitory synapses is a far less characterized phenomenon. The bed nucleus of the stria terminalis (BNST) is a structure known to be an interface between homeostatic neuro-regulation and circuits mediating higher cognitive processes. We have recently shown that changes in synaptic plasticity in the oval nucleus (ovBNST) is significantly correlated with drug taking behaviors. Thus, the ovBNST serves as a region of interest for studying the role of plasticity, specifically, that of plasticity at inhibitory synapses. Using whole-cell patch clamping in the slice, low frequency stimulation (LFS; 1 Hz 900 pulses) at inhibitory synapses in the ovBNST produced long-term potentiation (LTP) of GABAa inhibitory post-synaptic currents (IPSC). Twenty-minutes following LFS, IPSCs increased on average 173% ± 77% (SE) above baseline values and was sustained and sometimes continued to increase for up to 60 minutes post-induction (n=9/8). This effect appears to be post-synaptically mediated as there was no change in paired-pulse ratios (0.9± 0.04:1.1 ± 0.09, pre ± SE:post ± SE) and no significant change in the coefficient of variation (1/CV2 pre ± SE:post ± SE, 26.8 ± 8.2: 24.3 ± 6.4). The ubiquity of this phenomenon in the brain has yet to be determined.

Title: Synaptic spill-over of LTP in old animals through excitatory GABAergic transmission

Authors: *G. C. FAAS[1], I. FERANDO[1], I. MODY[2]
[1]Neurol., [2]Neurol. and Physiol., UCLA, Los Angeles, CA

Abstract: Age-related neurological disorders correlate with poor memory performance, but few studies have examined synaptic plasticity in mice at the end of their life span. We present new data about our ongoing LTP study in brain slices of old mice (21-25 months). We earlier reported that fEPSPs in the hippocampal CA1 area (evoked by Schaffer collateral stimulation) were significantly more potentiated >20 min after theta burst stimulation (TBS) in slices of old C57BL6/J mice (old-slices), at 30-35 min after TBS the slope of the line as quantified by a novel regression analysis of LTP potentiated by 173±37% (±SD, n=30) in contrast to slices of adult mice (adult-slices, 11-17 weeks old, +62±7%, n=15). Furthermore, pharmacological experiments with $GABA_AR$ modulators indicated that an excitatory switch in GABAergic transmission took place in old-slices, which was responsible for the added potentiation during the maintenance phase of LTP. Upon further analysis we now show that the time course of LTP in 9/30 (30%) old- slices is similar to that seen in 15/15 (100%) adult-slices showing a large post-tetanic potentiation (PTP, t=0-5 min, 115±6%) reduced within 20 minutes to a smaller steady potentiation (t=30-35 min, +62±7%). In 21/30 (70%) old-slices we found a markedly different time course where the potentiation after PTP remains steady or increases (+210±65%). In 3/4 adult-slices the KCC2 blocker VU-0240551 (10μM) converted the time course of LTP to that seen in the majority of old-slices. Thus a switch to an excitatory GABAergic transmission due to a shift in E_{Cl} may be responsible for the GABAergic component of LTP in old-slices. It has been well established that excitatory LTP is highly specific so that LTP is only induced in the pathways that receive the LTP inducing stimulation, while neighboring synapses remain unchanged. However, GABAergic transmission via synapses on spine necks and dendritic shafts is less precise and a depolarization or Ca^{2+} entry generated by such synapses might spill over to neighboring synapses. To address this synapse specificity of LTP we stimulated two distinct afferent fiber tracts and gave only one a TBS. In 3/3 of adult-slices, potentiation did not occur in the pathway that did not receive the TBS. In contrast, 8/10 old-slices showed a steady increasing

potentiation (t=35 min, +45±16%) of the pathway that did not directly receive TBS , indicating that some component of potentiation in old-slices spills over to neighboring inputs. We conclude that in old animals GABAergic transmission can significantly contribute to LTP and that this contribution makes the overall potentiation less synapse specific which likely interferes with memory formation.

Title: Cell type-specific GABAergic plasticity in the prefrontal cortex

Authors: ***C. Q. CHIU**, M. J. HIGLEY
Dept. of Neurobio., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Neurons communicate via excitatory glutamatergic and inhibitory GABAergic synapses. The interplay between excitation and inhibition not only shapes spike output but also regulates activity-dependent changes in synaptic efficacy. Indeed, several forms of GABAergic plasticity depend on the activation of glutamatergic receptors. However, in most cases, the underlying molecular mechanisms and cellular specificity are poorly understood. This information is vital for the understanding of how plasticity of GABAergic synapses impacts neural circuit function. Using cell type-specific optogenetic stimulation in mouse prefrontal cortical slices, we studied the capacity of GABAergic synapses formed by different interneuron subtypes to exhibit activity-dependent plasticity. Brief activation of NMDA-type glutamate receptors (NMDARs) produced an increase in GABAergic inhibition mediated by somatostatin-positive (SOM) but not parvalbumin-positive (PV) nor vasoactive intestinal peptide-positive (VIP) interneurons. Potentiation of SOM-mediated inhibition (SOM-iLTP) requires postsynaptic activation of NMDARs, a rise in intracellular calcium and activation of CaMKIIa. Similar potentiation of dendritic inhibition evoked by optical uncaging of GABA indicates that SOM-

iLTP is expressed postsynaptically. Our results indicate a crucial role for SOM-iLTP in regulating dendritic signaling and circuit activity within the prefrontal cortex.

Title: Presynaptic or BDNF-dependent postsynaptic STDP Expression relies on postsynaptic action potential pattern during STDP induction

Authors: E. EDELMANN[1], P. LICHTENECKER[1], *T. BRIGADSKI[1,2], V. LESSMANN[1,2]
[1]Otto-von-Guericke Univ., Magdeburg, Germany; [2]Ctr. of Behavioral Brain Sci. (CBBS), Magdeburg, Germany

Abstract: Long-term potentiation (LTP) relying on repeated precisely timed firing of action potentials in pre- and postsynaptic neurons, is a physiologically relevant type of synaptic plasticity. The resulting plasticity is called timing-dependent (t-)LTP. These activity patterns are considered to represent a cellular correlate of memory formation. While brain-derived neurotrophic factor (BDNF) is known to regulate LTP in the CA1 area of the hippocampus upon high frequency stimulation, the signaling mechanisms mediating the physiologically more relevant t-LTP, have remained elusive. Using patch clamp electrophysiology we now investigated different forms of hippocampal spike timing-dependent plasticity (STDP), and identified postsynaptic and presynaptic types of t-LTP, which recruit either BDNF-dependent or -independent signaling mechanisms. Furthermore, we determined patterns of electrical activity inducing release of BDNF from CA1 hippocampal neurons which underlie the BDNF-dependent t-LTP. To analyze an involvement of endogenous BDNF in STDP in hippocampal CA1 region, we used distinct low frequency pairing protocols with different numbers of postsynaptic stimuli and repetitions. Short positive spike timings led to t-LTP for both paradigms (1EPSP/1AP and 1EPSP/4AP). However, the LTP expression mechanism differed between the paradigms. While

the 1EPSP/1AP paradigm recruited a BDNF/TrkB-independent pathway, chronic and acute depletion of BDNF impaired t-LTP induced by the 1EPSP/4AP paradigm. Accordingly, scavenging of extracellular BDNF with TrkB-Fc, selectively impaired t-LTP induced by the 1EPSP/4AP protocol. Pre- vs. postsynaptic changes after t-LTP induction were explored and indicate presynaptic LTP expression for the BDNF-insensitive protocol, but postsynaptic expression for the BDNF-dependent 1EPSP/4AP paradigm. As revealed by inhibition of t-LTP by application of k252a via the patch pipette, postsynaptic TrkB signaling was required for BDNF-dependent t-LTP. Furthermore, postsynaptic release of endogenous BDNF (induced by backpropagating APs in CA1 pyramidal neurons) paired with synaptic stimulation, induced plasticity that occluded BDNF-dependent t-LTP. Fluorescence microscopy of BDNF-GFP release confirmed postsynaptic BDNF secretion under these stimulation conditions. Together, our data suggest that expression of t-LTP in CA1 of the hippocampus is regulated in a stimulus dependent manner, with 1EPSP/4AP pairing eliciting activity-dependent secretion of BDNF from postsynaptic CA1 neurons and postsynaptic t-LTP expression, while 1EPSP/1AP induced t-LTP proceeds by a BDNF-independent mechanism.

Title: A cellular and synaptic level model for reconsolidation

Authors: *D. B. KASTNER[1], T. SCHWALGER[2], L. ZIEGLER[2], W. GERSTNER[2]
[1]Neurobio., EPFL - LCN, Lausanne, Switzerland; [2]EPFL, Lausanne, Switzerland

Abstract: Reconsolidation, the process by which previously learned memories become susceptible to perturbation and require renewed stabilization, reflects the dynamic nature of memory. Reconsolidation has largely been studied at the behavioral level, providing insight into

its molecular components, but the cellular and computational features of the phenomenon remain unclear. Since the molecular machinery of reconsolidation is distinct from that of the preliminary storage process of consolidation, we developed a model of reconsolidation by extending a previous model of synaptic consolidation. The consolidation model captures the changes in synaptic strength by modeling synapses onto a cell with three interacting bistable equations. The three equations reflect the weight of the synapse, its tagged state, and whether or not it is consolidated. To capture reconsolidation we added a shared pool of molecules that bind to the synapses and stabilize the consolidated state. The unbinding of the molecules is activity dependent, causing a destabilization of the consolidated state exclusively when the neuron is stimulated, mimicking the exclusive loss of a memory at the behavioral level when memory reactivation is coupled with protein synthesis blockade, but not when protein synthesis blockade occurs by itself. Over time these molecules build up a reservoir that can withstand protein synthesis blockage, linking the size and dynamics of the reservoir to the boundary conditions of reconsolidation--situations when reconsolidation does or does not occur. The model replicates hippocampus slice based experiments thought to potentially underlie reconsolidation, firmly establishing those experiments as cellular substrates for reconsolidation. Furthermore we developed a theoretically compact description of the model that allows for an exploration of the parameter space of reconsolidation, and an exact description of the boundary conditions of the model. With such a model we can explore the computational nature of reconsolidation, providing for a better understanding of the dynamic nature of memory.

Title: Engineering a memory with LTD and LTP

Authors: *S. NABAVI
CNCB bldg., UCSD, La Jolla, CA

Abstract: It has been hypothesized that memories are encoded by modification of synaptic strengths through cellular mechanisms such as long-term potentiation (LTP) and long-term depression (LTD). However the causal link between these synaptic processes and memory has been difficult to demonstrate. Here we show that fear conditioning, a type of associative memory, can be inactivated and reactivated by LTD and LTP, respectively. We begin by conditioning an animal to associate a foot-shock with optogenetic stimulation of auditory inputs targeting the amygdala, a brain region known to be essential for fear conditioning. Subsequent optogenetic delivery of LTD conditioning to the auditory input inactivates memory of the shock. And finally, subsequent optogenetic delivery of LTP conditioning to the auditory input reactivates memory of the shock. Thus, we have engineered inactivation and reactivation of a memory using LTD and LTP, supporting a causal link between these synaptic processes and memory.

Title: Learning induced LTP in mice

Authors: *J. REMAUD, F. ROUMIER, S. PECH, B. FRANCÈS, L. DAHAN
Ctr. De Recherches Sur La Cognition Animale (CRCA - UMR 5169), Toulouse, France

Abstract: Long-term potentiation (LTP) is a process by which the strength of the synaptic connection between neurons increases when the synapse is repeatedly activated. It can be "artificially" triggered by electrical stimulation protocols such as high frequency or theta burst stimulations (TBS). There is now a strong body of evidence demonstrating common molecular mechanisms underlying LTP and long term memory, and LTP is currently the best candidate for a neural correlate of memory. However, only few studies succeeded in showing that LTP actually occurs in the hippocampus during learning. We recorded evoked field potentials (fEPSP) in area CA1 of the hippocampus in freely moving mice before and after a session of

contextual fear conditioning. Here we report that this kind of electrophysiological measurement allows monitoring the "natural" LTP triggered by the training session. Moreover we show that conditioning-induced LTP partially occludes TBS-induced LTP, suggesting that natural and artificial LTP share some mechanisms. This study provides the first electrophysiological evidence of a robust LTP induced by a single session of learning in mice.

Title: Molecular plasticity signature in hippocampal area CA1

Authors: *J. JEDRZEJEWSKA-SZMEK, A. M. CHAY, K. T. BLACKWELL
The Krasnow Inst. For Advanced Study, Fairfax, VA

Abstract: Hippocampal plasticity is considered one of the major cellular mechanisms of learning and memory. Molecular mechanisms responsible for long lasting forms of LTP (L-LTP) which last from several hours up to days, are of interest because this form of plasticity resembles long term memory storage. Plasticity inducing protocols vary in their activation of signal transduction pathways and resulting dependence on signaling molecules: train (1 s) of 100 Hz stimulation (HFS) elicits only a short-lasting form of LTP (E-LTP) whereas multiple trains of HFS elicit L-LTP, Bath application of isoprotenerol (ISO) followed by electric stimulation produce L-LTP that differs in their molecular dependence: 3 min of 5 Hz stimulation (ISO + LFS) is protein kinase A (PKA) dependent whereas ISO + HFS is not.To investigate how temporal pattern of synaptic activation determines activation of signaling pathways, we employed a multi-compartmental, stochastic reaction-diffusion model of calcium (Ca) and cyclic adenosine monophosphate (cAMP) activated signaling pathways in CA1 pyramidal neurons. We started with the model presented by Kim et al. (2011) and added stimulative regulatory G protein (Gs) to

inhibitory regulatory G protein (Gi) switching (Havekes et al., 2012). We simulated Ca influx and β-adrenergic receptor stimulation produced by eight commonly used plasticity induction paradigms. We discovered that the following plasticity signature can explain the direction of plasticity: a combination of PKA, phosphatatases, and Ca2+/calmodulin-dependent protein kinase II (CaMKII) phosphorylation in the spine may act to "tag" the spine. Specifically, the spine signature is proportional to the sum of CaMKII and PKA activity divided by the phosphatase activity. Three regimes leading to LTP, no change, and long term depression are visible. A combination of PKA, pCaMKII, exchange protein activated by cAMP (Epac) and βγ subunit of Gi (Giβγ), in the dendrite may act to initiate production of plasticity related proteins. Though 1 train of HFS produces a spine signature of LTP, it does not produce a dendritic signature for protein synthesis initiation, explaining why 1 train of HFS only elicits E-LTP. Furthermore, Epac activation is the highest with ISO + HFS, explaining why this paradigm produces PKA independent, but cAMP dependent L-LTP. The molecules required for the dendritic signature are related by their downstream target extracellular signal-regulated kinase (ERK) which is implicated in learning, memory and plasticity. The combination of spine signature and dendritic signature are required to predict the outcome and molecular dependence of synaptic plasticity protocols.

Title: Incorporation of Calcium-Permeable AMPA receptors at silent synapses during hippocampal long-term potentiation

Authors: *J.-C. RAH[1], D. MORITA[2], J. T. R. ISAAC[2]
[1]Neural Network, Korea Brain Res. Inst., Daegu, Korea, Republic of; [2]Developmental Synaptic Plasticity Section, Natl. Inst. of Neurolog. Disorders and Stroke, Natl. Inst. of Hlth., Bethesda, MD

Abstract: Despite decades of study, the mechanisms by which synapses express the increase in strength during long-term potentiation (LTP) remain an area of intense interest. Here, we have studied how AMPA receptor subunit composition changes during the early phases of hippocampal LTP in CA1 pyramidal neurons. We studied LTP at silent synapses that initially lack AMPA receptors, but contain NMDA receptors. We show that strongly inwardly rectifying AMPA receptors are initially incorporated at silent synapses during LTP and are then subsequently replaced by non-rectifying AMPA receptors. These findings suggest that silent synapses initially incorporate GluA2-lacking, calcium-permeable AMPA receptors during LTP that are then replaced by GluA2-containing calcium-impermeable receptors. We also show that LTP consolidation at CA1 synapses requires a rise in intracellular calcium concentration during the early phase of expression, indicating that calcium influx through the GluA2-lacking AMPA receptors drives their replacement by GluA2-containing receptors during LTP consolidation. Taken together with previous studies in hippocampus and in other brain regions, these findings suggest that a common mechanism for the expression of activity-dependent glutamatergic synaptic plasticity involves the regulation of GluA2-subunit composition and highlights a critical role for silent synapses in this process.

School, MGH, Charlestown, MA; [4]Lab. of Neurosciences, Natl. Inst. of Aging, NIH, Baltimore, MD; [5]Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Inflammation and metals play critical roles in AD. The finding that alleles in the hemochromatosis gene advance the onset of AD sparked research in the metallobiology of AD. The presence of an Iron-Responsive Element (IRE) in the 5'UTR of the APP transcript (APP 5'UTR) supports APP a metaloprotein. Iron, copper and zinc were shown to accelerate the aggregation of the amyloid-β (Aβ) peptide and enhance metal catalyzed oxidative stress associated with amyloid plaques, the central hallmark of AD. The participation of metals in plaque formation and of metal-dependent translation of APP mRNA support chelators as a major therapeutic strategy for AD (Bandyopadhyay et al-2013). APP is regulated post-transcriptionally with changes in iron homeostasis. In the absence of iron, IRP1 binds to an IRE in the APP 5'-UTR and inhibits translation. MicroRNAs (miRNAs) also post-transcriptionally regulate APP expression. Indeed, miR-101 and miR-153 negatively regulate APP expression via the APP 3'-UTR (Long, Ray & Lahiri- 2012; 2014). Here we report that miR-346 stimulates APP expression via the APP 5'-UTR at a site that overlaps with the IRE. The miRanda algorithm predicted a miR-346 target site in APP 5'-UTR that overlapped a known IRE. Reporter assays in HeLa cells transfected with miR-346 mimic and APP 5'-UTR reporter construct revealed that miR-346 significantly stimulated reporter expression via the APP 5'-UTR. With miR-346 transfection, endogenous APP levels were also significantly increased vs. controls, an effect reversed by target protectors confirming the site of interaction. APP mRNA levels were unchanged suggesting a post-transcriptional mechanism. The stimulatory effect of miR-346 on APP was significantly attenuated when AGO2 or IRP1 was knocked down by siRNA. Thus, miR-346 apparently requires the presence of AGO2 to stimulate APP expression and mediates its effect by interfering with IRP1's binding to the IRE sequence in the APP 5'-UTR. miR-346 was successfully transfected into primary human fetal brain mixed cultures as described (Long et al-2014), but miR-346 transfection did not stimulate expression under standard culture conditions. However, APP levels were stimulated by miR-346 transfection following iron chelation by deferroxamine, a condition that would enhance IRP binding to the IRE. This is consistent with miR-346 interfering with IRP1 binding. Therefore, miR-346 may represent a novel drug target in AD, and miR-346 inhibition should then synergize with iron chelation strategies as an AD treatment.

Title: Calpain mediates degradation of novel APP C-terminal fragments

Authors: *H. WANG[1,2], A. SAUNDERS[1]
[1]Biol., Drexel Univ., Philadelphia, PA; [2]Drexel Univerisity Col. of Med., Philadelphia, PA

Abstract: Alzheimer's disease (AD) is a progressive neuro-degenerative disease. One of its hallmarks is the deposition of extracellular plaques, composed of amyloid β (Aβ). Aβ is a small peptide generated from proteolytic processing of its precursor, amyloid precursor protein (APP). The process of APP proteolysis and the generation of Aβ have been studied extensively. Canonical APP proteolysis occurs via α-/ β- and γ-secretases. By inhibiting protein degradation systems, including cathepsin, calpain and the proteasome, we have identified hitherto undocumented APP fragments. These novel fragments are not a result of apoptosis induced proteolysis. Utilizing pharmacological approaches suggests that calpain inhibition is likely responsible for the accumulation of the observed novel APP fragments. This indicates that besides canonical processing by α-/ β- and γ-secretases, APP can be processed by yet unidentified mechanism, and the resulting products are degraded via protein degradation, likely calpain.

Abstract: β-amyloid precursor protein (APP) is transported to the plasma membrane, where it is sequentially cleaved by α-secretase and γ-secretase. This pathway is called non-amyloidogenic pathway, since it precludes the production of hydrophobic β-amyloid peptide (Aβ), the main culprit of Alzheimer's disease (AD). Alternatively, once APP undergoes clathrin-dependent endocytosis, it can be sequentially cleaved by β-secretase and γ-secretase at endosomes, producing Aβ (amyloidogenic pathway). O-GlcNAcylation is a novel type of O-linked glycosylation attaching the monosaccharide β-N-acetylglucosamine (GlcNAc) to serine and threonine residues. Recently, we found that O-GlcNAcylation of APP increases the non-amyloidogenic processing of APP and decreases the production of Aβ. In this study, we identified specific increase of O-GlcNAcylation of APP by Justicidin A, which is one of lignin derivatives. Justicidin A increased the level of APP in the plasma membrane. We also found that Justicidin A selectively attenuated the endocytosis of APP, but not that of transferrin receptor. The level of sAPPα increased, while the level of sAPPβ and Aβ was concomitantly decreased by Justicidin A. Blocking the clathrin-dependent endocytosis by inhibitor prevented the effect of Justicidin A, suggesting that the effect of Justicidin A on Aβ production was mainly mediated through the decrease of APP endocytosis. These results strongly indicate that O-GlcNAcylation by Justicidin A increases the plasma membrane targeting of APP and selectively decreases endocytosis rate of APP, thereby enhancing non-amyloidogenic processing of APP. Thus, O-GlcNAcylation of APP could be a new novel therapeutic target for AD.

Abstract: O-linked β-N-acetylglucosamine (O-GlcNAc) modification of protein, a post-translational modification that links GlcNAc to the hydroxyl group of Ser or Thr residues, is one of the major forms of protein glycosylation affecting various intracellular events. However, the role of O-GlcNAc modification of proteins in the pathogenesis of neurodegenerative disease such as Alzheimer's disease (AD) is poorly understood. ATP synthase is multi-protein complex that synthesizes ATP from ADP and Pi using the proton gradient generated by electron transport chain as a driving force. Since ATP generation is significantly reduced in AD mouse model and Aβ (major causative factor for AD)-treated neuronal cells, ATP synthase might be affected by Aβ or other pathological condition in AD. Since we found ATP synthase is O-GlcNAcyalted and it binds to Aβ directly, we tried to figure out the relationship between O-GlcNAcylation on ATP synthase and their function under AD pathological condition, especially in the presence of Aβ. We will discuss more details about how Aβ reduces ATP synthase activity and what is the role of O-GlcNAcylation on ATP synthase to regulate ATP synthase function.

Abstract: Secreted amyloid precursor protein-alpha (sAPPα), a peptide derived from the same parent molecule as amyloid-ß (Aß), has been shown to enhance synaptic plasticity in rats and in an Alzheimer's mouse model, although the mechanisms of its wide ranging effects are not well understood. Its effects on metaplasticity have not yet been explored and its action on glutamate receptor trafficking, a mechanism that supports long-term potentiation (LTP), is unknown. Here we (i) investigated the effect of sAPPα delivered prior to versus at the time of LTP induction, and (ii) determined whether sAPPα alone can regulate NMDA and AMPA receptor localization. Slices were prepared from adult male Sprague-Dawley rats and allowed to recover for 2 h. Baseline field excitatory postsynaptic potentials (EPSPs) were evoked in area CA1 by electrical stimulation of the Schaffer collateral/commissural pathway, and recorded in stratum radiatum. Bath-applied recombinant sAPPα (1-10 nM) did not affect the initial slope of the EPSPs. Application of mild theta-burst stimulation (TBS, 5 trains (5 Hz) of 5 pulses (100 Hz)) induced post-tetanic potentiation (PTP) but not LTP in untreated slices. In contrast, when applied 20 min before, during and following TBS, sAPPα (10 nM) facilitated both PTP and LTP compared to non-treated controls (responses 1h post-TBS = 139.6 ± 3.3% vs 103 ±1.3% of baseline; $p<0.01$). Lower sAPPα (1 nM) and shorter application (30 min just prior and during TBS) also produced LTP (145.6 ± 3.6% of baseline). To determine whether sAPPα has metaplastic properties, we washed the sAPPα (1 nM, 30 min) out of the bath for 30 min prior to TBS. Under these conditions, LTP was still 149 ± 5% of baseline. To probe underlying mechanisms of this plasticity, we tested whether sAPPα (30 min) affected NMDA or AMPA receptor localization using biotin labelling of cell surface proteins followed by Western blot analysis of the NMDAR subunit GluN1and the AMPAR subunit GluA1. Relative changes in cell surface concentrations in response to sAPPα were determined by comparison with levels in control slices. sAPPα induced significant concentration-dependent biphasic effects on plasma membrane-bound GluN1 and GluA1 expression, with decreases relative to control occurring at low doses and increases occuring at intermediate doses ([GluN1: 0.1 nM, 0.79 ± 0.07, $p<0.01$; 1 nM, 1.32 ± 0.12, $p<0.01$; 100 nM, 0.84 ± 0.19, n.s. GluA1: 0.1 nM, 0.65 ± 0.04, $p<0.001$; 1 nM, 1.55 ± 0.05, $p<0.001$; 100 nM, 1.12 ± 0.26, n.s.). These findings support a fundamental role for sAPPα in regulating synaptic plasticity and raise the possibility that this occurs by regulating NMDA and AMPA receptor localization.

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder that mostly affects the elderly. AD is characterised by excessive accumulation of the neurotoxic protein amyloid-β (Aβ). If the mechanism is from enhanced processing at the β,γ site of amyloid precursor protein (APP), there will be a concomitant reduction at the α processing site and thereby production of the neurotrophic and neuroprotective secreted amyloid precursor protein-α (sAPPα). To date there has been limited success in treating established AD cases, research has begun to focus on preventive strategies, inadvertently leaving a gap in combating this disease. We hypothesized that established behavioural and electrophysiological deficits caused by amyloid accumulation could be mitigated or reversed by promoting sAPPα production. To test this, we overexpressed sAPPα bilaterally in the hippocampus of 10-month-old transgenic APPswe/PS1ΔE9 mice using lentiviral gene transfer. These mice develop increased extracellular Aβ deposition and behavioural deficits as early as six months of age. Postulating that sAPPα could ameliorate neurotoxic effects of Aβ, these mice were electrophysiologically tested 3-months post-transduction. Hippocampal slices were prepared and synaptic transmission, paired-pulse facilitation (PPF), paired-pulse recurrent inhibition (PPI) and long-term potentiation (LTP) in area CA1 was examined. Extracellular field recordings revealed no significant differences in basal synaptic efficacy, PPF or PPI between groups. However, the magnitude of LTP measured one hour post-theta burst stimulation in the transgenic mice that received control vector (no sAPPα overexpression) was significantly reduced (136 ± 10%, n=9, $p < 0.05$) compared to litter-matched wild-type controls treated with control vector (171 ± 7%, n=11). LTP in the transgenic mice was rescued by the sAPPα vector (172 ± 7% of baseline, n=11, $p<0.05$). These results

indicate that sAPPα overexpression using lentiviral gene transfer can rescue the deficit in LTP seen in this progressive AD mouse model, which suggests a role for sAPPα in reducing at least some of the neurotoxic effects of Aβ, even after plaque development.

Abstract: Synaptic plasticity is the ability of synapses to increase or decrease in strength and important in learning and memory. As a form of synaptic plasticity, homeostatic plasticity is a tuning process of synapse strength up or down in order to counter excessive excitation or inhibition in chronic perturbation of neuronal activity. One of the proteins mediated in the homeostatic plasticity is Plk2, an activity inducible member of the polo family of serine/threonine kinases. It is expressed at low level under basal condition but induced by strong synaptic stimulation such as seizure and picrotoxin (PTX). In this plasticity, AMPA receptor trafficking is regulated by many interacting proteins such as NSF. The function of NSF is to maintain AMPAR at postsynaptic membrane by selectively binding to GluA2 subunit. Our lab showed that Plk2 bound to NSF via a novel binding site of Plk2 and disrupted NSF and GluA2 interaction. Alzheimer disease is the most common neurodegenerative disease, characterized by the formation of neurofibrillary tangles and amyloid plaques. These plaques are composed of amyloid β-protein (Aβ) derived from amyloid precursor protein (APP). Proteolytic cleavage of APP is regulated by proteases. β-secretase cleaves APP to generate a secreted extracellular domain and a membrane tethered-C-terminal fragment (β-CTF). The β-CTF is further cleaved by γ-secretase, which releases Aβ. This amyloidogenic processing of APP appears to be involved in

synaptic plasticity since enhanced synaptic activity generates more Aβ which leads to AMPAR removal from the synapse, which implies a mechanism liking Plk2 effect on activity induced APP processing. In this study, we found that Plk2 was induced by PTX and directly bound to and phosphorylated APP at T668/S675. The phosphorylated APP was internalized and promoted Aβ generation. Therefore, Plk2 expression in APP-SwDI mice temporally increased in the vicinity of plaques whereas transgenic inhibition of Plk2 kinase function reduced amyloid plaque formation and Aβ production *in vivo*. Both AMPA receptors and APP were involved in synaptic plasticity by altering spine formation and density. We also showed that GluA2, not GluA1, was changed by APP expression. Therefore, APP and GluA2 seems to have a potential relationship. Indeed, Plk2 induced two phosphorylation sites in APP is necessary for overactivity-induced loss of surface GluA2. Moreover, surface residence of APP appeared to govern GluA2 maintenance on cell surface. As mechanism of APP and GluA2 co-trafficking, we confirmed that NSF also interact with APP *in vitro* and *in vivo*. Therefore, NSF seems to function as a bridge to connect between APP and GluA2 at the membrane.

Abstract: The amyloid-βpeptides, the major protein component of brain senile plaques in Alzheimer's disease (AD), derived from the proteolytic cleavage of an amyloid precursor protein (APP) by β- and α-secretase. However, the mechanisms mediating APP processing is poorly understood. We previously reported that the increase of a homeotic transcription factor ATBF1 (AT-motif binding factor 1) is shown in the brains of 17-month-old Tg2576 mice compared with wild-type controls, and that Aβ42 increases ATBF1 expression, resulting in cell death in primary rat cortical neurons. To clarify whether ATBF1 expression is involved in the mechanism of cell death in human AD, we first investigated the expression of ATBF1 in human AD brains, and found that ATBF1 levels are increased in the cytoplasm of hippocampal neurons in AD brains compared with non-AD brains. We then investigated how ATBF1 induces the cell death focusing APP processing. Cotransfection of human embryonic kidney (HEK293T) and human neuroblastoma (SH-SY5Y) cells with ATBF1 and APP695 increased steady-state levels of APP via the binding of ATBF1 to the APP cytoplasmic domain (amino acids 666-690), resulting in increased Aβ production and cellular and soluble APP (sAPP) levels without affecting the activity or levels of APP processing enzymes (α-, β- or α-secretase). Conversely, knockdown of endogenous ATBF1 reduced levels of cellular APP, sAPP and Aβ in HEK293 cells overexpressing human APP695. In addition, cotransfected APP with ATBF1 into SH-SY5Y cells seems be accumulated and colocolized on Rab5 and 7, early and late endosomes markers, respectively. Our findings provide insight into the dynamics of APP processing and Aβ production, and suggest that ATBF1 is a novel APP binding protein that might be a suitable therapeutic target for AD.

Title: Amyloid precursor protein (APP) is ubiquitinated at multiple sites in the COOH-terminal domain as a signal for endosomal sorting

Authors: *R. WILLIAMSON[1], Z. M. LASIECKA[2], E. MOREL[2], Z. CHAMOUN[2], C. VETANOVETZ[2], S. A. SMALL[3], G. DI PAOLO[2]
[1]Taub Inst. for Res. on Alzheimer's Dis. and the Aging Brain, Columbia Univ., New York, ; [2]Dept. of Pathology and Cell Biol., [3]Taub Inst. for Res. on Alzheimer's Dis. and the Aging Brain, Columbia Univ., New York, NY

Abstract: Alzheimer's disease (AD) is the most common neurodegenerative disorder, characterized clinically by a progressive cognitive decline and neuropathologically by amyloid plaques and neurofibrillary tangles. Amyloid plaques are largely composed of amyloid beta peptide derived from cleavage of its parent protein, amyloid precursor protein (APP). According to the amyloid cascade hypothesis, limiting amyloid beta generation in neurons may help prevent or treat AD. The trafficking of APP and its processing enzymes is closely linked to production of toxic metabolites, such as amyloid beta and the C-terminal fragment beta. Though the subcellular locations where APP processing occurs remain poorly understood, growing evidence suggests that amyloidogenic cleavage occurs in endosomes. Our lab implicated an endosomal sorting pathway for APP that has major implications for its amyloidogenic processing. The molecular basis involves recognition of ubiquitinated APP by components of ESCRT (endosomal sorting complex required for transport) to sort APP from the limiting membrane of endosomes into intraluminal vesicles (ILVs) for eventual lysosomal degradation. Remarkably, our published work showed that ubiquitination and ESCRT-dependent sorting of APP into ILVs alters amyloid beta generation, suggesting that this pathway may be exploited for therapeutic purpose in AD. Because APP ubiquitination is critical for ILV sorting, a fundamental question is the identity of the sites that undergo ubiquitination in APP's C-terminus and the type of ubiquitin modification involved. Our lab originally identified an APP mutant with a triple lysine-to-arginine mutation (K724-726R, termed APP-3R) that is deficient in ubiquitination, leading to mislocalization of APP from the endosome interior to the limiting membrane, and an increase in amyloid beta generation. Here, we dissect the individual contribution of each lysine mutated in the APP-3R mutant, and identify other lysine residues in the APP C-terminus that are deficient in ubiquitination and represent sites that may be critical in APP trafficking and processing. In addition, we characterize an APP missense mutation of the leucine residue adjacent to the APP-3R triple lysine site (L723P), which phenocopies the APP-3R mutant by exhibiting a reduction in APP ubiquitination, mislocalization of endosomal APP, and an increase in amyloid beta. Of particular note, the APP-L723P mutation was first discovered as the cause of early-onset AD in one family. By understanding APP ubiquitination and the endosomal sorting pathway, we expect to uncover new targets and avenues for development of urgently needed AD therapeutics.

Abstract: Residues located at the ectodomain of β-C-terminal fragment (ECD-βCTF) might be pivotal for wild-type β-amyloid precursor protein (APPwt) processing. In this study, using specific monoclonal antibody recognizing ECD-β-CTF (mAbECD-βCTF), we found that the *in vitro* bindings of mAbECD-βCTF and its F(ab')2 fragment shifts APPwt processing from α- to β-cleavage, as evidenced by elevated accumulation of cell-surface full-length APP and β-CTF together with a marked reduction of sAPPα. This effect was mediated by inhibition of APPwt endocytosis and blocking of ADAM10 mediated α-cleavage. Consistent with these *in vitro* data, intracerebroventricular injection of mAbECD-βCTF markedly increases membrane-associated β-CTF levels in TgAPPwt mice brain. All together these findings suggest that the ECD-β-CTF is critical for APPwt processing and may provide the foundation for a novel family AD therapeutics. Abstract: **Abstract** Circadian rhythm disruption is commonly found in patients with neurodegenerative disease including Alzheimer's disease (AD). AD is an age-related neurological disorder and Aβ is one of major causative molecules in the pathogenesis of AD. Since it is largely unknown whether and how circadian clock molecules affect the circadian rhythm disruption in AD patients, we tried to investigate the link between Aβ and circadian clock molecules such as PER2, BMAL1 and CBP in AD animal model mouse, 5XFAD mice. We found that AD mice showed the increases of both home cage activity and body temperature with clock molecule alteration. To elucidate the molecular mechanism of these changes in AD, Aβ was treated to HT22 cells, hippocampal neuronal cell line. Aβ reduced BMAL1 stability by increase of sumoylation on BMAL1. At the same time, Aβ reduced CBP level and increased N-cadherin cleavage, which is occurred by γ-secretase. Treatment of γ-secretase inhibitors to the cells caused blockade of N-cadherin cleavage, resulting in increase of CBP level, suggesting that Aβ-induced CBP degradation is through the γ-secretase dependent N-Cadherin cleavage. Both BMAL1 and CBP stabilities affected PER2 expression. It suggests a critical role of Aβ in circadian rhythm disruption and implicates the underlying molecular mechanism in the progress of AD pathogenesis. Key words: Alzheimer's disease, Circadian rhythm, Amyloid-beta (Aβ), BMAL1, CBP

Title: Transcription regulation of the human USP25 gene

Authors: ***B. SONG**, F. CAI, W. SONG
The Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Dysregulation of the ubiquitin proteasome pathway has been implicated in the pathogenesis of neurodegenerative diseases and Down Syndrome. The ubiquitin-specific proteases 25 (USP25) gene spans over 150kb and located in Chr21q11.2. To define the molecular mechanism of USP25 gene transcriptional regulation, we isolated a 2.2-kb 5'UTR of USP25 gene. A series of nested deletions of the 5'UTR fragments were subcloned into a luciferase reporter plasmid pGL3-Basic. HEK293 cells were transfected with the USP25 promoter constructs and luciferase activity was measured to assay its promoter activity. We identified a 104-bp fragment containing the transcription initiation site as the minimal region necessary for USP25 gene promoter activity. Several putative cis-acting elements, such as SP1, HIF and CdxA are found in the 5' flanking region of USP25 gene. Further analysis will reveal which transcription factor regulates the promoter activity of the human USP25 gene. Supported by Canadian Institute of Health Research

Title: Detecting and blocking the intracellular caspase cleavage of amyloid precursor protein as a biomarker of Alzheimer's disease - screening for inhibitors and validation of a new cleavage site-specific antibody that detects APP delta C31

Authors: K. S. POKSAY[1], J. CAMPAGNA[1], P. R. SPILMAN[1], D. KANE[1], R. LIU[2], J. ZIELINSKI[2], M. MULLENIX[2], D. J. SHEFFLER[3], *D. E. BREDESEN[1,4], N. D. P. COSFORD[3], V. JOHN[1,4]

Abstract: In addition to β-amyloid-containing extracellular plaques and tau-containing intracellular tangles, Alzheimer's Disease (AD) is characterized by neuronal and synaptic loss in specific areas of the brain. One process that likely contributes to this destruction is the intracellular caspase cleavage of the amyloid precursor protein (APP) resulting in the release of the toxic and short-lived C-terminal 31 aa fragment (C31). We previously found that if we block this C-terminal cleavage of APP, cell death as well as many mouse AD phenotypes were prevented. Here, we show methods we have developed and findings we have made using a new D664 (of APP695) cleavage site-specific antibody (APP delta C31) to measure the level of the resulting N-terminal fragment and our progress toward discovering inhibitors of this process. The techniques we have utilized and developed thus far with this APP delta C31 antibody include immunoassays (ELISA and AlphaLISA), immunoblot, and immunoprecipitation. The cell model we use here is Chinese Hamster Ovary cells stably transfected with APP770 (CHO-7W). We are able to generate cleavage at the D739 site (of APP770) by treating the cells with some statins or staurosporine and we are also able to knock down this signal with the pan caspase inhibitor Q-VD-OPh in a dose-dependent manner. AlphaLISA is used as a high-throughput screening tool to identify hits and an APP delta C31 ELISA kit is used to validate these hits. Thus far, we have tested caspase inhibitors and small molecule compound libraries where we have identified several hits that are effective at lowering the APP delta C31 signal in a dose-dependent manner. As further validation of hits, we are using *ex vivo* organotypic hippocampal slice cultures from young I5 mice (overexpressing hAPPwt). Using this model system, we are able to show significant APP delta C31 signal stimulation with cerevastatin and almost complete knockdown with Q-VD-OPh. In addition, we have performed immunoblots to detect APP delta C31 where we demonstrate results similar to those obtained by ELISA as well

as the antibody's specificity for cleaved APP. This antibody is also able to immunoprecipitate APP delta C31. In summary, this new APP delta C31 antibody and ELISA kit have proven to be extremely useful tools for detecting the N-terminal fragment resulting from the intracellular caspase cleavage of APP in cell lysates, organotypic hippocampal slice cultures and CSF. This APP fragment could be a potential biomarker for AD and thus, in addition to the *in vitro* and *ex vivo* testing shown here, these techniques would also be useful for *in vivo* testing of caspase inhibitors and other compounds found effective at inhibiting this cleavage.

Title: Modulation of amyloid precursor protein (APP) processing by growth associated protein 43 (GAP-43)

Authors: K. TRACY, A. MILLER, E. SAVAGLIO, *E. M. NORSTROM
Biol. Sci., Depaul Univ., CHICAGO, IL

Abstract: The neurodegenerative disorder Alzheimer's disease is characterized by the accumulation in the brain of the beta-amyloid (Aβ) peptide, which is derived from the proteolytic processing of the amyloid precursor protein (APP). The peptide is released by proteolytic cleavage of APP, first by the β-secretase enzyme and subsequently by the enzyme complex γ-secretase which releases the peptide into the extracellular space. In an alternative processing pathway, APP can first be cleaved by α-secretase activity within the Aβ segment precluding its formation. In this case, subsequent cleavage by γ-secretase releases the non-pathogenic P3 peptide. Thus, cellular proteins that may modulate these processing fates are of great interest. A previous proteomic screen of *in vivo* APP-interacting proteins identified growth associated protein 43 (GAP-43) as a potential APP-interacting protein. Like APP, GAP-43 is present at the presynaptic terminal and in growth cones, and brain levels are decreased in severe Alzheimer's disease. Here, we show that APP and GAP-43 can be co-immunoprecipitated from cultured cells expressing both proteins. Expression of GAP-43 alters APP processing by reducing the generation of C-terminal fragments that result from the activity of α- and β-secretase. These effects are dependent on the palmitoylation of GAP-43 at cysteines 3/4. Mutations of cysteines 3 and 4 to alanine eliminated the effect of GAP-43 on APP processing. Moreover, mutant GAP-43 did not co-immunoprecipitate with APP. These effects were consistent with co-localization experiments by fluorescence microscopy. The effect of GAP-43 phosphorylation at serine was also tested for its effect on APP processing using co-expression in cell culture. These data support a model in which palmitoylation of GAP-43 induces membrane localization in the molecule where efficient interaction with APP can occur to modulate its processing.

Title: Aberrant Subcellular Distribution of CREB/PCREB in Alzheimer's disease

Authors: *P. MEMAR ARDESTANI, M. SHAMLOO
Stanford Univ., Palo Alto, CA

Abstract: Cyclic AMP response element-binding protein (CREB) is a nuclear transcription factor that regulates the expression of genes involved in neuronal survival and cognitive

function. The phosphorylated form of CREB (pCREB) binds to the coactivators, CREB binding protein (CBP) and p300, and facilitates expression of its target genes. Previous studies have reported that CREB-mediated gene expression is impaired in Alzheimer's disease (AD). An impairment in nuclear translocation of phosphorylated proteins has previously been shown in other experimental models of the neurodegenerative diseases such as Parkinson's disease (PD). Here we evaluated cellular distribution of CREB /pCREB in experimental model of the AD. We have shown that CREB and pCREB levels are lower in nuclear fraction of brain lysates from Thy1-APP$^{Lond/Swe}$ mouse model of AD compared with their wild type littermates. Furthermore in primary hippocampal neurons of Thy1-APP$^{Lond/Swe}$ mice, pCREB/CREB is localized to the cytoplasmic fraction while in wild type neurons pCREB/CREB is localized to the nucleus. In conclusion, we have shown an aberrant localization of the CREB/pCREB to cytoplasm in both *in vivo* and *in vitro* models of AD.

Title: Characterizing G-quadruplex mediated regulation of the amyloid precursor protein expression

Authors: *E. M. CRENSHAW[1], B. LEUNG[1], N. SEBASTIAN[1], S. ANSALONI[1], P. BEVILACQUA[2], A. J. SAUNDERS[1]
[1]Drexel Univ., Philadelphia, PA; [2]Penn State Univ., University Park, PA

Abstract: Alzheimer's disease is an age-related, progressive, neurodegenerative disease, which is the most common form of dementia in the developed world. It is the 6th leading cause of death in the United States and the prevalence of this disease is increasing. Neuropathologically, Alzheimer's disease is defined by the accumulation of the β-amyloid (Aβ) peptides and hyperphosphorylated forms of tau. The accumulation of these species leads to synaptic dysfunction, neuronal loss that eventually results in cognitive decline. Most cases occur after the age of 65 years (late-onset), however there are a small number of cases that occur before the age of 60 years (early-onset). Alzheimer's disease can be caused by genetic changes that result in increased Aβ production. Aβ is produced by the proteolytic cleavage of the Amyloid Precursor

Protein by the β- and γ-secretases. Individuals with Down's syndrome (Trisomy 21) have an additional copy of the APP gene, which is located on chromosome 21, and invariably develop Alzheimer's disease because of increased APP proteolysis and Aβ production. This strongly suggest that dysregulation of APP expression could play a role in Alzheimer's disease pathogenesis. Therefore it is imperative to identify mechanisms underlying the regulation of APP expression. Our lab has recently identified the presence of a Guanine Quadruplex located in the 3'untranslated region of APP. A Guanine Quadruplex is a sequence of guanine repeats that fold into secondary structures which can regulate gene expression. Guanine Quadruplexes are conserved sequences that have been located in DNA as well as in the 5' or 3' untranslated regions and coding sequences of mRNAs. Guanine Quadruplexes are emerging as important regulatory sequences of expression. Using Circular Dichroism, we structurally confirmed the presence of the Guanine Quadruplex in the 3' untranslated region of the Amyloid Precursor Protein; as well as a Luciferase Assay and reporter constructs to demonstrate that the Guanine Quadruplex sequence negatively regulates Amyloid Precursor Protein expression in a post-transcriptional manner.

Title: Acute effects of amyloid beta 42 on the GUT enteric nervous System (ENS)

Authors: *H. RABE, A. BRAUN, K.-H. SCHÄFER
IMST/ALS, Fh-Kaiserslautern, Zweibrücken, Germany

Abstract: Introduction The enteric nervous system (ENS) is one component of the neural control system of the digestive tract. It works in concert with the CNS, integrative pathways that pass through sympathetic ganglia and the gastro-enteropancreatic endocrine system. The ENS mirrors the central nervous system in its inner architecture, the dense neuropil and the variety of individual neuronal subtypes. Therefore, molecules like amyloid beta (Abeta), which influences CNS neurons via its neurotransmitter receptors, have theoretical the ability for direct interactions with ENS neurons. Here we investigated influences of Abeta on the ENS, in particular the

participation of the alpha7 nicotinic acetylcholine receptor (α7nAChR) with electrophysiological methods, calcium-imaging, and GUT motility measurements. Methods and Results Abeta was generated with a transgenic neuroblastoma cell line (SH-SY-5Y). The neuronal activity of dissociated ENS cell cultures was measured with a multi electrode array system (MCS). Counts of action potentials and spikes amplitudes were analysed in control medium, in pre-incubated control medium, in medium containing Abeta peptides, and in Abeta medium with 0.1 μM methyllycaconitine (MLA), respectively. The Abeta42 peptides containing medium strongly reduces firing frequencies in about two thirds of all responding electrodes. Additionally applied MLA moderates the Abeta effect significantly. In calcium imaging experiment with Fluo-4 AM we could confirm a cytotoxic effect of Abeta on short time cultured ENS cells. We observed a strong dose dependent increase of the intracellular calcium concentration when 1 μM and 10 μM Abeta was applied to cells. Furthermore MLA significantly blocked the calcium elevation induced by Abeta. Gastrointestinal motility changes were monitored and evaluated as described by Schreiber (Schreiber et al., 2013). Small intestine with mesenteric arteries were dissected from healthy adult rats. In an organ bath approach the gut segment was perfused with amyloid containing medium and with Abeta medium containing MLA, respectively. The perfusion of the gut with Abeta conditioned media led to a dramatic increase of the smooth muscle tonus, combined with a decrease of the gut diameter. This effect was significantly weaker when the small intestine was perfused with Abeta medium containing 0.1 μM MLA. Conclusion Amyloid beta features strong and direct effects on the electrical activity of ENS cells and on the network activity of the ENS in the GUT. Due to the prohibiting effects of the specific blocker MLA an important part of Abeta effects on the ENS were induced via the α7nACh receptors.

Title: Endothelin-converting enzymes modulate intracellular Aβ accumulation and aggregation

Authors: ***J. PACHECO-QUINTO**, A. MESZAROS, E. ECKMAN
Biomed. Res. Inst. of New Jersey, Cedar Knolls, NJ

Abstract: It is widely accepted that the extensive accumulation of amyloid beta peptide (Aβ) aggregates in the brain, in the form of insoluble amyloid deposits and soluble oligomers, contributes to synaptic dysfunction and neuronal loss in Alzheimer's disease (AD). However, the pathophysiological mechanisms leading to imbalances in Aβ homeostasis and eventual Aβ accumulation and aggregation are not well understood. Of the several physiologically relevant Aβ degrading enzymes, the endothelin-converting enzyme family (ECE) has the unique characteristic of degrading Aβ in compartments where Aβ production takes place. Our work has brought to light that ECEs, rather than participating in the clearance of excess extracellular Aβ, degrade the peptide before secretion, in early and recycling endosomes, and degrade *in situ* a pool of intracellular Aβ produced along the endosomal/lysosomal pathway. In SH-SY5Y cells overexpressing human wild type APP, we found that pharmacological inhibition of endogenous ECEs caused Aβ to accumulate to micromolar levels within late endosomes, and led to the formation of soluble Aβ oligomers. Combining ECE inhibition with other factors known to influence AD pathology such as ApoE, high levels of cholesterol, or disruption of lysosomal function, led to the formation of insoluble Aβ species associated with intracellular lipid rafts. While in undifferentiated cells Aβ was found accumulated in the soma, in polarized/differentiated cells the accumulation of intracellular Aβ was predominantly observed along neurites, suggesting that ECEs may degrade Aβ along the retrograde transport pathway. Using synaptosomal preparations from rat brain, we also obtained evidence of ECE activity in synapses. Secretion of Aβ from these preparations was enhanced when ECEs were inhibited. Based on these results, we propose that ECEs degrade Aβ within at least two types of Aβ-producing vesicles; presynaptic vesicles that discharge Aβ at the synaptic cleft and vesicles of synaptic origin that preserve the ability to generate Aβ during retrograde transport. Failure in ECE activity may enhance synaptic Aβ secretion and accumulation of Aβ along axons and presynaptic ends, in concentration high enough to induce Aβ aggregation. Understanding whether ECE dysfunction represents an early step in AD progression may help to formulate novel therapeutic and prevention strategies.

Title: SHRSP - a valid model for mixed neurodegenerative and vascular pathologies?

Authors: ***S. NIKLASS**[1], C. GARZ[1], C. Z. BUECHE[2], K. G. REYMANN[2,3], H.-J. HEINZE[1,2,3], M. M. M. WILHELMUS[4], S. SCHREIBER[1]
[1]Otto-von-Guericke Univ., Magdeburg, Germany; [2]German Ctr. for Neurodegenerative Dis. (DZNE), Magdeburg, Germany; [3]Leibniz-Institute for Neurobio. (LIN), Magdeburg, Germany; [4]VU Univ. Med. Ctr., Amsterdam, Netherlands

Abstract: Background: In human autopsy studies of the non-demented elderly and Alzheimer's disease small vessel pathology, parenchymal amyloid-ß (Aß) aggregates and accumulations of intraneuronal hyperphosphorylated tau (ptau) and neurofibrillary tangles (NFT) are observed simultaneously. Whether neurodegeneration and cerebral small vessel disease (CSVD) occur independently or whether there is a link between both phenomena is poorly understood; indeed, corresponding non-transgenic animal models are rarely established. Within our study we assessed whether spontaneously hypertensive stroke-prone rats (SHRSP) - a valid model of human CSVD - are suitable to investigate the interplay of mixed neurodegenerative and vascular pathologies. Methods: Brains of 88 SHRSP and 44 Wistar controls (12-44 weeks) with age-related microangiopathic changes were investigated for the existence and expression of the amyloid precursor protein (APP, western blotting, immunohistochemistry), Aß accumulations (HE-staining, Congo red (CR) staining, immunohistochemistry), ptau, (immunohistochemistry) and NFT (silver staining). Pilot studies using Methoxy-X04 (CR derivate, 2-photon-microscopy) were conducted for intravital detection of Aß in SHRSP. Results: SHRSP develop different age-related CSVD stages: blood-brain-barrier (BBB) disturbances (starting at an age of 18 weeks), microbleeds (24 weeks), microthromboses and infarcts (31 weeks). Already at an age of 20 weeks, when CSVD is dominated by BBB breakdown, SHRSP show a significant higher APP expression compared to the control group. Starting at an age of 20 weeks there was a significantly age-dependent incidence of parenchymal Aß depositions in SHRSP compared to controls; contrary cerebral amyloid angiopathy (CAA) was seen in only few animals. In Aß positive SHRSP ptau and NFT were detectable four to six weeks after Aß depositions occurred. Pilot data suggest a possible intravital detectability of perivascular Aß. Conclusions: SHSRP, a non-transgenic experimental model of CSVD, develop temporal neurodegenerative changes in line with the "amyloid cascade hypothesis". SHRSP might therefore serve as suitable model to investigate the interplay between vascular and neurodegenerative pathologies. Further investigations have to shed light on the issue whether APP up-regulation or Aß drainage disturbances drive the amyloid pathology in this model.

Title: Impaired cholesterol homeostasis increases the secretion of Aβ peptide in FAD-associated presenilin mutant

Authors: *Y. CHO, O.-H. KWON, Y. CHUN, S. CHUNG
Dept. of Physiol., Sungkyunkwan Univ., Suwon, Korea, Republic of

Abstract: Mutations in presenilin genes (PS1 and PS2) are responsible for the majority of Familial Alzheimer's disease (FAD). PS mutations lead to several key cellular phenotypes, including alterations in proteolysis of β-amyloid precursor protein (APP) and Ca^{2+} entry. We previously showed that the level of phosphatidylinositol-4,5-bisphosphate (PIP2) is down-regulated in FAD mutant cells, which is responsible for the increased secretion of β-amyloid peptide (Aβ) (Landman et al., 2006). It is also reported that PS mutant elevates levels of cholesterol due to the increased expression of CYP51, which plays a critical role for the cholesterol synthesis (Tomboli et al., 2008). Thus, in addition to a diverse array of molecular and cellular functions, PS is involved in the metabolism of both cholesterol and PIP2. In this study, we tested whether there exists functional link between the impaired cholesterol homeostasis and the down-regulation of PIP2 in PS mutant cell. Consistent with previous report, cholesterol level was increased in PS mutant cell compared to PS wild type cell. When PS mutant cell was incubated with CYP51 specific inhibitor, cholesterol level was decreased to that of control cell. In contrast, cholesterol level in PS wild type cell was not changed by CYP51 inhibitor. PIP2 level was increased significantly to that of control cell by CYP51 inhibitor, which suggest that the impaired cholesterol homeostasis caused the down-regulation of PIP2. Consistent with the close relationship between PIP2 level and secretion of Aβ, CYP51 inhibitor decreased Aβ levels from PS mutant cell. These results suggest that cholesterol and PIP2 metabolism is closely linked under the regulation of PS, and that the impaired cholesterol homeostasis is underling mechanism for the increased secretion of Aβ.

Title: Roles of insulin-like growth factor-II receptor and lysosomal enzymes in Alzheimer's disease pathology

Authors: *Y. WANG[1], D. WESTAWAY[2], S. KAR[3]
[1]Psychiatry, [2]Med., [3]Psychiatry and Med., Univ. of Alberta, Edmonton, AB, Canada

Abstract: The insulin-like growth factor-II (IGF-II) receptor is an important regulator of the endosomal-lysosomal (EL) system involved in the transport of newly synthesized lysosomal enzymes cathepsins B and D from the trans-Golgi network to endosomes. Evidence suggests that up-regulation of certain lysosomal enzymes within lysosomes can prevent sub-lethal damage, whereas sustained release of the enzymes into cytosol can induce cell death via cytochrome c release from mitochondria. However, very little is known about functional interrelationship between the IGF-II receptor and lysosomal enzymes and their significance in Alzheimer's disease (AD). Since EL system is critical in the generation of β-amyloid (Aβ) peptides, which play important roles in the degeneration of neurons and development of AD pathology, we hypothesize that release/activation of lysosomal enzymes may participate in Aβ-mediated toxicity and development of AD pathology. We used oligomeric human β-amyloid (Aβ)1-42-induced primary mouse cortical neuronal death model to evaluate the levels/activities and subcellular distributions of IGF-II receptor and lysosomal enzymes i.e. cathepsins B and D during neurodegeneration. In addition, we explored the neuronal death mechanisms using different cell death pathways. Ongoing experiments are also being carried out in the cortex of mutant APP transgenic mice such as TgCRND8 mouse models of AD. We found levels of cathepsins B and D and to some extent the IGF-II receptor were increased with time during the oligomeric Aβ1-42-induced neuronal death. The increased cytosolic release of cathepsins B and D was associated with increased expression of pro-apoptotic molecular markers such as Bcl-2-associated X protein, cytosolic cytochrome c, cleaved caspase 3 and nuclear translocation of apoptosis inducing factor. In parallel, our experiments with transgenic mice overexpressing Aβ also showed increased levels of IGF-II receptor and cathepsins B and D in the vulnerable cortical regions of the brain compared to control mice. These results, taken together, suggest a direct role

for cathepsins B and D in AD pathogenesis. Supported by grant from Canadian Institutes of Health Research.

Title: Alzheimer's disease transgenic mice exhibit impairments in spatial discrimination that coincide with alterations in hippocampal neurogenesis

Authors: U. TOSI[1], M. S. PYFER[2], A. HAZRA[2], X. ZHANG[2], *J. CHIN[2]
[1]Biol. Basis of Behavior, Univ. of Pennsylvania, Philadelphia, PA; [2]Dept. of Neurosci., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Alzheimer's disease (AD) is characterized by progressive cognitive deficits and memory loss. Studies in transgenic mouse models of AD can provide insights that are difficult to obtain in human patients. Transgenic mice that overexpress human amyloid precursor protein (APP) carrying mutations linked to familial autosomal dominant forms of AD are often used to assess the role of APP and the Abeta peptides produced from it. Our studies in APP mice aimed to understand how APP and/or Abeta affect cognitive function. We focused on the hippocampus, a brain region that is critical for memory formation and is particularly vulnerable in AD. We developed a novel task to assess spatial discrimination, the ability to distinguish and remember similar patterns or contexts, which is heavily dependent on the hippocampus. Using this task, we found that APP mice exhibit age-dependent deficits in spatial discrimination. Because adult-born neurons in the dentate gyrus of the hippocampus are particularly important for spatial discrimination, we examined the timecourse of alterations in neurogenesis with respect to the development of deficits in spatial discrimination. Our studies demonstrate that alterations in hippocampal neurogenesis develop in concert with deficits in spatial discrimination in APP mice,

suggesting a link between the two. Finally, we found that alterations in Wnt signaling pathways in the hippocampus of APP mice may play an important role in initiating dysregulation of neurogenesis and downstream hippocampal function. Together these results suggest that restoring Wnt signaling may normalize hippocampal neurogenesis and improve cognitive function.

Abstract: Previous research has shown that diabetes type 2 is a risk factor for developing Alzheimer's disease (AD), and emerging research has implicated AD brain dysfunction in the pathogenesis of diabetes. Both diseases processes are associated with increased oxidative stress, inflammation, increased expression of Advanced Glycation End products, and cognitive deficits. While some studies have looked at the effect of the AD state on the development of obesity, very little research has examined the effect of an obese, insulin-resistant state on the development of AD, or the possible therapeutic value of diet reversal interventions on cognition and behavior. The present project was designed to test the hypothesis that obesity and insulin resistance would accelerate AD neuropathology (amyloid levels, inflammatory response, oxidative stress), and cognitive dysfunction in a mouse model of AD. Seventy-two male and female APPSWE/PSEN1deltaE9 transgenic mice and wildtype littermates were used in the present study. Mice were group-housed, and diet interventions (high-fat: 60% kcal fat from lard; low-fat:

10% kcal fat. Research Diets) began at 2-months of age and continued for 4 months. At 6-months of age, mice were tested in a variety of behavioral tasks: open-field, elevated zero maze, y-maze, contextual fear conditioning, and nest building. Fasted blood sugar levels were taken to confirm diabetic state in high fat fed mice. Inflammatory and astrocytic markers (TNF-alpha, IL-1b, IL-6, S100b, GFAP) and RAGE were measured in cortex using western blotting. Amyloid-beta levels in hippocampus were measured using ELISA. After behavioral testing, a subset of mice were switched from a high-fat to a low-fat diet to examine whether diet intervention could ameliorate inflammation, as well as behavioral and cognitive dysfunction. High-fat diet fed mice showed higher fasting blood sugar levels compared to low-fat diet fed mice. Both genotype and high fat diet impacted locomotor activity, with APP/PSEN1 mice traveling greater distances than wildtype mice and hypoactivity seen in high fat fed mice. Given the greater numbers of people reaching older ages and becoming at-risk for AD, and the increasing prevalence of obesity, it is critical to demonstrate both the pathological changes that drive cognitive deficits, and more critically, low-cost interventions that can ameliorate them.

Title: The effect of progranulin loss on an alzheimer's mouse model

Authors: ***C. VOLLERT**, K. NGO, H. POURZARGHAM, J. L. ERIKSEN
Pharmacol. and Pharmaceut. Sci., Univ. of Houston, Houston, TX

Abstract: Alzheimer’s Disease (AD) is the most common cause of neurodegeneration in patients over the age of 65. Pathological hallmarks of AD include the formation of plaques and neurofibrillary tangles in the brain that lead to gross loss of brain function. Recent evidence has shown that mutations in the human progranulin gene (GRN) are associated with frontotemporal lobar dementia with ubiquitinated TDP-43 inclusions. Current studies suggest that reductions in

progranulin expression have a broad importance for neurodegenerative disease and may represent a possible a risk factor for AD. Despite a growing interest in the role of PGRN in dementia, there are no studies characterizing the behavioral and neuropatholgical effects of PGRN haploinsufficiency in an AD transgenic mouse model. In this study, we conducted a series of behavioral tests assessing motor performance, emotion and memory in an AD mouse model. In addition we examined the effect of PGRN reduction on amyloid-associated pathology using immunohistochemistry and western blot techniques. We report that PGRN haploinsufficiency in an AD transgenic mouse model results in significant behavioral alterations.

Title: The role of copper deficiency and zinc in a mouse model of early onset Alzheimer's disease

Authors: ***S. N. HOWELL**, P. B. BOZZELLI, J. M. FLINN
Psychology, George Mason Univ., Fairfax, VA

Abstract: While significant advances have been made in understanding the neural mechanisms of Alzheimer's disease (AD), many aspects remain unknown. A more recent theory revolves around the effects of metals in the diseased brain. Building on research previously conducted in our lab, this study examined the roles of two particular metals, zinc (Zn) and copper (Cu), in a mouse model of early onset AD. The aforementioned studies found that excess Zn caused behavioral impairments in rats and mice. Further, it was found that the addition of Cu to the Zn enhanced water remediated the negative effects seen in the purely Zn group; this information supports the theory that excess Zn causes a Cu deficiency. To test this theory it is necessary to look at a Cu deficiency directly. For this purpose, we developed a specialized Cu control and Cu deficient diet (differing only in levels of Cu) with Harlan laboratory nutritionists. Wildtype (Wt)

(C57Bl/6J) and transgenic (Tg) mice with one copy of a mutated human amyloid precursor protein (hAPP) gene (J20, breeders obtained from the Jackson Laboratory) were raised according to one of three groups: a strictly control group (lab water + control diet), or one of two experimental conditions involving excess Zn (Zn water + control diet) and a diet deficient in Cu (+ lab water). Mice were ran in two behavioral tasks, novel object recognition (NOR) and Morris water maze (MWM), aimed at identifying the effects of the metals on memory deficits seen early in AD patients. Mice were tested beginning at 6 months of age. Preliminary data indicates an early protective role of Cu deficiency for the Tg mice. Tg mice on the Cu deficient diet performed better than Tg controls, but not significantly so, and significantly different in some measures of object recognition (NOR) and latency (MWM) than the zinc enhanced animals. Tg Cu deficient mice show similar trends in both tasks to the Wt mice on the Cu control diet.

Title: Modeling the co-morbidity of vascular dementia and amyloid pathology of Alzheimer's disease

Authors: ***E. M. WEEKMAN**, T. L. SUDDUTH, H. M. BROTHERS, K. BRAUN, D. M. WILCOCK
Physiol., Univ. of Kentucky, Lexington, KY

Abstract: Vascular dementia (VaD) is the second most common cause of dementia behind Alzheimer’s disease (AD) and it is estimated that 40% of AD patients have VaD. Due to a lack of mouse models, VaD is a relatively understudied area and the effects of VaD on AD is also undetermined. The goal of this study was to determine the effects VaD has on amyloid pathology. Induction of hyperhomocysteinemia (HHCy) through a diet deficient in folate, B6, B12 and enriched in methionine in wildtype mice leads to cortical microhemorrhages and cognitive deficits and provides a mouse model to study one form of VaD. In this study, both wildtype (WT) and APP/PS1 transgenic mice aged 6 months were placed on the HHCy or

control diet for 6 months. Cognition was assessed through the radial arm water maze. Aβ levels were quantified using immunohistochemistry, Congo red staining and ELISA measurement. Neuroinflammation was assessed by qPCR for gene markers specific for peripheral macrophage phenotypes. Matrix metalloproteinase (MMP) activation was measured by gelatin zymography and microhemorrhages were assessed by Prussian blue staining. In the radial arm water maze, wildtype mice on the HHCy diet and APP/PS1 mice on control diet were similarly impaired when compared to WT mice on control diet. APP/PS1 mice on the HHCy diet had an even greater impairment than WT mice on the HHCy diet or APP/PS1 mice on control diet. Aβ measurement through both immunohistochemistry and ELISA quantification showed no significant changes, but Congo red staining for dense plaques showed an increase in cerebrovascular amyloid and a decrease in parenchymal amyloid in APP/PS1 mice on the HHCy diet. The HHCy diet induced an M1 phenotype in WT mice and caused a switch from an M2a to an M1 phenotype in APP/PS1 mice. Finally, MMP2 and MMP9 activity and microhemorrhages were increased in WT mice on the HHCy diet and were even higher in APP/PS1 mice on the HHCy diet. Overall, we have successfully modeled mixed dementia through induction of VaD with the HHCy diet and amyloid deposition in APP/PS1 transgenic mice. This mixed dementia results in a neuroinflammatory phenotype switch, increased cerebrovascular amyloid, activation of MMPs and increased microhemorrhages. There is also an additive effect on cognitive outcomes that is similarly seen in human patients with VaD and AD.

Title: Accelerated impairment of learning and memory by presenilin 2 mutation in APP transgenic mouse model of Alzheimer's disease

Authors: *Y. KIRINO, Y. KISHIMOTO, A. FUKUTA, A. NAGAO, E. HIGASHIHARA
Tokushima Bunri Univ., Tokushima, Japan

Abstract: Alzheimer's disease (AD) is a chronic neurodegenerative disorder characterized clinically by neuropathological features including abnormal deposition of amyloid β (Aβ) peptides, neurofibrillary tangles, and neuronal loss in selective brain regions. Aβ is produced after sequential cleavage of the amyloid precursor protein (APP) by two proteases, β- and γ-secretases, and highly homologous proteins presenilin 1 and 2 (PS1 and PS2) are important components of the γ-secretase complex. In mouse model studies, it was shown that the PS1 or PS2 mutation accelerated AD-like pathologies with increased Aβ42 production through enhanced γ-secretase activity. Furthermore, cognitive deficits in various types of learning tasks have been reported in PS1/APP double transgenic mice. In contrast, however, there was no report of non-spatial hippocampal learning task including contextual fear conditioning or trace eyeblink conditioning in the PS2/APP double transgenic mice. Hence, in the present study, we aimed to investigate whether PS2 mutation accelerates the onset of learning deficits in AD mouse model overexpressing human amyloid precursor protein (APP) with the Swedish mutation (K670N, M671L) (Tg2576 mice). For this purpose, we generated a double transgenic mouse (PS2Tg2576 mice) by cross-breeding transgenic mice carrying human mutant PS2 (N141I) with the Tg2576 mice. We then tested two types of nonspatial memory task, contextual fear conditioning and long-trace interval (trace interval = 500 ms) eyeblink conditioning as well as a spatial memory task, Morris water maze in the PS2Tg2576 double transgenic mice and in Tg2576 mice, at the age of 3, 4, 6, and 12 months. In Tg2576 mice, the onset of learning deficits in fear conditioning and EBCC was observed at 6 months of age while that in MWM was at 10 months. In contrast, in PS2Tg2576 mice the onset of learning deficits in fear conditioning and EBCC was detected at 3 and 4 months of age, respectively, while that was at 6 months in MWM. Our cross-sectional study has clearly indicated that PS2 mutation significantly accelerates the onset of cognitive impairment of nonspatial and spatial task memory and that it is detected in earlier stage in fear and trace eyeblink conditioning than in MWM.

Title: Nebula/DSCR1 ameliorates APP-induced learning and memory impairments in *Drosophila*

Authors: *J. SHAW[1,2], K. T. CHANG[1,2]
[1]Zilkha Neurogenetic Inst., Los Angeles, CA; [2]USC Neurosci. Grad. Program, Los Angeles, CA

Abstract: Despite the inevitability of developing Alzheimer's disease (AD) neuropathologies for most Down Syndrome (DS) individuals, there is a delay in the onset of dementia suggesting the activation of a neuroprotective pathway. AD is characterized by an age-dependent deterioration in the ability to remember newly learned information. Post-mortem brains from DS and AD patients show an upregulation of a gene called DSCR1 (Down syndrome critical region 1 gene) that encodes an inhibitor of calcineurin, but the relationship between DSCR1 upregulation and memory deficits in AD is not well understood. By using the classical Pavlovian olfactory conditioning test, we demonstrate that *Drosophila* with APP overexpression fails to avoid a shock-paired odor in both a learning and memory task. Interestingly, we show that co-upregulation of Nebula, *Drosophila* homolog of DSCR1, protects against APP-induced learning and memory impairments early in life. Here we systematically evaluate how altering different kinase and phosphatase pathways downstream of nebula/DSCR1 influences APP-induced learning and memory deficits during aging. A greater understanding of the cell signaling pathways abnormally regulated in aging Alzheimer's and Down syndrome patients has the potential to identify targets for therapeutic intervention in delaying declines in learning and memory performance.

Title: Early amyloid deposition in the anterior olfactory nucleus correlates with specific mixture discrimination deficits in 5xFAD mice

Authors: *D. K. MURPHEY[1], D. KOYYAGUNTALA[2], B. ARENKIEL[1]
[1]Neuroscience, Genet., Baylor Col. of Medicine/Jan and Dan Duncan Neurolog. Res. Inst., Houston, TX; [2]Duke Univ., Durham, NC

Abstract: The same circuits that subserve complex odorant processing are exquisitely susceptible to dysregulation/attrition in neurodegenerative conditions such as Alzheimer's Disease (AD). Studies reveal that early olfactory phenotypes coincide with the onset of memory impairment. In both humans and mouse models of AD, Aβ plaque deposition occurs early in the anterior olfactory nucleus (AON). The 5xFAD mouse represents a robust AD model in its early and severe amyloid pathology, memory deficits, and pyramidal cell loss. However, olfactory deficits in this model have not been well characterized either anatomically or functionally, an endeavor which may prove diagnostically useful in AD patients, who demonstrate early compromise of olfaction. To determine the earliest olfactory area affected by AD, we performed immunohistochemical stains of Aβ in mice ages 4 months, 6 months, and 12 months and found that marked plaque deposition is present in the AON prior to the main olfactory bulb (MOB). Unlike the MOB, which processes mostly monomolecular odorants, the AON is thought to process odorant mixtures. We therefore devised a behavioral screen in which 8 2-4 month old 5xFAD animals and 6 age-matched controls performed a cross-habituation task using monomolecular pairs and mixtures of varying degrees of constituent monomolecular odorant overlap. We found that while the control animals could perform all discriminations ($p < 10\text{-}4$ for monomolecular and mixtures of intermediate overlap, $p < 0.02$ for mixtures with more overlap), 5xFAD animals could only perform discriminations of monomolecular pairs ($p < 0.04$). Determining the anatomical and functional abnormalities in an experimentally tractable system affected early in AD will provide opportunities to identify early disease diagnostic markers.

Abstract: Alzheimer's disease associated with development of both amyloid and tau pathologies, and alterations in the neurovascular compartment, that have been hypothesized to play a role in the progression of pathology and cognitive decline. Three decades ago, prostacyclin, an extremely short-lived endogenous lipid metabolite, was first used for the treatment of pulmonary hypertension; this prostanoid has potent vasodilatory, anti-atherothrombotic and pro-angiogenic effects, and is suggested to be protective to neurovascular function, but little is known about its role within the CNS. We hypothesized that elevated prostacyclin expression might be protective in Alzheimer's disease. In this study, we have characterized the effect of constitutively elevated prostacyclin biosynthesis in an APP-overexpressing mouse model of Alzheimer's disease. We found that elevated prostacyclin levels exerted significant effects on learning and behavior, and induced significant changes in pathology. Our data suggest that prostacyclin may be a potential therapeutic target for amyloid-associated pathologies within the CNS.

Title: Cued and contextual fear learning in APP/PS1 mice

Authors: *T. ENDRES[1], G. HÖLZL[1], L. PSOTTA[1], E. EDELMANN[1], V. LESSMANN[1,2]
[1]Inst. of Physiol., Otto-von-Guericke-University, Magdeburg, Germany; [2]Ctr. for behavioral brain sciences (CBBS), Otto-von-Guericke Univ., Magdeburg, Germany

Abstract: To identify novel treatment approaches for Alzheimer's disease (AD) is probably one of the most challenging topics in neuroscience. A couple of studies demonstrated that emotional processing like the recognition of fearful faces or the learning of fear is impaired in AD patients. Interestingly, these impairments occur already at early stages of the etiopathology of AD. Thus, altered emotional processing might be regarded as an early symptom in the development of AD. In the present study, we analyzed different aspects of fear learning in differently aged APP/PS1 mice. This mouse model for AD combines the Swedish APP (KM670/671NL) mutation with the PS1-L166P mutation under control of the Thy1 promoter (Radde et al., 2006, EMBO), resulting in a constant post-developmental expression of Aß and subsequent plaque formation. By testing amygdala-dependent cued fear learning, we observed only slight impairments in 12 months old APP/PS1 mice. In the adjacent fear extinction training, we observed no impairments in the extinction of these cued fear memories, neither in short nor in long-term extinction memory. In contrast to the cued fear learning, we observed deficits in contextual fear learning in six months old APP/PS1 animals. However, the subsequent extinction of these contextual fear memories remained intact. As a non-emotional control experiment we also tested the object recognition memory of these animals and observed no impairments in the short-term memory of these animals. Currently, we are analyzing the amounts of Aß40/42 proteins in the hippocampus, amygdala and medio-prefrontal cortex of the tested animals in order to correlate the local occurrence of these toxic Aß-species with the behavioral performance of the animals. In addition, we started to analyze long-term potentiation (LTP) in hippocampal slices of these mice. Here, first results indicate an impaired LTP in the CA1 region of six months old APP/PS1 mice. In conclusion, these results demonstrate a selective impairment in contextual fear learning in middle-aged APP/PS1 mice. Ongoing experiments aim at detecting a possible inter-individual correlation between expression levels of soluble forms of Aß protein and altered hippocampal synaptic plasticity. This work was supported by the Center for behavioral brain sciences (CBBS) and the Deutsche Forschungsgemeinschaft (DFG, SFB 779/B6).

Title: Age and human Aβ-dependent effect of PS1 mutation in development of Alzheimer-like pathology: Studies in transgenic knock-in mice for Alzheimer's disease mutant Presenilin-1 (PS1(M146V)) and wild-type human APP (hAPPwt)

Authors: *H. S. ZANJANI[1], K. KINUGAWA[1,2], M. DOULAZMI[1,2], M. P. MATTSON[3], J. MARIANI[1,2], C. ROVIRA[1,2]

Abstract: Memory impairment is the major and early cognitive symptom of Alzheimer disease (AD) and has been linked to synaptic deficits. Understanding the mechanisms of these synaptic deficits is essential for preventing dementia. The vast majority of familial AD (FAD) cases are related to presenilin-1 (PS1) mutation. PS1 is part of the gamma-secretase complex and involved in the release of the neurotoxin amyloid Aβ, and PS1 variants activate GSK3β and cause Tau hyperphosphorylation. There are evidences that, independently of its effect on amyloid secretion, PS1 influences the synaptic function and transmitters release. In PS1(M146V)KI transgenic mice there is an overproduction of Aβ42, but murine Aβ fails to aggregate and it is much less toxic than human Aβ. In this study we crossed PS1(M146V)KI and overexpressing wild type human APP AD mice models (hAPPwt) to generate double transgenic hAPPwt/PS1(M146V)KI mice that can secrete human Aβ. In these mice we tested the effect of PS1 mutation on the neuronal function and synaptic plasticity in the presence of human Aβ. We recorded in the CA1 region from hippocampal slices the early LTP in 9-month-old mice. We found no significant differences between control mice: +/+ mice (1,29 ± 0,0027, n=11); +/APP mice (1,242 ± 0,0027, n=10); PS1 KI/KI mice (1,2563 ± 0,0032, n=10). On the other hand there was a clear deficit in the early LTP in the hAPPwt/PS1(M146V)KI mice (0,0997 ± 0,0018, n=11). Therefore this study revealed early Aβ-dependent synaptic deficits caused by the PS1(M146V)KI mutation. For imunohistopathological analysis, brain sections from young and aged WT and transgenic mice were immunostained with anti- β-amyloid protein and anti-paired helical filament-tau (PHF-tau) antibodies. Intracellular immunoreactivities for PHF-tau staining were observed in the transgenic but not in the wild-type mice brains. We found a deposition of fibrillar β-amyloid within cerebral vessels, indicating presence of a cerebral amyloid angiopathy (CAA), in the PS1(M146V)KI, hAPPwt and double transgenic mice at the age of 15 and 21 months but not in the WT mice. An amyloid plaque deposition was observed as well in the 21-month-old double transgenic mice brain indicating progression of PS1 induced pathology in presence of human Aβ and aging.

Title: Voluntary exercise leads to preservation of spatial memory in the TgSwDI mouse model of cerebral microvascular amyloid without reducing Aβ

Authors: M. E. ANDERSON[1], M.-H. OU-YANG[2], F. XU[2], A. KUMAR[1], G. SINGH[1], T. SHUB[1], B. J. ANDERSON[1], W. E. VAN NOSTRAND[2], *J. K. ROBINSON[3,1]
[1]Psychology, [2]Neurosurg., [3]Stony Brook Univ., Stony Brook, NY

Abstract: Despite recent advances in our understanding of the mechanisms that underlie Alzheimer's disease (AD) and related disorders, current pharmacological treatments are only partially effective in improving symptoms. In light of this, modification of life-style factors has become increasingly attractive as a means of delaying the onset or slowing the progression of AD. Epidemiological studies have shown cardiovascular exercise to protect against cognitive impairment in AD. Studies in murine models of AD also suggest that cardiovascular exercise improves cognitive function and some report corresponding alterations of AD pathology. Presently, we investigate the specific effects of voluntary cardiovascular exercise on vascular amyloidosis by using the Tg-SwDI transgenic mouse model of cerebral amyloid angiopathy. Tg-SwDI mice express low levels of familial Dutch/Iowa CAA mutant human APP and develop fibrillar Aβ exclusively in the cerebral microvasculature in the thalamus, subiculum and forebrain, beginning at 3-4 months. Age-matched female Tg-SwDI mice were given 24-hour access to exercise wheels in their home cage for 4 months. At 7.5 months of age, spatial memory and exploratory behavior were assessed in the Barnes maze and 8 radial arm maze. Brain tissue was harvested for quantitative ELISA, as well as immunostaining, for Aβ species. Our results indicate that 4 months of voluntary exercise leads to a preservation of spatial memory task performance without decreasing pools of Aβ or amyloid deposition in the cerebral vasculature and suggest that long-term voluntary exercise provides benefits to cognitive function through targets downstream of Aβ deposition.

Title: titration of biologically active amyloid-β seeds in a transgenic mice model of alzheimer's disease

Authors: ***J. B. BRAVO-ALEGRIA**[1,2], R. MORALES[1], C. DURAN-ANIOTZ[1,3], C. SOTO[1]
[1]Mitchell Ctr. For Alzheimer's Dis. and Related Disorders, Univ. of Texas Hlth. Sci. Ctr. At Houst, Houston, TX; [2]Sch. of Med., Univ. of Los Andes, Santiago, Chile; [3]Univ. of Chile, Santiago, Chile

Abstract: A hallmark feature of Alzheimer's disease (AD) is the misfolding, aggregation and brain accumulation of amyloid-β (Aβ) and tau proteins. AD is considered as a Protein Misfolding Disorder (PMDs), a group of diseases characterized by the misfolding of a native protein into a toxic isoform. PMDs comprise several pathological conditions, including Parkinson's disease, and Transmissible Spongiform Encephalopathies (TSEs) or prion diseases. TSEs are so far the only PMDs considered as infectious. Recent evidence suggests that misfolding of disease-associated Aβ can be transmitted following a prion-like mechanism. However, additional studies need to be done in order to analyze whether Aβ has the biological properties of prions. One of these characteristics is that the extent of pathological transmission should directly depend on the amount of Aβ aggregated seeds administered, i.e. the material must be titrable in transmission bioassays. The aim of this work was to titrate Aβ aggregates in an animal model of AD (tg2576), as well as to find the minimum amount of particles able to accelerate amyloid pathology *in vivo*. A pool of brain extracts coming from old Tg2576 animals was serially diluted. Samples from each dilution were injected into the hippocampus of young tg2576 mice (50 days old). Animals were sacrificed at 285 days old and brain samples were analyzed for amyloid pathology by IHC and ELISA. As previously shown, administration of misfolded Aβ containing brain materials was able to seed the aggregation of endogenous Aβ in Tg2576 mice. A significant increase was

observed for animals injected with the brain dilutions ranging from 10^{-1} to 10^{-6}. Animals injected with the sample representing the higher dilution (10^{-7}) did not show any significant difference when compared to non-injected controls. Importantly, the burden of aggregates observed in animals injected with the samples bearing the highest concentration of Aβ seeds was increased ~400 folds. The titration curve obtained in this experiment was compared to the natural Aβ load spontaneously accumulated by these mice overtime. Our findings suggest that administration of the largest dose of Aβ seeds led to an acceleration of pathology equivalent to several months. Our findings, together with previously published reports, suggest that some aspects of AD pathology might be transmissible. These results show that active Aβ seeds present in the brain of old Tg2576 mice can seed brain amyloidosis in a titrable manner, similarly as observed for infectious prions. These results may contribute to understand the mechanisms implicated in the initiation of Aβ pathology and therefore be useful to develop new therapeutic strategies.

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder that leads to dementia and death. Despite the intense efforts studying AD, we still do not understand its cause(s), and this adversely affects our ability to develop effective treatments and means to prevent it. Recent reports have shown that the antidepressant drug, fluoxetine (Flx), enhances memory and cognition in AD patients. We decided to investigate the influence of fluoxetine over the expression of the potassium channel KCNQ2 in the hippocampus using the McGill Thy1-APP transgenic model carrying the Indiana and Swedish double mutations in the human APP,

which leads to an overproduction of amyloid β peptides (Aβ) and cognitive dysfunction. Previous results show that at the age of 7 months, LTP is affected in the model perhaps due to the distinct presence of plaque formation. Groups were treated for 21 days with saline (placebo) or Flx by intraperitoneal injections in doses of 5mg/kg (diluted in 0.9% saline, total volume will be 100µl). The placebo group included wild-type (n=3) and transgenic mice (n=3) as controls. The Flx treated group included wild-type (n=4) and transgenic mice (n=6). Our results show that KCNQ2 protein levels in wild-type mice, both placebo vs Flx treated groups did not differ. When we compare the placebo groups, lower levels of KCNQ2 where found in the transgenic group vs the wild-type (p=0.01). Another significant difference was observed between transgenic mice, were the treated with Flx showed increased levels of the protein vs the mice that only receive saline solution (p=0.01). When the wild-type and transgenic groups receive Flx, the levels of KCNQ2 did not differ among them, proving that the use of the antidepressant can restore the protein values to the levels observed in animals without APP deposition or AB plaque formation. The information provided showed that fluoxetine treatment can restore KCNQ2 to normal values in treatment for AD.

Title: Age-related changes in feeding behaviour, activity levels, hormones and metabolism in female 5xFAD mice

Authors: *W. H. GENDRON[1], S. PELLETIER[1], R. E. BROWN[1], Y. ANINI[2]
[1]Psychology, [2]Physiol. and Biophysics, Dalhousie, Halifax, NS, Canada

Abstract: The 5xFAD mouse is a double transgenic model of Alzheimer's disease (AD) which carries an amyloid precursor protein (APP) transgene with three mutations and a presenilin-1 transgene with two mutations. The 5xFAD mice have increased beta amyloid (AB)-peptides and develop AB-plaques by two months of age. Weight-loss is a common problem in human AD

patients and we have observed age-related weight-loss in 5xFAD mice. We therefore investigated age-related changes in activity levels, feeding behaviour, body weight, body composition, and feeding-related hormones in female 5xFAD mice and their WT (C57BL/6JxSJL/J F1) controls from 3 to 12 months of age. Levels of grooming and rearing did not differ but 5xFAD mice showed less climbing and jumping ($p<0.05$) and spent more time remaining still ($p < 0.05$) than WT mice. No differences were found in food intake between genotypes but WT mice weighed more than 5xFAD mice ($p < 0.05$). Muscle tissue was collected to evaluate whether mice suffer from sarcopenia (muscle loss) but 5xFAD mice did not differ in muscle mass compared to WT mice. However, the 5xFAD mice had less fat than WT mice ($p < 0.05$). There were no differences in plasma insulin levels or glucose concentrations between genotypes. We conclude that the 5xFAD mice are hypoactive compared to WT mice, that the 5xFAD mouse model does not suffer from sarcopenia, and that the 5xFAD mice have less fat than WT mice, suggesting fat loss is the main contributor to weight-loss in this mouse model. We found no abnormalities in blood glucose or insulin levels in this mouse model, and the poster will report on plasma concentrations of ghrelin and leptin.

Title: A mouse model with distinct features of the Alzheimer disease with psychosis phenotype

Authors: *S. L. ERICKSON[1], P. S. MURRAY[1], E. THIELS[2], P. PENZES[6,7], M. L. MACDONALD[1], M. D. IKONOMOVIC[3], N. A. YATES[4,5], R. A. SWEET[1,8,3]

Abstract: Psychosis in Alzheimer's disease denotes a more severely progressive phenotypic variant of the disease, characterized by more rapid decline in cognition compared to AD without psychosis (AD-P). AD+P aggregates within families with an estimated heritability of 61%. In dorsolateral prefrontal cortex of AD+P cases, we previously found increased disruption of synapse integrity, lower kalirin expression, and greater Aβ42/Aβ40 ratio. As kalirin signaling is particularly important to dendritic spine function in the cortex, lower kalirin expression in AD+P may contribute to the cognitive profile of the AD+P phenotype. To assess the relative contributions of reduced kalirin expression and β-amyloid overproduction *in vivo*, we have generated a genetic mouse model aiming to recapitulate the distinct cognitive and neuropathologic deficits of AD+P. We paired double transgenic Borchelt mice obtained from the Mutant Mouse Regional Resource Center (B6C3- Tg(APPswe,PSEN1dE9) 85Dbo/Mmjax, Jax #004462, [APPswePS1]) with kalirin heterozygotes (Kal+/-) rederived on a C57Bl/6J background. All four genotypes resulting from this cross (Kal+/+APPswePS1 mice, Kal+/-APPswePS1, Kal+/-, WT) were viable and represented in the approximate expected Mendelian ratios. Both Kal+/+APPswePS1 mice and Kal+/-APPswePS1had significantly greater mortality postweaning than WT. Male mice resulting from this cross (n = 11-16/genotype) were evaluated at six months of age in open field (OF), spontaneous alternation (SA), acoustic startle (AS) and prepulse inhibition (PPI) of AS tests. After testing, mice were sacrificed and their cerebral cortex isolated and frozen at -80°C for targeted proteomic analysis. Behavioral performance of both Kal+/+APPswePS1 mice and Kal+/-APPswePS1 was impaired compared to WT on a summary measure of all tests. On individual tests, Kal+/-APPswePS1 mice exhibited significantly greater activity in the OF test compared to WT, as did Kal+/+APPswePS1. Conclusion: At six months of age, when Kal+/+APPswePS1 are just beginning to show significant Aβ deposition, reduced levels of kalirin protein did not appreciably alter behavioral deficits associated with incipient neuropathological features. Future studies will use targeted proteomics to quantify synaptic protein alterations in these animals, and will assess the combined impact of reduced kalirin levels and β-amyloid overproduction on behavior and the synaptic proteome in older animals with extensive amyloid deposition.

Title: Genome-wide transcription and DNA methylation profiling in an APP mouse model of Alzheimer's disease

Authors: *M. C. GUZMAN-KARLSSON[1], Z. LI[1], J. J. DAY[1], E. D. ROBERSON[2], J. D. SWEATT[1]
[1]Dept. of Neurobio., [2]Dept. of Neurol. and Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Epigenetic mechanisms are regulated in response to experience, allowing for dynamic, bidirectional regulation of gene expression necessary for neuronal plasticity and long-term behavioral memory. Evidence from our lab and others suggests that dysregulated epigenetic mechanisms, like post-translational modifications of histones and DNA methylation, may contribute to the neuronal dysfunction and cognitive impairment in Alzheimer's disease (AD). Previous research has focused on the role of histone acetylation with observed reductions in global and locus-specific histone acetylation in animal models of AD that are associated with repressed transcription of memory-related genes. Furthermore, pharmacological inhibition of histone deacetylase (HDAC) enzymes, a manipulation that effectively increases histone acetylation, ameliorates deficits in gene expression, synaptic plasticity and hippocampus-dependent memory. Recently, attention has turned towards DNA methylation, a similarly potent regulator of transcription, plasticity, and behavior that shares extensive cross-talk with histone modifications. Although emerging data suggest that the AD brain might be characterized by global hypomethylation as well as locus-specific hypermethylation, a comprehensive understanding of the role of DNA methylation in AD is still lacking. To further examine this topic we utilized the hAPPJ20 AD mouse model in combination with next-generation sequencing technologies to systematically characterize genome-wide alterations in hippocampal gene expression and DNA methylation. Identification of biologically relevant loci with altered DNA methylation will further our understanding of the role of DNA methylation in amyloid-beta (Aβ)-induced transcriptional dysregulation and cognitive impairment.

Title: Transgene expression in the neuropsin tTA driver line is not restricted to the entorhinal cortex

Authors: T. B. LEERGAARD[1], M. J. YETMAN[2], S. LILLEHAUG[1], J. G. BJAALIE[1], *J. L. JANKOWSKY[2]
[1]Anat., Univ. of Oslo, Oslo, Norway; [2]Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The entorhinal cortex (EC) plays a central role in episodic learning and memory formation, and is among the earliest sites of neuronal loss and neurofibrillary tangle formation in Alzheimer's disease. The EC has therefore been an attractive target for genetic manipulation to selectively modify gene expression or neuronal function in various models of neurological disease. Many such conditional models utilize the neuropsin (Nop) promoter to limit spatial distribution of the tetracycline transactivator (tTA). When crossed with a second tet-responive transgenic line, the resulting bigenic mice will express the transgene of interest in neurons where tTA is active. The Nop-tTA mouse line was reported to restrict tet-responsive transgenes to the superficial layers of medial EC and parts of the pre- and parasubiculum (Yasuda and Mayford, Neuron, 2006), and Nop-tTA mice have been used in several experimental studies examining functional properties of the entorhinal-hippocampal circuitry. The utility of this transgenic driver line is contingent on the specificity of the spatially restricted gene expression, yet detailed neuroanatomical mapping of its expression has not yet been done. We therefore crossed the Nop-tTA driver line with a reporter strain expressing β-galactosidase, and established an online

histological atlas of Nop-tTA regulated gene expression. This atlas resource (available through the Rodent Brain Workbench, www.rbwb.org) was used to perform a detailed brainwide analysis of β-galactosidase labeling in bigenic (Nop-tTA-LacZ) mice. Our findings highlight strong expression in regions beyond the EC and suggest caution in interpreting experiments that depend on precise localization of gene products controlled by the Nop-tTA driver.

Title: A novel target protects against APP-induced age-related neurodegeneration

Authors: *J. T. PIERCE-SHIMOMURA[1], L. L. SCOTT[2], S. IYER[2], G. ZUNIGA[2], J. SAHN[2]
[1]Univ. Texas, Austin, AUSTIN, TX; [2]Univ. of Texas at Austin, Austin, TX

Abstract: Alzheimer's disease (AD) is the sixth leading cause of death in the US, affecting more than 5 million people with sadly no treatment in sight. AD is characterized by protein aggregates and selective degeneration of cholinergic neurons. The sigma receptor family and progesterone receptor membrane component 1 (PGRMC1) have been implicated as mediators of cell death, though a specific role for the sigma receptor 2 (Sig2R) and PGRMC1 in neurodegeneration has not been shown. It is hotly contested whether Sig2R and PGRMC1 is the same target; thus here we use Sig2R as a pharmacological designation and PGRMC1 for the gene. To test for a neurodegenerative role of Sig2R/PGRMC1, we used a *C. elegans* model of neurodegeneration that expresses a single extra copy of the human Amyloid Precursor Protein (*APP*) gene. This SC_APP model displays progressive, age-dependent changes in APP protein regulation in specific cholinergic neurons that subsequently die. Moreover, PGRMC1 has a highly conserved sequence and function in this animal. We found that PGRMC1 null alleles significantly reduced the selective degeneration of cholinergic neurons in older adult SC_APP animals but had little effect on baseline neurodegeneration in control animals. We have previously determined that the accumulation of APP protein in our SC_APP model precedes the apoptosis of cholinergic

neurons. To ascertain if PGRMC1 plays a role upstream of abnormal protein accumulation, we asked if deletion of PGRMC1 in our SC_APP model altered patterned accumulation of APP in the neurons susceptible to degeneration. SC_APP animals bearing a deletion of *PGRMC1* showed significantly lower levels of accumulated APP compared to age-matched middle-aged SC_APP adults with a WT copy of PGRMC1. These data indicate that PGRMC1 can be targeted to restrict the inappropriate accumulation of APP that in turn leads to neuron death in our SC_APP model. To find molecules that might influence the PGRMC1 pathway we screened novel Sig2R ligands for the ability to reduce neurodegeneration. We found two compounds that increase neurodegeneration in both the SC_APP model and control strains. More importantly, we found two compounds that decrease APP accumulation and neurodegeneration in the SC_APP model. These Sig2R ligands do not further reduce neurodegeneration in the presence of PGRMC1-directed knockdown suggesting that Sig2R and PGRMC1 act in the same pathway. Together, our results indicate that Sig2R/PGRMC1 can be targeted to reduce both protein accumulation and neurodegeneration providing promising target(s) for age-related neurodegenerative diseases.

Title: Nitric oxide, platelet and microvascular involvement in AD pathophysiology in aging APP transgenic mice

Authors: R. JAGADAPILLAI[1], A. M. ROBERTS[2], R. VAISHNAV[3], R. P. FRIEDLAND[4], L. R. SACHLEBEN, Jr.[1], *E. GOZAL[5]
[1]Pediatrics, [2]Physiol., [3]Neurology, Physiol., [4]Neurol., [5]Pediatrics, Pharm & Tox, Physiol., Univ. Louisville, LOUISVILLE, KY

Abstract: Alzheimer’s disease (AD) is associated with vascular pathology, small vessel disease, oxidative stress, inflammation and deficiencies of the blood brain barrier (BBB). Vascular injury

is associated with Aβ formation and compromises its clearance, contributing to the pathological evolution of Alzheimer's disease. We have previously shown increased superoxide production, lipid peroxidation, and gliosis in a transgenic mouse model of AD, expressing the human APP gene 770 isoform, with the Swedish, Dutch and Iowa mutations in neurons, under the control of the mouse Thy1.2 promoter. This genetic alteration causes amyloid deposits with Aβ plaque accumulation in parenchyma and cerebral vessels, apparent at 6 months and fully developed at 12 months. Fibrinogen accumulation, interacting with Aβ may also affect clot formation and degradation. NO regulates platelet function and affects fibrinogen binding to platelets and the endothelium, suggesting a central role for platelets in AD physiopathology. Therefore, we investigated a potential role for microvascular injury and platelets in the pathology developed by TgAD mice. We assessed the expression of inducible nitric oxide (iNOS), 3-nitrotyrosine (3-NT), fibrinogen and CD61, a marker of platelets and megakaryocytes in 12 month old wild type mice (WT) and transgenic AD mice (TgAD). Immunohistochemical staining showed significant increases in iNOS, 3-NT, fibrinogen and CD61 cortical expression in TgAD mice compared to WT. While fibrinogen staining appeared localized in WT, the staining seemed more diffuse and abundant in TgAD mice. Increased iNOS expression and superoxide formation in TgAD mice result in enhanced peroxinitrite expression and protein nitrosylation, decreasing NO bioavailability, thus affecting platelet function. These data indicate that Aβ accumulation in TgAD mice is associated with increased fibrinogen and platelet adhesion which in turn may enhance Aβ plaque accumulation.

Title: Epigenetic gene regulation in alzheimer's disease: Neuroprotection versus neuroplasticity

Authors: *J. YOU, B. F. CORBETT, X. ZHANG, A. HAZRA, J. CHIN
Dept. of Neurosci. and Farber Inst. for Neurosciences, Thomas Jefferson Univ., Philadelphia, PA

Abstract: Alzheimer's disease (AD) is characterized by progressive cognitive decline and severe memory loss. As current therapies for AD offer limited benefit, it is critical to better understand the mechanisms underlying cognitive decline in AD. The key finding that AD is associated with seizures may provide valuable insight into these mechanisms. Recent evidence suggests that seizures in AD are not just incidental, but may rather play an active role in contributing to cognitive decline early in disease progression. Consistent with this, treatment of both AD patients and AD mouse models with antiepileptics improves cognitive function. Therefore, understanding the mechanisms by which seizures contribute to cognitive impairment so may enable the discovery of novel strategies to improve cognitive function. Our studies of seizure-related changes in the hippocampus of a transgenic AD mouse model, as well as a pharmacological model of epilepsy, have revealed that expression of the transcription factor ΔFosB is markedly increased by seizures. ΔFosB has an unusually long half-life (on the order of weeks) and interacts with various histone modification enzymes. Identification of key ΔFosB gene targets in AD mice suggests that ΔFosB may serve a neuroprotective function during states of chronic neuronal excitation (such as in epilepsy and AD), but may do so at the cost of synaptic plasticity. Thus, delineation of the actions of ΔFosB in the hippocampus may provide critical insight into the mechanisms by which seizures induce synaptic dysfunction and cognitive impairment in neurological conditions such as epilepsy as AD.

Title: Amyloid-beta (Aβ)-induced depolarization and abnormal responses to leptin in hypothalamic neuropeptide Y (NPY) neurons

Authors: *G. WANG, M. ISHII, C. IADECOLA
Brain and Mind Res. Inst., Weill Med. Col. Cornell Univ., NEW YORK, NY

Abstract: Leptin is an adipocyte-derived hormone that negatively regulates feeding and energy homeostasis, mainly through hypothalamic pathways. In a companion presentation (Ishii et al., this meeting), we expand on our prior studies demonstrating that mice overexpressing the Swedish mutation of amyloid precursor protein (Tg2576) exhibit: (a) low fat mass and pathologically low plasma leptin levels, prior to cognitive decline and amyloid plaques, and (b) lack of the expected neuropeptide Y (NPY) transcriptional response to the low leptin state in the hypothalamus (Ishii et al., SFN 2013). Here, we examined whether the electrophysiological characteristics of hypothalamic NPY neurons are altered in Tg2576 mice and if exogenous $A\beta_{1-42}$ could recapitulate such alterations. Tg2576 mice expressing GFP in NPY neurons were developed by crossing male Tg2576 mice with female NPY-GFP mice and studied at 2-5 weeks of age. Using whole-cell current-clamp in hypothalamic slices (total 69 cells), we found that Tg2576 NPY neurons of the arcuate nucleus have a less negative resting potential (-63.1±4.5 mV; mean±SE) and a reduced spontaneous activity (2.2±0.3 Hz) than WT mice (-73.2±2.0 mV; $p<0.05$, n=10-17 cells/group; WT: 8.5±0.1 Hz; $p<0.01$). Application of leptin (100 nM) hyperpolarized NPY neurons in WT (-9±1.8 mV; $p<0.01$), but not in Tg2576 slices (-1.7±1.8 mV; $p>0.05$). Leptin did not affect spontaneous activity both in WT ($p>0.05$) and Tg2576 NPY neurons ($p>0.05$). On the other hand, application of ghrelin (100 nM), a peptide with physiological effects opposite to leptin (Neuron, 37:649), depolarized NPY neurons in WT slices (+19.9±5 mV; $p<0.01$), an effect attenuated in Tg2576 slices (+5.7±2.1 mV; $p>0.05$). Ghrelin did not affect spontaneous activity in NPY neurons both in WT ($p>0.05$) and Tg2576 slices ($p>0.05$). Oligomeric $A\beta_{1-42}$ (3-100 nM) depolarized WT NPY neurons dose-dependently (EC_{50}=29.7 nM). Furthermore, $A\beta_{1-42}$ (100 nM) suppressed leptin-mediated hyperpolarization (+0.6±0.5 mV, $p>0.05$ form control), and inhibited the depolarizing response to ghrelin (3-100 nM; IC_{50}=10.2 nM). Spontaneous activity was not affected by $A\beta_{1-42}$ ($p>0.05$). These data indicate that oligomeric $A\beta_{1-42}$ disrupts hypothalamic responses to leptin and ghrelin by changing the excitability of arcuate NPY neurons, recapitulating the electrophysiological alterations observed in Tg2576 mice. Collectively, the findings identify hypothalamic NPY neurons as a previously unrecognized target of the deleterious effects of $A\beta_{1-42}$, which may underlie the body weight deficits and pathologically low leptin state seen in young Tg2576 mice and, possibly, in patients with early-stage Alzheimer's disease.

Title: Hypothalamic leptin signaling deficits underlie the metabolic dysfunction in mice overexpressing amyloid precursor protein

Authors: *M. ISHII, G. WANG, C. IADECOLA
Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Weight loss is a prominent feature of Alzheimer's disease (AD) that often occurs before the mental decline and worsens as AD progresses (Arch Neuro 63: 1312, 2006). Low plasma levels of leptin, a fat derived hormone that acts on the hypothalamus to regulate body weight, are associated with increased risk of AD (JAMA 302: 2565, 2009). We previously found that mice overexpressing mutated forms of the amyloid precursor protein (Tg2576) have lower body weight, adiposity and plasma leptin compared to wild-type (WT) littermates, prior to amyloid plaque formation or cognitive decline (Ishii et al., SFN 2013). In addition, the transcriptional response of hypothalamic NPY to the low leptin state was abnormal. We tested the hypothesis that hypothalamic leptin signaling is altered in Tg2576 mice, leading to the low leptin state and associated metabolic dysfunction. To this end, we first used phospho-STAT3 immunohistochemistry to evaluate the hypothalamic signaling response to alterations in circulating leptin in Tg2576 and WT littermates. Acute leptin administration (5mg/kg i.p., n=4/group) led to robust increases in phospho-STAT3 throughout the hypothalamus. However, compared to WT mice, Tg2576 mice had a reduced number of phospho-STAT3 positive cells in the arcuate nucleus (-22±3.4%; $p<0.05$), a critical target of leptin. In a companion presentation (Wang et al. this meeting), we show that the excitability of arcuate NPY neurons is altered by exogenous amyloid-beta1-42 and in Tg2576 mice, providing the electrophysiological correlate of the hypothalamic dysfunction. Next, we evaluated the effects of aging and increasing brain amyloid burden on the metabolic deficits in 14 month-old Tg2576 mice. Aging enhanced the reduction in body weight (3 months: -12±1.3%, 14 months: -24.9±1.2%, n>6/group, $p<0.01$) and plasma leptin levels (3 months: -47.5±7.1%, 14 months: -86.6±3.2%, n=4-15/group, $p<0.05$) in Tg2576 mice. The effect was associated with reduced food intake (-15.6±2.3%, n=6/group, $p<0.05$) and lower plasma insulin levels (-32.6±4.7%, n>4/group, $p<0.05$), changes not seen in younger mice. This suggests that with aging and advanced amyloid pathology alterations in feeding behavior contribute to the metabolic deficits. We conclude that leptin dysfunction is a critical factor in the metabolic alterations observed in Tg2576 mice prior to amyloid deposition and cognitive deficits. The data establish that leptin signaling in hypothalamic neurons is highly

vulnerable to the deleterious effects of amyloid-beta leading to metabolic dysfunction, and, as such, represents a potential therapeutic target for AD. Supported by Leon Levy Fellowship (M.I.) and NS37853 (C.I.).

Title: Behavioral and histopathological analysis of Ames dwarf x Alzheimer's disease (APP/PS1) mice

Authors: ***K. L. PUIG**, S. G. RAKOCZY, H. M. BROWN-BORG, C. K. COMBS
Basic Sci., Univ. of North Dakota, Grand Forks, ND

Abstract: APP/PS1 double transgenic mice expressing human mutant amyloid precursor protein (APP) and presenilin-1 (PS-1) demonstrate robust brain Aβ peptide containing plaque deposition, increased markers of oxidative stress, behavioral dysfunction, and proinflammatory gliosis. On the other hand, lack of growth hormone, prolactin, and thyroid-stimulating hormone due to a recessive mutation in the Prop 1 gene (*Prop1df*) in Ames dwarf mice results in a phenotype characterized by potentiated anti-oxidant mechanisms, improved learning and memory, and increased longevity in homozygous mice. Based upon this, we hypothesized that a similar hormone deficiency might attenuate disease changes in the brains of APP/PS1 mice. To test this hypothesis, APP/PS1 mice were crossed to the Ames dwarf mouse line and brains and behavior were examined. APP/PS1 x Df/Df, APP/PS1 x Df/+, APP/PS1, wild type, Df/+, and Df/Df mice were compared at 6 months of age by behaviorally testing and assessing amyloid burden, reactive gliosis, and brain cytokine levels. As expected, Df/Df mice demonstrated attenuated brain growth hormone (GH) and insulin-like growth factor 1 (IGF-1) concentrations. This correlated with attenuated astrogliosis and microgliosis in the APP/PS1 x Df/Df mice and, surprisingly, attenuated Aβ plaque deposition and Aβ 1-40 and Aβ 1-42 concentrations.

APP/PS1 x Df/Df mice also demonstrated significantly elevated brain levels of multiple cytokines in spite of the attenuated gliosis. Finally, the APP/PS1 x Df/Df mice also demonstrated improved behavioral performance. These data suggest that by crossing these two lines we created a unique resource in which to study aging and resistance to disease.

Title: Amyloid precursor protein localizes in pancreatic islets

Authors: *J. KULAS, C. K. COMBS
Basic Sci., Univ. of North Dakota, Grand Forks, ND

Abstract: Alzheimer's disease (AD) is a neurodegenerative condition characterized by brain accumulation of amyloid beta peptide containing plaques and hyperphosphorylated tau containing tangles. A growing body of literature has also demonstrated a possible link between AD and dysfunction in insulin signaling, including an increased prevalence of AD among patients with type 2 diabetes. Previous work, including our own, has revealed expression of amyloid precursor protein (APP) in a variety of cells outside the brain including those exhibiting a secretory phenotype. Since pancreatic beta cells serve as the primary source of peripheral insulin secretion, we hypothesized that APP may play a role in pancreatic physiology. To begin testing this idea, four different mouse lines were compared; wild type, APP knockout, APP/PS1 and APP/PS1xAPP knockout. Western blot analysis revealed endogenous pancreas APP expression in wild type mice as well as significant over-expression of mutant human APP in the pancreas of both the APP/PS1 and APP/PS1xAPP knockout lines. APP immunoreactivity localized to the pancreatic islets with a dramatic increase in intensity in human APP over-expressing mice. However, there was no detectable immunoreactivity for Aβ in the pancreas nor any quantifiable increase in Aβ1-40 or Aβ1-42 via ELISA from the APP/PS1 and APP/PS1xAPP knockout lines. Comparison to human pancreas supported the murine findings demonstrating

robust APP immunoreactivity within the islets of both normal and diabetic pancreatic islets with no detectable Aβ immunostaining. These data support the idea that wild type or mutant APP may directly regulate pancreatic endocrine cell function perhaps contributing to the proposed insulin receptor signaling dysfunction hypothesized to occur in the brains of Alzheimer's disease patients.

Title: Amyloid precursor protein regulates microglial phenotype in a mouse model of alzheimer's disease

Authors: *G. D. MANOCHA, A. M. FLODEN, K. RAUSCH, L. ROJANATHAMMANEE, K. R. PUIG, K. L. PUIG, C. K. COMBS
Basic Sci., Univ. North Dakota, GRAND FORKS, ND

Abstract: Beta-amyloid peptide containing plaques are one of the major histopathological characteristics of Alzheimer's disease brains. Aβ peptides are derived from the proteolytic cleavage of the ubiquitiously expressed amyloid precursor protein (APP). Although much research has focused on APP cleavage products less effort has been spent studying APP itself. Our prior work demonstrated that APP can behave as a proinflammatory receptor on monocytic lineage cells mediating tyrosine kinase-based activation. Therefore, we hypothesized that it may serve a similar function in microglia. To test this idea, primary murine microglia cultures from wild type and APP knockout mice were stimulated with oligomeric or fibrillar Aβ. Although fibrillar Aβ stimulated increased protein phosphotyrosine levels and TNF-α secretion from both cultures, oligomeric stimulation of APP knockout microglia was significantly attenuated. Although APP knockout microglia cultures had no attenuation of phagocytic ability, they demonstrated significant impairment in migratory ability *in vitro* compared to wild type microglia. Similarly, intracerebroventricular infusions of oligomeric Aβ produced significantly less microgliosis in APP knockout compared to wild type mice. These findings suggested a role for APP in modulating the microglial response to selectively oligomeric Aβ. We next crossed APP knockout mice with mice expressing human mutant APP/PS1 in order to assess whether

absence of murine APP attenuated microgliosis in the presence of accumulations of Aβ oligomers and fibrils *in vivo*. The APP/PS1 x APP-/- mice had significantly reduced microgliosis in spite of similar plaque loads compared to APP/PS1 mice. This correlated with improved memory performance and decreased anxiety in the APP/PS1 x APP-/- mice. These data define a novel function for microglial APP in regulating their migratory ability and response to Aβ peptides which may be relevant for modulating their behavior in Alzheimer's disease.

Title: Effects of physical exercise on cognitive function: endothelial nitric oxide synthase contributing to Aβ accumulation in spontaneous hypertensive rats

Authors: L.-Y. ZHANG[1], J. LUO[1], Z. PEI[2], *R. A. ESPAÑA[4], W.-J. GAO[4], F. LI[3], X.-Q. HU[1]
[1]Rehabil. Med., [2]Neurol., [3]Neurobio. and Anat., Sun Yat-Sen Univ., Guangzhou, China; [4]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Objective This study was aimed to examine whether the effect of physical exercise on nitric oxide synthase(eNOS) is benefit to decrease Aβ accumulation. Methods Twenty spontaneous hypertensive rats (SHR) were randomly divided into physical exercise hypertensive group (PE, n=10), which was given running wheel exercise for 3 months, and a sedentary hypertensive group (SED, n=10). Another 10 Wistar rats were used as normotensive group (NC, n=10) and they were fed in standard cages without any special training exercise. The blood pressure (BP) was monitored and measured every week. The rats were tested with Morris water maze for cognitive performance and were sacrificed for histological and biochemical study. The specific marker heme oxygenase -1(HO-1), endothelial eNOS, and β-site APP-cleaving enzyme

1(BACE1)/Aβ in endothelial cells cerebral cortex, and hippocampus were examined with immunofluorescence staining and western blotting analyses. Results BP in PE was significantly lower than that in SED ($p<0.05$), but was significantly higher compared to that in NC ($p<0.05$). Water maze performance in PE was significantly improved compared with that in SED ($p<0.05$), but was slightly and significantly worse than that in NC ($p>0.05$). Immunofluorescence analysis and western blotting assay in SED showed less HO-1/eNOS expression as compared to NC, but BACE1/Aβ accumulation was significantly up-regulated in endothelial cells, cerebral cortex, and hippocampus. After 12 weeks's training with physical exercise, there were significant up-regulation of HO-1/eNOS expression and down-regulation of BACE1/Aβ expression in endothelial cells, cerebral cortex, and hippocampus. Conclusions Physical exercise decreases BP and improves cognitive function in hypertensive rats through up-regulation of HO-1/eNOS, which may in turn decrease BACE1 expression and Aβ accumulation.

Title: Characterization of amyloid beta oligomeric composition using matrix assisted laser desorption ionization mass spectrometry

Authors: *J. S. WANG[1], K. JURCIC[2], S. WHITEHEAD[3], K. K. C. YEUNG[1]
[1]Chem., [2]Biochem., [3]Anat. and Cell Biol., Western Univ., London, ON, Canada

Abstract: Alzheimer's disease (AD) is currently the most prevalent neurodegenerative disorder, as well as the most common cause of dementia. Accumulating evidence supports the correlation between amyloid beta (Aβ) oligomers and severity of AD. Therefore, research emphasis has been placed on the analysis of amyloid-β aggregation and its influences on the pathology of AD. Aβ is known to aggregate and form soluble oligomers of various sizes, but the primary target of

AD research focuses on the major composition of amyloid plaques found in AD patients, peptides $A\beta_{1-42}$ and $A\beta_{1-40}$. Numerous protocols have been reported for *in vitro* oligomeric $A\beta_{1-42}$ preparations, yet the effect of variations among protocols on the resulting composition is poorly understood. Methods that provide qualitative and quantitative characterization of the monomeric and oligomeric Aβ species are therefore extremely important to oligomeric $A\beta_{1-42}$ research in AD progression and severity. The most common means of Aβ oligomer quantification is gel electrophoresis. However, it has low sample throughput, and gel smearing poses as a significant resolution limitation. Alternatively, the use of electrospray ionization mass spectrometry (ESI-MS) in conjunction with ion mobility (IMS) has been applied to study the assembly of Aβ oligomers. IMS is critical in differentiating oligomers of different sizes with the same m/z; circumvent the issue of overlapping m/z from non-covalent homo oligomers with multiple charge states from ESI. The research described here focuses on a simpler mode of MS based on matrix assisted laser desorption ionization (MALDI). MALDI produces predominantly singly-charged ions, allowing for oligomers of varying sizes to be resolved by a time-of-flight (TOF) mass analyzer. Our results demonstrate that MALDI-MS offers a fast and easy method to measure the extent of Aβ oligomerization. The method has been applied to determine the effect of protocol variations on the resulting composition of the Aβ assemblies.

Title: Evaluating the pathological and behavioural outcomes of amyloid beta oligomers in the rat

Authors: *R. WONG[1], D. F. CECHETTO[2], S. WHITEHEAD[2]
[1]Anat. and Cell Biol., [2]Western Univ., London, ON, Canada

Abstract: Alzheimer’s disease (AD) is the most common form of dementia and is characterized by a progressive neurodegeneration that ultimately leads to cognitive decline. AD typically occurs in the elderly, and with an aging population worldwide, it is projected to increase accordingly. Amyloid beta (Aβ) deposition is considered a key event in the progression of AD, yet Aβ can exist in many structural forms, and each form likely plays a different role during the development of AD. Recently, significant amounts of research have begun to focus on a soluble

oliogomeric form of A. *In vitro* studies have suggested that A oligomers may play a significant role in the progression towards AD from a normal healthy brain. Human studies have also shown the correlation between clinical diagnoses of AD with elevated levels of A oligomers. However, to date, there are few studies studying the effects of A oligomers in an *in vivo* model. The purpose of this project is to identify the spatial and temporal consequences of injecting A oligomers into the rat brain by evaluating pathological and behavioural outcomes. We hypothesize that injecting A oligomers into the rat brain will result in neurodegeneration, neuroinflammation that are concomitant with behavioural and cognitive deficits. A oligomers were characterized by western blot and injected either cortically or intracerebroventricularly into the rat brain. Survival time points were 1, 3, 7 or 21-days post surgery. Pathological using immunohistochemistry and behavioural analyses using the Morris Water Maze were done. Results demonstrate that A oligomers crossed into the parenchyma of the rat brain leading to a neuroinflammatory responses. Overall our results indicate that injection of A oligomers into the rat brain may be an alternative, non-transgenic strategy to investigate the effects of A oligomers in an *in vivo* model.

Title: The interaction between ZnT3 and Amyloid-β in Alzheimer's disease

Authors: *S. M. HANCOCK, D. I. FINKELSTEIN, A. I. BUSH, P. A. ADLARD
The Florey Inst. of Neurosci. and Mental He, Parkville, Australia

Abstract: Introduction: Alzheimer's disease (AD) is the most common form of dementia for which there is currently no treatment or cure. Zinc has been repeatedly linked to AD with alterations in Zn distribution suggested to have a key role in AD. Moreover, a high binding affinity of zinc to amyloid-β (Aβ) has been demonstrated, along with the presence of Aβ plaques around glutamatergic synapses. Zinc transporter 3 (ZnT3) is responsible for loading Zn ions into presynaptic vesicles and is prevalent at glutamatergic synapses within the cortex. Past studies have shown that both ZnT3 mRNA and protein expression levels are altered in AD. We have demonstrated that ZnT3 is present in primary cultured mouse cells (neurons and astrocytes) and

expression levels can be influenced by treatments with zinc and copper. We have further examined the interaction between ZnT3 and Aβ *in vivo*. Method: Transgenic ZnT3 KO and WT mice at either 3 or 12 months of age were anaesthetised and Aβ was unilaterally injected (2ug/5µl in 0.02M PBS) into the right hippocampus (2.54mm from Bregma, lateral 2mm and 2mm depth). Behavioural testing was performed at 7 and 14 days post injection, with animals subsequently culled for biochemical and histological analysis. Conclusion: These analyses will further define the interaction between Aβ and ZnT3, providing insight into the pathogenesis of AD.

Title: N-truncated and pyroglutamate-modified (pGlu) Aβ: On the molecular pathway of formation in Alzheimer's disease

Authors: *S. SCHILLING, D. SCHLENZIG, H. CYNIS, H.-U. DEMUTH
Fraunhofer IZI-MWT, Halle/Saale, Germany

Abstract: A significant proportion of amyloid-beta (Aβ) peptides in Alzheimer's disease (AD) is truncated at the N-terminus and may be post-translationally modified by pGlu. In particular, Aβ3pE-40/42 and Aβ11pE-40/42, have been shown to correlate with disease progression and being overrepresented in early-onset forms of inherited AD. Recently, we could show that Aβ3pE-40/42 form oligomeric structures with considerable surface hydrophobicity which, in turn, mediates a significantly enhanced neurotoxicity. The modification is formed by the enzyme glutaminyl cyclase (QC), which has been shown to be upregulated in AD. A competitive inhibitor of QC is going to enter Phase 2 clinical studies. On our quest to study the role and formation of N-truncated Aβ peptides, we characterized the processing of different APP proteins (wt or familial Alzheimer's mutations) in cell culture models. Using specific ELISA techniques, we could show that APP carrying the Swedish (APP695KM595,596NL]) mutation leads to generation of full-length Aβ (Aβ(1-40/42)), whereas processing of APPwt results in significant formation of N-truncated peptides suggesting alternative processing. Hence, we introduced

several mutations close to the primary β-secretase cleavage site of APP and could demonstrate suppression of BACEI - related Aβ but insignificant reduction of total Aβ formation. Among these constructs, processing of APP695[E599/Q] showed enhanced formation of pGlu-Aβ, which was not influenced or even slightly increased after BACE1-inhibition or expression in a BACE1-ko background. Co-expression of Meprin β, but not Meprin α, resulted in production of N-truncated Aβ peptides Aβ(2-40/42) and Aβ(3-40/42). These results were corroborated by cleavage of APP-related peptides by Meprin *in vitro*. Taken together, these data support that BACE-independent processing of APPwt contributes to formation of N-truncated Aβ. Several proteases have been suggested as potential APP-β site cleaving enzymes. Among such candidate enzymes of alternative processing routes, Processing of APPwt by Meprin can contribute to the formation of N-truncated Aβ. The truncated peptides might be prone to further N-terminal truncation or cyclization by glutaminyl cyclase. Therefore, meprin might represent a potential upstream target to suppress formation of pGlu-Aβ.

Title: Interaction of Alzheimer's β-amyloid peptides with cholesterol: Mechanistic insights into amyloid pore formation and inhibition by bexarotene

Authors: *C. DI SCALA, H. CHAHINIAN, N. GARMY, N. YAHI, J. FANTINI
Aix-Marseille Univ., Marseille Cedex 20, France

Abstract: Brain cholesterol plays a critical role in Alzheimer's and other neurodegenerative diseases. The molecular mechanisms linking cholesterol to neurotoxicity have remained elusive for a long time, but recent data have allowed to identifying functional cholesterol-binding domains in several amyloidogenic proteins involved in neurodegenerative disease, including Alzheimer's disease. We analyse the cholesterol-binding properties of β-amyloid (Aβ) peptides and the impact of these interactions on amyloid pore formation. We show that the cholesterol-binding domains of Aβ peptides and of its transmembrane precursor C99 are partially overlapping but involve distinct amino acid residues, so that cholesterol has a greater affinity for Aβ than for C99. Synthetic 22-35 and 25-35 fragments of Aβ retained the ability of the full-

length peptide 1-42 to bind cholesterol and to form zinc-sensitive, calcium permeable amyloid pores in cultured neural cells. Studies with mutant peptides allowed to identifying key residues involved in cholesterol binding and channel formation. Cholesterol promoted the insertion of Aβ in the plasma membrane, induced α-helical structuration, and forced the peptide to adopt a tilted topology that favoured the oligomerization process. Bexarotene, an amphipathic drug currently considered as a potential candidate medication for the treatment of neurodegenerative diseases, competed with cholesterol for binding to Aβ, and efficiently prevented oligomeric channel formation. These studies indicate that it is possible to prevent the generation of neurotoxic oligomers by targeting the cholesterol-binding domain of Aβ peptides. This original strategy could be used for the treatment of Alzheimer's and other neurodegenerative diseases that involve cholesterol-dependent toxic oligomers.

Title: Development of an ex-vivo assay to measure solubility characteristics of plaque associated Aβ from human alzheimer disease (AD) frontal cortex

Authors: *J. A. TZAFERIS[1], H. B. OLUOCH[2], M. M. RACKE[2], J. T. HOLE[2], F. LIU[2], R. B. DEMATTOS[2]
[1]Eli Lilly & Co., INDIANAPOLIS, IN; [2]Eli Lilly and Co., Indianapolis, IN

Abstract: Background: A large anti-Aβ study performed in aged PDAPP mice revealed differences in the Aβ composition of diffuse and cored plaques and suggested possible in-vivo solubility differences for different Aβ fragments. Histological analyses in the aged PDAPP mice indicated that BACE inhibitor treatment resulted in removal of diffuse plaque, whereas antibody treatment selectively lowered cored plaques. Furthermore, biochemical analyses of brain lysates revealed a greater lowering effect of the BACE inhibitor on Aβ 4-42, 9-42, and 11-42 as compared to the plaque-specific antibody treatment, thus suggesting an enrichment of these truncated peptides in diffuse plaque. Conversely, plaque-specific antibody treatment enhanced lowering effects on Aβ p3-42 and 8-42, suggesting enrichment in cored plaque. Based on these

findings, we sought to develop an ex-vivo assay to measure solubility characteristics of plaque associated Aβ species from human AD frontal cortex. **Methods:** Human AD frontal cortical sections (40 μm) were placed in 24-well plates and incubated in PBS containing 50μg/ml of a mid-domain antibody for 5, 30, 60, and 180 minutes. The antibody was incorporated to stabilize soluble Aβ in the PBS buffer to increase recoveries from non-specific binding. Following the specified times, the PBS supernatant and AD tissue sections (for normalization of PBS fraction) were analyzed by acid urea gels followed by Western blotting. Aβ levels were determined using antibodies selective for N-terminally truncated epitopes as well as full length Aβ. **Results:** The ex-vivo study in human cortical tissue identified differences in the solubilization of Aβ fragments associated with diffuse and cored plaques. We observed that Aβ species differentially diffused from the cortical tissue into the PBS buffer over time. Acid urea gel Westerns showed an increase of Aβ 4-42 (~1.5 fold), Aβ 1-42 (~2 fold), and Aβ 11-42 (~2 fold) levels in the PBS buffer over time, whereas, Aβ p3-42 and Aβ 8-42 levels remained constant. The maximal diffusion separation amongst Aβ analytes occurred at 30 minutes. Further analysis, at this time point, revealed a 1% diffusion of total Aβ 11-42, which is 4 fold greater than full length Aβ 1-42 and 10-30 fold greater than the rest of the N-terminally truncated Aβ fragments. **Conclusions**: We have identified plaque associated Aβ that solubilize from human AD frontal cortex with Aβ 11-42 exceeding the rest of the Aβ analytes. These findings parallel data obtained in aged PDAPP mice that suggested an enrichment of Aβ 11-42 in diffuse plaque and an increased solubility of Aβ 11-42 as compared to other N-terminally truncated Aβ fragments.

Title: Modulated zinc levels may preserve insulin responsiveness in CNS synapses of non demented individuals who resist Alzheimer's Disease neuropathology

Authors: *M. M. COMEROTA[1], R. WOLTJER[3], G. TAGLIALATELA[2]
[2]Dept. of Neurol., [1]Univ. of Texas Med. Br., Galveston, TX; [3]Dept. of Pathology, Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Alzheimer's disease neuropathology is characterized by deposits of aggregated amyloid beta (Aβ) and hyper-phosphorylated tau protein neurofibrillary tangles. In addition, the disruption of synaptic spines due to the binding of small Aβ oligomers on the post-synaptic density (PSD) is thought to be an early key event driving onset and progression of cognitive decline in AD. However, some individuals, here referred to as Non-Demented with Alzheimer's Neuropathology (NDAN), exhibit little to no cognitive decline despite the post mortem observation of plaques and tangles in the brain as seen in fully symptomatic AD, suggesting that NDAN individuals are resistant to the cognitive decline normally brought about by AD neuropathology. Understanding the mechanisms of such resistance would thus reveal important targets for the development of effective therapies for AD. Our previous results showed that several characteristics are associated with NDAN individuals that differ from demented AD patients, including absence of Ab oligomers at PSD, preserved insulin responsiveness and modulated levels of synaptic zinc. The goal of the current study was to investigate these characteristics and their relationship to the ability of Aβ oligomers to bind on to the PSD. Based on a previous report describing the inhibition of the autophosphorylation of the insulin receptor in the presence of 10 μM of zinc in a cell free system, in the current study, we investigated this phenomena in a whole cell system using human SY5Y neuroblastoma cells. Western blots were performed on total protein extracts from cells treated with 10 U of insulin in the presence of increasing concentrations of zinc; 10 μM, 100 μM, and 1mM. Our initial results indicated that also in a complex cell environment the presence of zinc inhibits the autophosphorylation of the insulin receptor, as well as, the associated signaling pathway (Akt and GSK-3β). These results were further compared to alterations in the binding of Aβ in SY5Y cells due to insulin resistance driven by elevated zinc levels. This study provides further understanding of the potential mechanisms associated with synaptic Aβ binding in the development of cognitive impairment which can lead to more effective therapeutic targets to prevent or slow cognitive decline associated with AD.

Abstract: Alzheimer's disease (AD) is by far the most common neurodegenerative disorder whose incidence exponentially increases in the aging population. Although signs and symptoms of clinically manifest AD are well defined, no effective therapy is yet available able to regress it yet and the pathogenesis is still matter of discussion. One of the most accredited theory posits the crucial role in AD pathogenic pathways of amyloid beta peptide (Aβ), especially when organized as oligomers. These small Aβ aggregates are neurotoxic both *in vitro* and *in vivo*. In addition, Aβ oligomers have been shown to induce alterations of mitochondria and disrupt long term potentiation (LTP) in amyloid precursor protein (APP) overexpressing transgenic mice that recapitulate salient AD pathology. Despite this established experimental knowledge, potential mechanisms able to inhibit this cascade remain elusive. Compelling evidence by us and others indicates a mechanism of interaction between the Aβ peptide and the Hsp60, a mitochondrial chaperonin that may be involved in preventing mitochondrial deficits associated with AD pathology. Indeed, post mortem studies on AD brains revealed a significant increase of oxidative stress when compared to age-matched control subjects. Furthermore, there are combined and multiple variations in chaperones and proteasome activities, responsible for the accumulation of neurotoxic species in senescent central nervous system especially when AD occurs. While the involvement of Hsp60 in mitochondrial oxidative metabolism caused by Aβ is well documented, there are few studies describing the biophysical mechanism of direct interaction between these two proteins. Here, we investigate the inhibitory effect of Hsp60 on the Aβ1-40 aggregation by the Thioflavine T assay and Circular Dichroism analysis. Furthermore, Isothermal Titration Calorimetry experiments are conducted in order to characterize the Hsp60/ Aβ1-40 binding parameters. Our preliminary results show a direct interaction between Aβ1-40 and Hsp60 responsible for a significant slowdown in the aggregation kinetic and perturbation of the Aβ peptide secondary structure. Overall, these results suggest Hsp60 as a new target for the

development of innovative therapies for AD centered on prevention of Aβ-driven mitochondrial damage.

Title: Monitoring the early phase of beta-amyloid peptide aggregation using targeted and quantitative mass spectrometry

Authors: ***A. W. SCHMID**[1], N. RUDINSKIY[2], D. DEMURTAS[1], M. MONIATTE[1]
[1]EPFL, Lausanne, Switzerland; [2]Harvard Med. Sch., Boston, MA

Abstract: Soluble beta-amyloid (Abeta) oligomers account for the decline in synaptic plasticity and memory associated with dementia and therefore represents an important, early diagnostic and therapeutic target for the treatment of Alzheimer's disease (AD). In order to elucidate the mechanisms of peptide misfolding in the early stages of AD pathogenesis, it is important to develop sensitive and specific assays to identify and monitor key molecular triggers and biological markers before the development of clinical symptoms. We are interested in monitoring key molecular changes associated with the early stages of Abeta peptide oligomerization using high resolution mass spectrometry (MS) analysis. In this project we have investigated the early events of Abeta peptide folding using targeted and quantitative mass spectrometry and revealed that, Abeta peptide aggregation is associated with the generation of a typical peptide fragment fingerprint. These findings have enabled us to design and develop a new type of anti-Abeta antibodies, which specifically target key molecular changes associated with the early events of peptide oligomerization and therefore serve as a novel and indispensable analytical tool for monitoring peptide aggregation *in vitro* and *in vivo*. Screening of transgenic mice and human post-mortem AD brain tissue, using a combination of immunoprecipitation and quantitative MS revealed that these molecular changes are highly relevant events found *in vivo*. We believe that this observation provides novel and crucial information for quantifying absolute

Abeta levels in biological samples, such as CSF and plasma, as well as for understanding and targeting the inhibition of protein aggregation.

Abstract: Alzheimer's disease (AD) is characterized by aggregation of amyloid-β (Aβ) and tau protein along with progressive dementia. Soluble Aβ oligomers (sAβo) / Aβ-derived diffusible ligands (ADDLs) have been shown to be toxic for neurons, and they are believed to be key factors in synaptic degeneration and memory loss in AD. We sought to investigate the molecular mechanisms that couple ADDLs to dysfunction of neuronal networks. In this study, we used array tomography, a technique that allows precise quantification of synapses based on ultrathin tissue sectioning and immunohistochemistry, to quantify the reductions of synaptic density in the presence of sAβo in transgenic mice and human AD tissues and we observed a significant decrease in postsynaptic density associated with microdeposits of oligomeric Aβ. In primary neuronal cultures, application of Tg2576 conditioned media or synthetic ADDLs led to an increase in intracellular calcium that was prevented with immunodepletion using the soluble Aβ oligomer selective antibody ACU-3B3. Furthermore, we used multiphoton imaging in wildtype mice to measure neuronal calcium in individual cortical neurons *in vivo* by using the genetically

encoded ratiometric calcium indicator Yellow Cameleon 3.6. After topical application of synthetic ADDLs (5 nM) onto the exposed cortical surface, the average intracellular calcium levels in layer 5 neuronal soma increased by ~1.2-fold compared to resting calcium levels. Pre-treatment with ACU-3B3 (1ng/ml) significantly reduced the ADDL-induced elevation in intracellular calcium. These data demonstrate that ACU-3B3, the murine precursor of humanized antibody ACU-193, selectively inhibits the toxicity of sAβo, and is able to restore neuronal calcium homeostasis *in vitro* and *in vivo*.

Title: The injection of the beta amyloid peptide 25-35 in magnocelular nucleus decreases learning and spatial memory associated with the inflammatory process and decrease signaling Trk-A receptor

Authors: *A. PATRICIO[1], I. MARTÍNEZ[2], I. ESPINOZA[1], A. SÁNCHEZ-GONZÁLEZ[1], E. RÁMIREZ[1], A. CANDALIJA[3], J. AGUILERA[3], I. D. LIMÓN[1]

Abstract: Alzheimer´s disease (AD) is a syndrome of dementia, characterized by gradual degeneration of the basal-forebrain, cholinergic neurons innervating the cortex, amygdala, and hippocampus. In brains of AD patients the aggregation and accumulation of β-amyloid protein

(Aβ) contributes to cholinergic-neuronal degeneration, in turn causing learning and memory deficits. In particular, basal forebrain cholinergic cells have been found to be selectively vulnerable to the consequences of inflammation, suggesting that Aβ exerts its degenerative effect on cholinergic cells. The injection of Aβ25-35, the biologically active fragment, causes axonal and dendritic retraction followed by neuronal death. In recent years it has been shown that activation of the Trk-A receptor as white neurotrophins NGF has an essential role in cholinergic function. Trk-A downstream signalling is activated, and that the enhancement of Akt pathway leads to GSK-3β inhibitory phosphorylation. Given that GSK-3β inhibition reduces its ability to phosphorylate Tau, the TrkA/Akt activation may be interpreted as a response against the Aβ. In the present study, our aim was to evaluate the effects of the injection of the Aβ25-35 peptide in the magnocellularis nucleus on spatial memory, the GFAP protein, Trk-A receptor, GSK-3β and Akt. Male Wistar rats (270 g) were injected with 1 μL of Aβ35-25 [1 mM] (control group) in the magnocellularis nucleus. In a second group was injected with 1 μL of Aβ25-35 [1 mM]. The learning assessment was made in the eight-arm radial maze at 20 days after injection. The memory test was done ten days after the learning assessment. The immunoreactivity of GFAP and the evaluation of TrkA receptor, GSK-β and Akt by western blot were performed in in the magnocellularis nucleus, frontal cortex and temporal cortex (TCx, FCx). Our findings show that Aβ25-35 into the magnocellularis nucleus induces a reactive gliosis in the TCx and FCx at 1, 5, 10, 15 and 32 days after injection. Thirty days after Aβ25-35 injection we found that phosphorylation of TrkA receptor was decreased in the magnocellularis nucleus without changes in the CtxT. On another hand, we found an increment in the activity of GSK-3β phosphorylated at Tyr 216. Finally behavioral performance showed that the neurodegeneration evoked by Aβ25-35 delayed acquisition of learning and memory. These results show that the inflammatory reaction probably contributes degenerative process and induce dysfunction in the signaling TrkA receptor.

Title: Effects of Interleukin-1 and β-Amyloid on endosomal and endocytic function in neurons

Authors: *A. J. CARLOS, C. W. COTMAN
Inst. for Memory Impairments and Neurolog. Disorders, Univ. of California Irvine, Irvine, CA

Abstract: Inflammation plays both a protective and damaging role in Alzheimer disease (AD). To identify a long-lasting and effective treatment, it is important that we better understand its underlying processes in which chronic inflammation exerts deleterious effects in the brain. Our studies implicate a critical pro-inflammatory cytokine, interleukin-1β (IL-1β), as a factor that accelerates AD pathology via fundamental alterations to endosomal function. Pro-inflammatory molecules and beta amyloid accumulate in the brain with age and in AD, which is linked to impaired neuronal function and poor cognitive outcomes. Proper endosomal sorting is critical for many intracellular signaling systems and impaired endosomal function in neurons may be an underlying mechanism driving poor cognitive outcomes. In this study, we describe the mechanisms by which beta amyloid (Aβ) accumulation and inflammation (specifically IL-1β) impair plasticity and neuronal health. We have found that these molecules interfere with endosomal trafficking of brain-derived neurotrophic factor (BDNF) and its receptor TrkB, leading to impaired neuronal health, function and synaptic plasticity. Our data reveal that IL-1β and Aβ both interfere with retrograde axonal flow of TrkB/BDNF, impair events downstream of TrkB/BDNF signaling, and fundamentally alter cell-surface receptor endocytosis. These data indicate that Aβ and IL-1β deteriorate synapses by targeting both pre- and post-synaptic components, impairing signal transduction and synaptic plasticity and placing neurons at risk for degeneration. We propose that impairment of endosomal trafficking is a common mechanism by which Aβ and IL-1β impair neuronal signaling and plasticity. Supporting the hypothesis that dysfunctional endosomal trafficking is an important contributor to AD pathogenesis, several recently identified genetic risk factors for AD impact the function of endocytotic pathways (e.g., PICALM, BIN1, CD2AP). At present, we are currently investigating the interactions and implications of AD genetic risk factors as contributors to endosomal sorting and endocytic pathways. Ideally, our goal is to understand the nature of the interaction between AD, inflammation and endosomal function to determine if select intervention strategies can protect against the detrimental effects of IL-1β on endosomal sorting and cognition.

Title: A therapeutic miRNA for brain disorders

Authors: *K. C. SONNTAG, W. KIM, Y. LEE, D. MCPHIE, K.-S. KIM, B. COHEN
Psychiatry, McLean Hospital/Harvard Med. Sch., BELMONT, MA

Abstract: One of the main hurdles in developing novel therapeutics for age-related disorders is the still limited understanding of both the biology of normal aging and the mechanisms of disease pathology. Aging and age-related disorders are characterized by slow progressive deterioration or death of neurons, and are influenced by age- and disease-specific factors, including genetic predisposition, dysfunctional proteins, and compensatory mechanisms and molecules that are important in cell survival. If the cellular defense mechanisms are compromised, the penetrance of disease-specific mechanisms becomes higher and cell survival less likely. Among the regulatory factors that govern gene and protein networks and, consequently, influence neuronal health and function are small molecules such as miRNAs. It is increasingly appreciated that even small disturbances of these regulatory factors can have profound effects on cell survival in response to stress. We have identified a novel mechanism in neurons, mediated by miR-126, which regulates the effects of numerous neurotrophic and neuroprotective growth factors (GF). Specifically, we found that elevated levels of this miRNA are neurotoxic and increase the vulnerability of neurons to a variety of non-specific and disease-specific toxic factors, including Staurosporine (STS), Alzheimer's disease (AD)-associated amyloid beta 1-42 oligomers (Aβ1-42), and 6-OHDA which induces oxidative stress in dopamine (DA) neurons mimicking Parkinson's disease (PD) pathology. Mechanistically, miR-126 targets a series of factors in PI3K/AKT/GSK-3β and MAPK/ERK signaling pathways and small increases of this miRNA cause a downregulation of these signaling cascades, impairing the effects of neurotrophic and neuroprotective GF, such as IGF-1, NGF, BDNF, and soluble amyloid precursor protein α (sAPPα). In turn, inhibiting miR-126 enhances the actions of GF without disturbing normal neuronal cell function. Our data indicate that miR-126 may play a profound role in neuronal cell survival, at least in part by regulating GF/PI3K/AKT and MAPK/ERK signaling. While its elevation is neurotoxic, its inhibition is neuroprotective, suggesting that targeting this miRNA may have therapeutic potential for neurological and age-related disorders.

Title: Impact of ApoE polymorphisms on amyloid-beta oligomerization and associated cognitive decline

Authors: ***E. L. CASTRANIO**, N. F. FITZ, A. Y. CARTER, I. LEFTEROV, R. KOLDAMOVA
Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Recent studies suggest amyloid beta (Aβ) oligomers as the major source of pathogenicity in Alzheimer's disease (AD), as opposed to the characteristic senile plaques in the brain. It has been shown Aβ oligomers contribute to inhibition of long-term potentiation, synaptic dysfunction and overall cognitive decline. Inheritance of the APOEε4 allele, as opposed to APOEε3 or APOEε2, is the only recognized genetic risk factor for sporadic late-onset AD, increasing risk by up to twelve-fold. Furthermore, it has been proposed that apolipoprotein E (APOE) impacts the oligomerization process and clearance of these oligomers from the brain and these functions appear to be dependent on the lipidation state of APOE. The fact that APOE4 is poorly lipidated and found at significantly lower concentration than APOE3 could contribute to the overall oligomeric pathology and risk for AD. The goal of the current study is to determine

how equal concentrations of human APOE3 or APOE4 impact Aβ oligomerization and associated cognitive decline. Oligomers produced in the presence of the different APOE particles were first characterized by electron microscopy, A11 specific dot blot, and western blot. Three-month old wild-type mice received implantations of guide cannulas into their hippocampus. Prior to cognitive tests of novel object recognition and fear conditioning, the mice received an infusion into the hippocampus of either Aβ oligomers or scrambled Aβ peptide in combination with APOE3 or APOE4. Preliminary data shows that co-incubating Aβ oligomer with APOE3 reduces the levels of high molecular weight oligomers in EM pictures and infusion of APOE3 with Aβ oligomers into the hippocampus prevents learning deficits in cognitive testing compared to Aβ oligomers alone. This study shows a comparison of co-incubation of Aβ oligomers with APOE3 versus APOE4 and demonstrates the impact of APOE genotype and concentration on learning and Aβ oligomer induced pathology.

Title: Gene delivery of apoE2 reduces brain amyloid burden in apoE4-target replacement APP.PS1 transgenic mice

Authors: ***L. ZHAO**[1], A. J. GOTTESDIENER[2], M. PARMAR[1], M. LI[4], S. M. KAMINSKY[3], M. J. CHIUCHIOLO[3], D. SONDHI[3], D. M. HOLTZMAN[5], R. G. CRYSTAL[3], S. M. PAUL[1]

Abstract: Apolipoprotein E4 allele (APOE4) carriers have a markedly increased risk for developing Alzheimer disease (AD) whereas the APOE2 allele is protective, reducing AD risk by 50% and markedly delaying the age of onset. ApoE is also a major determinant of amyloid β-peptide (Aβ) deposition and brain amyloid burden in AD patients and transgenic mice

(E4>>E3>E2). We have previously reported that lentiviral-mediated gene delivery of apoE2 significantly reduces brain Aβ levels and amyloid burden in APP transgenic mice. We have now extended this finding using adeno-associated viral (AAV) vectors and a new APP.PS1/TRE4 mouse model where Aβ/amyloid deposition is dependent on apoE4 expression. We administered 0.25X1010, 0.5X1010, or 1X1010 viral genomes (vg) of AAVrh10-CAG-E2 bilaterally into hippocampi of young (2.5-month old) APP.PS1/TRE4 mice (mild to moderate amyloid pathology in hippocampus). Using specific ELISAs to quantify apoE and Aβ levels in brain, we observed an apoE dose-dependent reduction in Aβ 8 weeks post injection; however, when 1X1010 vg virus were delivered via the same route to 5-month old APP.PS1/TRE4 mice (≥ 8 times more Aβ in their hippocampi), there was no statistically significant reduction in Aβ burden even with apoE2 levels that are comparable in both groups of mice. This suggests that the "efficacy" of apoE2 gene delivery in reducing brain Aβ/amyloid burden may depend on the degree of preexisting amyloid pathology. We therefore defined an apoE2/Aβ42 ratio (apoE2 levels in E2 injected mice/Aβ42 levels in control mice) to assess the effectiveness of treatment. We calculated that the apoE2/Aβ42 ratio in effectively treated young APP.PS1/TRE4 mice was 17.8 but was only 3.7 in older (5-month old) APP.PS1/TRE4 mice, where pathology was already quite advanced. We next administered AAV9-CAG-E2 intrathalamically in young (2.5-month old) APP.PS1/TRE4 mice. ApoE2 levels were increased 7.5-fold in the thalamus, 2.6-fold in the hippocampus, 1.7-fold in the cortex. Correspondingly, Aβ42 levels were decreased 70% ($p < 0.001$) in the thalamus, 45% ($p < 0.05$) in the hippocampus, and 14% ($p > 0.05$) in the cortex. The apoE2/Aβ42 ratios in these same three brain regions were 32.7, 7.2, and 2.4, respectively, demonstrating a strong positive correlation between the level of apoE2 expression and the reduction in tissue Aβ42 levels. Taken together, our study confirms that AAV-mediated apoE2 gene delivery reduces brain Aβ burden in transgenic mice where the latter is dependent on apoE4 expression. Importantly, the level of apoE2 expression and the degree of already existent amyloid pathology were important determinants of the "efficacy" of apoE2 gene therapy in this model.

Title: ApoE4 and ApoE4 domain interaction induce gender vulnerability on progression of Alzheimer's disease in mouse models

Authors: *X. HOU[1], S. O. ADEOSUN[1], X. ZHAO[2,5], B. R. BARLOW[2], B. ZHENG[2], M. J. BRENTS[2], Q. ZHANG[2,6], J. WANG[2,1,3,4]
[1]Program in Neurosci., [2]Dept. of Pathology, [3]Dept. of Psychiatry and Human Behavior, [4]Ctr. of Memory Impairment and Neurodegenerative Dementia, Univ. of MS Med. Ctr., Jackson, MS; [5]Heilongjiang Chinese Med. Univ., Haerbin, China; [6]ShanXi Med. Univ., Taiyuan, China

Abstract: The increased prevalence and severity of Alzheimer's disease (AD) in women is strongly associated with age-related ovarian hormone loss and apolipoprotein E 4 allele (ApoE4), which is the most important genetic risk factor for sporadic AD. The interaction between ApoE4 and sexual hormone and how they interact in AD are still unclear. To evaluate the contribution of ApoE4, and specifically ApoE4 domain-interaction, on gender-dependent AD progression, we used three mouse models for AD: 3xTg AD mice bearing three familial AD mutations (APPSwe, PS1M146V, tauP301L); 3xTgAD with the human ApoE4 allele (Apoe4/3xTgAD); Mice with Arg-61 mutation that specifically exhibits only the domain interaction feature of human ApoE4. The transgenic mice were compared with age and gender matched nonTg background control mice. The results showed that all the transgenic mice showed learning and memory deficits compared to gender and age matched controls, with more severe in female ApoE4 transgenic mice. In radial arm water maze (RAWM) test, female ApoE4/3xTg mice took longer time and exhibited more errors to find the target than male ApoE4/3xTg mice and female 3xTg mice. Female ApoE4/3xTg mice also failed to locate the target arm during the probe trail of RAWM. In novel arm discrimination (NAD) test, only female 3xTg and ApoE4/3xTg mice failed to locate the novel arm. Interestingly, female Arg61 mice also took longer time and more errors to find the target than female C57BL/6J mice and male Arg61 mice; Only female Arg61 mice failed to locate the target arm during the probe trail of RAWM after two days training, and to recognize the novel arm in NAD. In the lacking of ovarian hormones (ovaries were removed by ovariectomy (OVX)), ApoE4/3xTg and Arg61 female mice showed more severe deficits to locate the target arm or the novel arm in RAWM and NAD, respectively. The OVX effect was not observed in nonTg or C57BL/6J background mice. Pathologically, amyloid precursor protein (APP) and amyloid β (Aβ) oligomer expression was significantly higher in female ApoE4/3xTg and female Arg61 mice than in male. OVX further increased APP and Aβ oligomer protein expression in the hippocampus in female

ApoE4/3xTg AD. Our study suggests that the ApoE4 allele, especially the domain interaction in ApoE4, play a pivotal role in gender dependent development on AD both in cognition and brain AD pathology, particularly in females in the estrogen-deficiency condition. This study will also provide several potential therapeutic strategies for AD therapy in females.

Title: Identification of an astrocytoma-enriched human liver X receptor alpha (LXRα) isoform

Authors: *M. BEYNA[1], H. S. XI[2], R. Y. YANG[2], E. K. SYLVAIN[1], N. POZDNYAKOV[1], W. L. BLAKE[3], G. RAMASWAMY[1]
[1]Neurosci. Res. Unit, Worldwide Res. and Develop., [2]Computat. Sci. CoE, Worldwide Res. and Develop., Pfizer Inc., Cambridge, MA; [3]Pharmacokinetics, Dynamics and Metabolism, Worldwide Res. and Develop., Pfizer Inc., Groton, CT

Abstract: Cholesterol is a vital component of cell membranes and myelin and is important for synaptogenesis and optimal neurotransmitter release. Because the blood-brain barrier inhibits lipid exchange with the periphery, almost all brain cholesterol is locally synthesized. Disturbances in the tight control of brain cholesterol homeostasis are linked to neurodegenerative disorders including Alzheimer’s disease (AD). Liver X receptor alpha (LXRα) is a master transcription factor regulating cholesterol homeostasis. One of its target genes is apolipoprotein E (apoE), a key cholesterol transport protein in the brain with critical roles in neuronal repair, synaptogenesis and clearance of amyloid-β peptide. One of the human apoE isoforms, apoE4, is associated with a strong risk for developing sporadic and late-onset forms of AD. LXRα activation upregulates apoE expression and secretion in astrocytes. Several LXRα isoforms arising from alternative splicing and differential promoter usage have been reported and are implicated in differential LXRα signaling and regulation. Given the importance of lipid metabolism in the brain, we investigated the presence and expression profiles of LXRα variants in the brain and different cell types. We utilized the Genotype-Tissue Expression database to investigate the possibility of alternatively spliced human LXRα gene transcripts. We identified a

novel transcript variant obtained from alternative splicing of exon 1 to exon 5. Compared to the major lipid-regulatory LXRα isoform, this new splicing event would result in a significantly smaller protein. This shortened isoform would lack the activation function 1 domain, DNA binding domain, and a part of the hinge region but retain the ligand binding and activation function 2 domains. Interestingly, the tissue distribution of the new splice junction frequency was significantly higher in the brain relative to other tissues, with the frequency in the liver being very low. We designed transcript-specific qPCR primers and measured the mRNA abundance of the isoforms in several human cell types: primary cortical astrocytes, astrocytoma and hepatocellular carcinoma cell lines, macrophage-like cells differentiated from a monocyte cell line, and primary peripheral blood mononuclear cells. The relative expression of the LXRα exon 1-5 splice variant was higher in the astrocytoma cells than that in the hepatocellular carcinoma cells. Further investigations will explore potential functions of this new isoform. Our results suggest that we have identified a new, putative LXRα splice variant with high expression levels in the human astrocytoma cells relative to that in a hepatocyte cell line.

Title: Mitochondrial peptide accumulation in cortical cytosolic compartments of APOE4(+) young adults

Authors: *M. PERKINS[1,2], D. SHONEBARGER[1], L. HENDERSON[1], J. VALLA[1,2]
[1]Midwestern Univ., Glendale, AZ; [2]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: The mechanism by which the apolipoprotein E ε4 (APOE4) allele increases risk for development of late-onset sporadic Alzheimer's disease (AD) is not known. However, young adult carriers of this genetic risk factor display significant functional deficits in cerebral glucose metabolism as well as mitochondrial oxidative metabolism, with features similar to AD patients. These functional changes in young adults were apparent in the absence of any significant changes in AD-related neuropathology such as amyloid or tau deposition. Recently, variants of another gene in linkage disequilibrium with APOE, TOMM40, which encodes the pore-forming subunit of the protein translocase of the outer mitochondrial membrane, were identified as a putative risk factor for late-onset AD. To determine whether APOE4 related to mitochondrial translocase function, we analyzed the levels of 4 nuclear-encoded mitochondrial proteins and 1 mitochondrially-encoded electron transport chain (ETC) protein in cortical lysates and in isolated mitochondria. Subjects consisted of 18-40 year-old APOE4 carriers (N=12) and APOE4 noncarriers (N=12). Frozen posterior cingulate/precuneus cortex samples were received from the NICHD Brain and Tissue Bank for Developmental Disorders (University of Maryland, Baltimore). A portion of the cortical block was homogenized in RIPA buffer. A second portion was homogenized in a sucrose-Tris-ATP buffer, the mitochondria were labeled with anti-TOMM22 paramagnetic beads, and then isolated in a magnetic field (Miltenyi Biotec). Both samples were similarly solubilized in RIPA buffer and subjected to SDS-PAGE and Western blotting. An antibody cocktail against select subunits of mitochondrial oxidative phosphorylation (Complexes I-V) was applied. In the isolated mitochondria, in accordance with the functional declines reported previously, each of the ETC subunit levels trended lower in APOE4(+) subjects (mean decline =17%). In stark contrast, the whole-tissue lysates from the same APOE4(+) subjects showed highly significant (mean increase =138%; $P<0.05$) increases in these same markers. While these findings can be interpreted in the context of mitochondrial protein translocation (i.e., a TOMM40 functional defect), the mitochondrially-encoded protein subunit showed the same effect. Thus, these results may be due to another mechanism. Nuclear pseudogenes for ETC proteins have been identified, and their overexpression and translation could explain these results. However, the rationale for such significant mitochondrial protein overexpression in the cytosolic compartments of APOE4(+) subjects remains unknown.

Title: Apolipoprotein E isoforms differentially regulate blood-brain barrier breakdown in Alzheimer's disease

Authors: ***M. R. HALLIDAY**[1], Q. MA[2], Z. ZHAO[2], C. A. MILLER[3], B. V. ZLOKOVIC[4]

Abstract: In humans, apolipoprotein E (apoE) has three isoforms: apoE2, apoE3, and apoE4. APOE4 is a major genetic risk factor for Alzheimer's disease (AD), a debilitating dementia characterized by early and progressive neurovascular dysfunction. Apolipoprotein E4 has direct effects on the cerebrovascular system, resulting in microvascular lesions and blood-brain barrier (BBB) damage. Our recent studies in transgenic mice have demonstrated that apoE4 leads to BBB breakdown by activating the proinflammatory cyclophilin A (CypA)-matrix metalloproteinase-9 (MMP-9) pathway in brain pericytes, which in turn results in degradation of BBB tight junction and basement membrane proteins. In this study, we analyzed post-mortem tissue from AD individuals with different APOE genotypes to determine whether apoE4-dependent activation of the CypA-MMP-9 pathway and resulting BBB breakdown as shown in APOE4, but not APOE3 or APOE2 transgenic mice, also occur in humans. Here, we show increased activation of the CypA-MMP-9 pathway in AD individuals compared with neurologically intact controls and that activation of the pathway is regulated in an APOE4 gene dose-dependent manner. We also show for the first time that cortical pericyte populations are reduced in AD individuals in an APOE4 gene dose-dependent manner and that reductions in

brain pericyte populations in AD significantly correlate with the magnitude of BBB breakdown as measured by extravascular accumulation of plasma proteins.

Title: Inhibition of Inducible Degrader of LDLR (IDOL) markedly increases extracellular Aβ clearance by astrocytes

Authors: ***J. KIM**[1], D.-E. CHUNG[2], H. YOON[2], J. KIM[2]
[1]Dept. of Neurol., Mayo Clin. Birdsall Rm216, Jacksonville, FL; [2]Dept. of Neurosci., Mayo Clin., Jacksonville, FL

Abstract: Accumulation of Aβ in the brain has been hypothesized to be the primary cause of Alzheimer's disease (AD). Prevailing evidence suggests that Apolipoprotein E (APOE) genotype, the strongest genetic risk factor for AD, plays critical roles in Aβ metabolism and AD pathogenesis. Previously, we and others have demonstrated that genetic deletion of Apoe markedly decreases Aβ deposition in the brain of Aβ-amyloidosis mouse models. Moreover, we have shown that overexpression of the low density lipoprotein receptor (LDLR), a major apoE receptor in the brain, markedly decreases apoE level and Aβ deposition in the brain of Aβ-amyloidosis mouse model by increasing extracellular Aβ clearance by astrocytes. Therefore, understanding the molecular mechanisms underlying apoE and apoE receptor metabolism in the brain is likely to provide better insights into Aβ metabolism and AD pathogenesis. Recently, inducible degrader of the LDLR (IDOL), an E3 ubiquitin ligase, has been identified as a novel regulator of LDLR in the periphery that ubiquitinates and targets LDLR for degradation. However, our understanding of IDOL function in the brain is limited and whether IDOL influences Aβ metabolism has not been investigated. Interestingly, IDOL is expressed in the brain as well as periphery. Moreover, IDOL is widely expressed in the brain and is well detected in both neurons and glial cells. Therefore, we hypothesized that IDOL may play a critical role in

Aβ metabolism by regulating LDLR in the brain. As in peripheral cells, overexpression of IDOL increases ubiquitination of LDLR and decreases LDLR level, while RNAi-mediated inhibition of IDOL dramatically increases LDLR level in neuronal cells. Moreover, inhibition of IDOL decreases extracellular apoE level in primary astrocyte culture. Furthermore, inhibition of IDOL markedly increases extracellular Aβ clearance by astrocytes. These findings suggest that inhibiting IDOL function in the brain may represent a novel therapeutic strategy for AD.

Title: ApoE dependent epigenetic regulation in brain: ApoE3 exports and ApoE4 imports HDAC4 and 6 to the nucleus

Authors: *A. SEN, D. L. ALKON
Blanchette Rockefeller Neurosci. Inst., Morgantown, WV

Abstract: Apolipoprotein E4 (ApoE4) is a major genetic risk factor for sporadic Alzheimer's disease (AD). ApoE 4 also increases the risk of cerebral amyloid-angiopathy, age-related cognitive decline, Parkinson's and multiple sclerosis. Abnormal acetylation of histones is involved in the pathology of AD. Abnormal acetylation of histones is involved in AD. Here we show for the first time the involvement of ApoE in epigenetic regulation through histone deacetylases (HDACs). ApoE3 increased histone 3 acetylation than ApoE4 in SH-SY5Y cells. ApoE4+Chol induced a 2-fold increase in nuclear import of HDAC6 (47.2 ± 5.6%) compared to ApoE3+Chol (28.8 ± 3.1%), HDAC4 also showed a significant increase in nuclear translocation in ApoE4+Chol-treated cells (55.3 ± 1.4%) compared to ApoE3+Chol (32.4 ± 3.8%; t-test, P=0.005). Nuclear abundance of HDAC4 & 6 was higher in the hippocampus of ApoE4 transgenic mice than ApoE3 and control. ApoE3 prevented amylosheroids (ASPDs) induced nuclear import of HDACs. Blocking ApoE receptors by receptor associated protein (RAP) abolished the ApoE effect on HDACs. ApoE3 activated protein kinase C epsilon (PKCε) and PKCε overexpression retained HDACs in cytosol. PKCε activation reversed the ASPD-ApoE4 induced nuclear import of HDACs. These data suggest that ApoE4 may suppress vital neuronal gene expression by nuclear translocation of HDAC4 & 6 via deactivation of PKCε and PKCε

activation reverses the condition, thus PKC activators along with HDAC inhibitors might be a suitable therapeutic option for AD.

Title: Apoplipoprotein E modulates activation of the extracellular signal-regulated kinase in response to Amyloid pathology

Authors: *Q. LI, A. LUSSIER, E. J. WEEBER
Mol. Pharmacology/Physiology, Byrd Alzheimer's institute, Univ. of South Florida, Tampa, FL

Abstract: Apolipoprotein E (ApoE) modulates extracellular signal-regulated kinases (ERK) signaling transduction and may contribute to the functional difference of apoE isoforms on the development of Alzheimer disease (AD). To test this idea, we first detected changes of ERK activation by acute application of amyloid β42 oligomer (AβO) on brain hippocampal slices from 3-month old apoE target replacement (TR) mice, which express one of three human apoE isoforms (ApoE2, ApoE3, and ApoE4),by using Western blotting. There was an increase in ERK activation (phosphorylation form) in slices of apoE4 TR mice but not in the apoE2 TR and apoE3 TR mice following acute exposure to the AβO (2μM) for 30 and 60 minutes. We next sought to determine how the apoE isoforms influence ERK activation in response to the deposition of amyloid β plaques in brain of the apoE TR/5xFAD mice, which co-express one of the human apoE isoforms and 5 mutant AD familial genes leading to a large Aβ42 load at an early age. Using Western blotting and immunohistochemistry, we found a significant increase in ERK activation in the CA1 region of hippocampus in the apoE4 TR/5xFAD when compared with the apoE2 TR/5xFAD and apoE3 TR/5xFAD mice. Intriguingly, the activated ERK was largely seen in the astrocytes in the subventricular zone in the apoE4 TR/5xFAD mice compared to the apoE3 TR/5xFAD mice. Taken together, our data indicate that apoE modulates ERK signaling in an isoform dependent manner in response to amyloid pathology and may contribute a novel mechanism of the apoE isoform-dependent development of AD.

Title: IDOL inhibitors offer the potential for the treatment of Alzheimer's Disease

Authors: S. KUMAR, *T. R. BUTT, M. EDDINS, J. WU, J. LAROCQUE, S. AGARWAL, J. MARBLESTONE, M. KODRASOV, B. NICHOLSON

Abstract: Progressive loss of cognitive skills including memory is a hallmark of neurodegenerative diseases, e.g. Alzheimer's (AD); mild cognitive impairment is an early sign of AD. More than 5 million Americans have AD and the number is expected to grow as the percentage of the population over age 65 increases, posing a huge healthcare challenge . There is no cure for AD; the few FDA approved drugs treat symptoms, have serious side effects, and work in only 50% of patients. Due to the underlying complexity of AD, several different approaches are needed for effective management. Due to the significant unmet need, various groups are seeking to develop drugs to ameliorate cognitive deficits associated with neurodegenerative disease. As a novel approach, we suggest that ubiquitin pathway enzymes, in particular E3 ligases, are attractive therapeutic targets for the treatment of neurodegenerative diseases including AD. The best understood role of the RING finger E3 ligase, IDOL (Inducible Degrader Of the LDLR) is the regulation of LDLR stability and serum cholesterol levels and as such IDOL is a promising target for hypercholesterolemia. IDOL also promotes degradation of two major receptors for the secreted glycoprotein Reelin in hippocampal neurons. Reelin plays a critical role in memory and cognition; its binding to ApoER2 or VLDLR induces a series of signaling events culminating in increased long term potentiation (LTP) and synaptic plasticity. Mutant mice that lack Reelin (reeler) or ApoER2 and VLDLR exhibit a similar neurological phenotype and elevated tau phosphorylation, associated with neurodegeneration. Furthermore, mice deficient in ApoER2 and VLDLR have defects in LTP and memory. More important, Reelin enhances learning and memory in mouse models. Thus, enhancing Reelin signaling should be beneficial in treating cognitive decline in AD. Here we report the discovery and characterization of novel IDOL inhibitors that modulate LDLR as well as Reelin receptors.

These molecules bind directly to IDOL and may perturb IDOL:Substrate interactions. The most promising compounds are being studied in cellular and translational models. Data will be presented summarizing our progress in targeting IDOL for the treatment of neurodegenerative diseases.

Title: Presenilin mutations influence processing and trafficking of the ApoE receptor apoEr2

Authors: W. WANG[1], *S. W. BARGER[2,3]
[1]Geriatrics, Univ. of Arkansas for Med. Sci., Little Rock, AR; [2]Dept Geriatrics, Univ. Arkansas Med. Sci., LITTLE ROCK, AR; [3]Geriatric Research, Educ. and Clin. Ctr., Central Arkansas Veterans Healthcare Syst., Little Rock, AR

Abstract: The apoER2 receptor is a member of a family of cell-surface lipoprotein receptors which have been associated with Alzheimer's disease (AD) by genetics, biochemistry, and neuropathology. An important link of apoER2 to AD is conferred by apolipoprotein E (ApoE), which binds apoER2 alone or as a component of lipoprotein complexes; polymorphisms in the ApoE gene are responsible for the most prevalent genetic risk factor for late-onset AD. Presenilin (PS)-1 also has a genetic impact on AD, with mutations in its gene (PSEN1) causing early-onset AD with a high-penetrance, autosomal-dominant inheritance. Presenilins contribute to the γ-secretase component of amyloid β-peptide (Aβ) production, and certain mutations in PSEN1 appear to alter this proteolysis. However, PS1 also influences other aspects of cellular

physiology, including calcium regulation and trafficking of proteins through the secretory pathway. ApoER2 has been shown to be a substrate of γ-secretase. We have begun to examine the influence of PSEN1 mutation on levels, processing, and trafficking of apoER2. In mouse embryonic fibroblasts (MEF) carrying the PS1 mutation R278I, we find impaired γ-secretase activity for apoER2 in the basal state or after ApoE binding. Other effects of PS1 mutation were unmasked by attenuating γ-secretase activity with the inhibitor DAPT. PSEN1/PSEN2-/- MEF were transfected with PS1 of wild-type sequence or the L282V mutation; in the presence of DAPT, more apoER2 C-terminal fragment (CTF) accumulated the L282V-expressing cells compared to WT transfectants. The combination of DAPT and the L282V mutant also prevented the loss of apoER2 from the cell surface stimulated by ligand. These findings suggest that mutations of PS1 that cause AD alter the processing and perhaps the trafficking of apoER2.

Title: The apolipoprotein E4 (apoE-ε4) allele is associated with neurovascular dysfunction and predisposes to white matter injury and cognitive impairment in mice

Authors: *K. KOIZUMI[1], L. PARK[1], L. ZHAO[1,2], W. LUO[1,2], S. PAUL[1,2], C. IADECOLA[1]
[1]Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY; [2]Appel Alzheimer's Dis. Res. Inst., Weill Cornell Med. Col., New, New York, NY

Abstract: The apolipoprotein E4 (apoE-ε4, apoE4) allele is a risk factor for microhemorrhages and white matter ischemic lesions (Neurology 81:292, 2013). However, the factors underlying the increased cerebrovascular risk remain to be defined. We tested the hypothesis that the apoE4 genotype is associated with alterations in the regulation of the cerebral circulation and increased white matter susceptibility to ischemic injury. To this end, we used human apoE targeted

replacement mice (apoE3 and apoE4) (Sullivan et al., JBC, 272:17972, 1997) (3-4 months; n=5/group) in which cerebral blood flow (CBF) was measured by laser-Doppler flowmetry in the somatosensory cortex under anesthesia. In apoE4 mice, the increase in CBF produced by whisker stimulation (WS) or by topical application of the endothelium-dependent vasodilator acetylcholine (ACh) was attenuated (WS, -49±3%; ACh, -38±3%; $p<0.05$). Next, we investigated if the neurovascular dysfunction increased the propensity of apoE4 mice to develop white matter ischemic lesions. White matter ischemia was induced in the corpus callosum by bilateral carotid artery stenosis (BCAS) with microcoils (0.18mm) for 4 weeks. BCAS led to more severe white matter injury in apoE4 than in apoE3 mice. Thus, BCAS reduced myelin density more in apoE4 (FluoroMyelin relative fluorescence units: 10±1) than in apoE3 mice (15±1), a reduction of 33% ($p<0.05$). Double immunolabeling with the voltage gated Na channel Nav1.6 and the paranodal contact protein Caspr revealed increased disorganization of the axonal nodal structure in apoE4 mice, assessed by the NaV1.6/caspr index (normal index 0.5; BCAS apoE3: 0.58±0.13; BCAS apoE4: 1.05±0.13; $p<0.05$ from apoE3). BCAS induced impairments in spatial memory, assessed by the arm alternation rate (%) in the Y-maze test, an effect worse in apoE4 (43±3%) than apoE3 (52±3) ($p<0.05$). These findings suggest that the apoE4 genotype is associated with cerebrovascular dysfunction, which leads to more severe white matter disruption and cognitive deficits following exposure to chronic cerebral hypoperfusion. Cerebrovascular alterations in apoE4 carriers are likely to play a role in the cognitive impairment associated with vascular risk factors and in the ischemic pathology associated with Alzheimer's disease.

Title: Influence of ApoE on LRP1 function

Authors: *B. SHACKLETON, F. CRAWFORD, C. BACHMEIER
Roskamp Inst., Sarasota, FL

Abstract: Alzheimer's disease (AD) is a neurodegenerative process characterized, in part, by accumulation of the beta-amyloid (Aβ) protein in the brain and cerebrovasculature. Mounting evidence suggests the excessive accumulation of Aβ in the AD brain is not due to aberrant Aβ production, but the result of impaired Aβ clearance mechanisms. One explanation for the attenuated clearance in AD is dysfunctional Aβ transport at the blood-brain barrier (BBB). The BBB transporter primarily responsible for the brain-to-blood elimination of Aβ is the low density lipoprotein receptor-related protein 1 (LRP1). While LRP1 interacts with an array of ligands, one of the more closely associated is apolipoprotein E (apoE). To determine the role of apoE in the regulation of LRP1 transport, we examined the effects of apoE on the proteolytic shedding of LRP1 to its non-functional soluble form. We identified apoE isoform-specific differences in LRP1 shedding *in vitro* and *in vivo*. Furthermore, LRP1 shedding showed a strong inverse correlation with the clearance of Aβ from the brain to the periphery. On further investigation, we identified the involvement of MMP9 and the α-secretase ADAM10 in the proteolysis of LRP1. Activity assays with these sheddases demonstrated apoE isoform specific modulations of their activity; with an inhibitory action demonstrated by MMP9 (apoE2>apoE3>apoE4) and an increase in activity with ADAM10 (apoE2>apoE3>apoE4). Our results indicate an inverse relationship between LRP1 shedding and Aβ transit across the BBB that is apoE isoform-specific. Moreover, we observed an interaction between apoE and the enzymes responsible for LRP1 proteolysis, which may explain the differential effects of the apoE isoforms in removing Aβ from the brain and offer new strategies for the treatment of AD.

Title: High-throughput screening for small molecule modulators of ApoE in primary human astrocytes

Authors: *G. M. FINAN[1], R. B. REALUBIT[2], C. KARAN[2], T.-W. KIM[1]
[1]Dept. of Pathology and Cell Biol., [2]Dept. of Systems Biol., Columbia Univ., NEW YORK, NY

Abstract: Apolipoprotein E (apoE) plays a key role in cholesterol transport in the brain. The ε4 allele of the gene encoding apoE (APOE) underlies the single most prominent risk factor for late-onset AD. Abundant evidence indicates that different apoE isoforms (E2, E3 or E4) differentially affect the clearance and accumulation of amyloid β-peptide (Aβ), as well as neuroinflammation and neuronal functions in the brain. Small molecule-mediated enhancement of brain apoE levels, especially regarding the E2 or E3 apoE isoforms, has been suggested as a promising therapeutic strategy. ApoE is mainly secreted from astrocytes in the brain, and certain agents that promote apoE secretion from astrocytes have been shown to potently reduce Aβ levels and reverse cognitive deficits in mouse models of AD. Nevertheless, molecular targets and pathways that mediate or modulate apoE secretion have not been systematically explored, particularly in primary CNS cells. In order to identify new chemical probes and potential therapeutic lead compounds based on apoE modulation in astrocytes, we performed 384-well plate high throughput screening (HTS) using immunological detection of secreted apoE in primary human astrocytes. Using this assay, we screened libraries consisting of known drugs and bioactive compounds as well as structurally-diverse scaffolds to identify new apoE-enhancing compounds. The identified hit compounds include small molecule modulators of cholesterol transport and synthesis, including neurotransmitter receptors and kinases. Our studies have a potential to identify new tool compounds that modulate apoE secretion through previously unknown mechanisms of action, or structurally novel compounds that are ideal for further AD drug discovery.

Title: APOE-associated biomarkers and their modulation by ibuprofen *in vivo*

Authors: *A. M. DIBATTISTA[1], S. B. DUMANIS[1,2], M. J. LADU[3], G. W. REBECK[1]
[1]Neurosci. Dept., Georgetown Univ., Washington, DC; [2]Max Delbrück Ctr. for Mol. Med., Berlin, Germany; [3]Univ. of Illinois at Chicago, Chicago, IL

Abstract: There is a growing body of evidence indicating that Alzheimer's disease (AD) risk factor apolipoprotein E (APOE) impairs brain processes before disease onset. While APOE research has focused on its effects on the pathological processes of AD, the role of APOE in the normal brain is not as well understood. Here, we characterize behavioral and biochemical differences accompanying the APOE risk genotype in an animal model without gross AD pathology (APOE Targeted Replacement (TR) mice). We previously published that APOE4 TR mice demonstrated impaired spatial memory and reduced dendritic spine density compared to APOE3 TR mice. In the present study, we report that APOE genotype alters levels and distribution of apoE-related proteins in the brains of APOE4 TR mice. APOE4 TR mice had an altered distribution of apoE protein between the TBS and TBS-X soluble brain fractions in both the hippocampus and cortex. Moreover, APOE4 TR mice had higher levels of ABCA1 and ABCG1 mRNA, and we confirmed a threefold higher level of ABCA1 in APOE4 TR brains through western blot analysis of brain extracts. Epidemiological studies have also shown non-steroidal anti-inflammatory drugs can reduce AD risk specifically in APOE4 carriers, and we tested whether treatment of mice with ibuprofen affected these various biomarkers. Two months of ibuprofen shifted the distribution of apoE and ABCA1 levels toward what we observed in APOE3 TR mice. Further, ibuprofen rescued spatial learning and memory deficits in APOE4 TR mice during the Barnes maze task in which mice are trained to locate an escape hole. While untreated APOE4 TR mice learn the task at a significantly slower rate, ibuprofen treated APOE4 TR mice learn the task at the same rate as APOE3 TR mice during training days. Similarly, while untreated APOE4 TR mice take significantly more time to locate the original location of the escape hole upon its removal, ibuprofen rescues this effect 24 hours, but not 72 hours, following training. We are currently investigating whether biochemical biomarkers can be modulated in APOE3 TR mice, and whether we can use other targeted drug treatments to induce similar effects.

Title: Young adult carriers of the Alzheimers disease risk factor APOE4 show broad dysregulation in cortical energy metabolism pathways

Authors: *J. VALLA[1,4], M. PERKINS[1,4], D. SHONEBARGER[2], P. PANGLE[2], L. BALLINA[2], J. VALLEJO[3,4], G. JENTARRA[1,4]
[1]Biochem., [3]Physiol., [2]Midwestern Univ., Glendale, AZ; [4]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: The apolipoprotein E ε4 (APOE4) allele dramatically increases risk for development of late-onset sporadic Alzheimer's disease (AD). Imaging studies using FDG PET showed that young-adult APOE4 carriers display a regional pattern of reduced cerebral glucose metabolism similar to that in AD patients. Similarly, we have previously demonstrated that young-adult (age 18-40y) APOE4 carriers show postmortem functional declines in cortical oxidative metabolism in a laminar pattern closely resembling that of AD patients. These functional changes were apparent in the absence of any significant changes in AD-related neuropathology such as amyloid or tau deposition. Thus, to determine the foundation of these changes, we analyzed select targets in glucose uptake and metabolism, ketone uptake and metabolism, and mitochondrial oxidative metabolism in a subset of these subjects via SDS-PAGE, Western blotting and qPCR. Subjects consisted of N=12 APOE4 carriers and N=12 APOE4 noncarriers, 18-40 years of age. Frozen posterior cingulate/precuneus cortex samples received from the NICHD Brain and Tissue Bank for Developmental Disorders (University of Maryland, Baltimore) were processed for Western blotting and RNA extraction. Analysis of protein levels demonstrated statistically significant ($p<0.05$) increases in neuronal glucose transport (GLUT3) and phosphorylation (HEX1), neuronal monocarboxylate (ketone/lactate) transport (MCT2) and ketone catabolism (succinyl CoA transferase [SCOT]), and the apparent expression of select subunits of mitochondrial oxidative phosphorylation (Complexes I-V). Several of these changes have been further validated via qPCR. In contrast, the primary blood-brain barrier monocarboxylate transporter (MCT1) showed significantly lower protein expression in the APOE4 carriers. GLUT1 and caveolin-1 (CAV1) as well as the metabolic transcriptional co-regulator PGC-1α showed no expression differences between groups. These findings confirm that brain bioenergetic dysregulation may contribute significantly to the risk APOE4 confers for future AD, although it is not yet known what mechanism confers this vulnerability. One potential candidate is the decrease of brain ketone transport and subsequent compensation for the loss of this important brain fuel, which may have connotations for recent attempts to ameliorate AD-related cognitive symptoms via ketogenic supplementation.

Title: Effects of global deletion of ApoA1 and ApoE on amyloid pathology and cognitive decline in a mouse model

Authors: ***N. F. FITZ**, A. Y. CARTER, E. L. CASTRANIO, I. LEFTEROV, R. KOLDAMOVA
Envrn. and Occup. Hlth., Univ. of Pittsburgh, PITTSBURGH, PA

Abstract: Apolipoprotein A1 and E (ApoA and ApoE) combine with lipids in the body to form molecules called lipoproteins, which are responsible for packaging and transport of cholesterol and other fats. The most important apolipoproteins in brain cholesterol homeostasis are ApoE, synthesized and secreted by astrocytes, and ApoA-I, derived from plasma. ApoA-I is also the most abundant apolipoprotein in the periphery and the major protein component of HDL in plasma. We previously shown that the lack of ApoA-I aggravates memory deficits in APP/PS1ΔE9 mice in parallel to significantly increased cerebral amyloid angiopathy (CAA). The overexpression of human ApoA-I in a mouse model of Alzheimer disease, however, preserves cognitive function and attenuates neuroinflammation and CAA. Furthermore, it has been demonstrated that the lack of endogenous ApoE increases the clearance of Aβ from the

brain and dramatically reduces amyloid plaque pathology. In regard to AD-like pathology, in AD models, reduced levels of both apoA-I-I and apoE of Abca1ko mice are poorly understood.Here we generated APP/PS1 transgenic mice with global deletion of ApoE and ApoA-I (APP/PS1/DKO). We are comparing the amyloid pathology and cognitive decline of APP/PS1/DKO to those of APP/PS1/Abca1ko and APP/PS1/wt at 6 and 12 months of age.. Our results shown that APP/PS1/ABCA1ko mice demonstrated the highest level of cognitive impairment, followed by APP/PS1/ApoA-Iko. We examined amyloid pathology by measuring soluble and insoluble Aβ levels in these mice by ELISA and IHC. Our experiments again show that the APP/ABCA1ko mice have highest level and APP/PS1/DKO displaying the lowest level of amyloid plaques. Surprisingly, APP/PS1/DKO and APP/PS1/ApoEko single knockout mice had very little soluble Aβ suggesting that in these mice its efflux from brain is increased. We also examined Aβ clearance through *in vivo* microdialysis and radioactive labeled Aβ clearance studies. We conclude that the complete absence of brain apolipoproteins E and A-I increases the clearance of Aβ from the brain and diminishes the overall amyloid pathology.

Title: Effects of LXR activation on dynamics within *in vitro* networks of neurons using a multielectrode array (MEA) system

Authors: *G. A. RODRIGUEZ[1,2], X. CHEN[4,3], G. W. REBECK[1,2], R. DZAKPASU[4,3,2]
[1]Neurosci., [2]Interdisciplinary Program in Neurosci., [3]Pharmacol. and Physiol., Georgetown Univ. Med. Ctr., Washington, DC; [4]Physics, Georgetown Univ., Washington, DC

Abstract: LXR agonists have received considerable attention in the recent literature for their ability to ameliorate cognitive deficits and reduce Aβ levels in the brains of transgenic AD mice. However, basic research investigating the influence of LXR activation on neuronal network signaling is lacking, and yet necessary to further elucidate mechanisms that underlie LXR agonists' therapeutic effects *in vivo*. In these studies, we address the hypothesis that LXR activation can facilitate network activity by impacting bursting dynamics within primary rat hippocampal neurons cultured on multielectrode (MEA) arrays. The MEA contains 59 titanium nitride electrodes arranged on an 8x8 grid capable of recording extracellular action potentials from a distributed network of neurons. The ability to record non-invasively from the networks over time makes this an ideal *in vitro* system for pharmacological studies. Primary hippocampal cells from E18 Sprague Dawley rats were treated with 1μM or 5μM TO-901317 for 120hr (DIV14-19). Media containing the drug was then exchanged for fresh media and the cells were maintained until DIV25. Dimethyl sulfoxide (DMSO) treated cultures served as vehicle controls. Parallel immunocytochemistry experiments showed ample astrocyte cell populations mixed with neurons. Western blot analyses showed activation of LXR due to chronic TO-901317, as secreted ApoE levels were increased in media from drug treated MEAs at DIV19 and 25. Spontaneous network activity was recorded for 15 min each day (DIV14-25). Overall, we found no difference in total number of spikes between treatment groups or number of spikes not in bursts. However, we discovered a modest effect of LXR-activation on bursting dynamics. While the number of bursts increased in untreated as well as DMSO-treated cultures over time (DIV17-25), hippocampal cells treated with TO did not exhibit similar increases in the burst counts over the recording sessions. Interestingly, burst duration appeared to increase in TO-treated cultures despite the decrease in the number of bursts, which might be accounted for by larger inter-spike intervals within bursts rather than an increased number of spikes within bursts. The effects of TO-901317 include an increased expression of genes encoding proteins involved in cholesterol metabolism, including ApoE and ATP-binding cassette transporters (ABCA1 and ABCG1). We suggest that these increases might facilitate network dynamics after modulations in excitability, such as synaptic potentiation. To this end, we will perform additional studies investigating the effects of LXR-activation in hippocampal cultures subjected to chemical Long-Term Potentiation.

Title: Human apolipoprotein E (APOE) isoforms differentially modulate glucose and amyloid metabolic pathways in female brain: Implications for Alzheimer's disease prevention and early but not late intervention

Authors: *J. T. KEENEY, L. ZHAO
Pharmacol. & Toxicology, Univ. of Kansas, Lawrence, KS

Abstract: Three major genetic isoforms of apolipoprotein E (APOE) exist in humans, APOE2, APOE3, and APOE4, leading to differences in susceptibility to Alzheimer's disease (AD). The most common genotype, APOE3, believed to be neutral in AD, is present in approximately 75% of the population. APOE4, potentially the strongest genetic risk factor for AD, occurs in only 20% of people but accounts for approximately 65% of AD cases. The third, APOE2, believed to be a protective variant against AD, is rare, present in 5% of the population. The purpose of this study was to elucidate differences in key mechanistic pathways in preclinical AD that arise from genetic differences in APOE isoforms and to identify potential targets for AD prevention and early intervention. Hippocampal RNA samples collected from middle-aged female mice with targeted human APOE2, APOE3, and APOE4 gene replacement were analyzed with a qRT-PCR custom array for the expression of a focused panel of genes involved in insulin/IGF signaling. APOE2 brain exhibits the most metabolically robust profile among the three APOE brains. When compared to APOE2 brain, APOE3 and APOE4 brains exhibit markedly reduced levels of insulin-like growth factor1 (IGF1), insulin receptor substrates (IRSs), and facilitated glucose transporter 4 (GLUT4). Additionally, APOE4 brain exhibits further reduction in insulin-degrading enzyme (IDE), a major enzyme that degrades amyloid beta (Aβ) peptide monomers in the brain as well as being involved in promoting glucose metabolism. This data provides the first documented evidence that human APOE isoforms differentially affect the IGF1/GLUT4/IDE system in the brain. Downregulation of IGF1, GLUT4, and IDE associated with APOE4 could lead to detrimental changes in downstream glucose and amyloid metabolism, both of which could further contribute to increased AD risk in APOE4 carriers. Supporting evidence is provided by protein level and post-translational modification assessment and functional outcomes of mitochondrial respiration and ATP production using Oxygraph high-resolution respirometry. IGF1 polymorphism has been associated with increased risk for AD. Elevation of monomeric Aβ and glucose hypometabolism have been shown as accentuated changes occurring in preclinical AD brains. Therefore, these data suggest that a therapeutic strategy that enhances brain IGF1/GLUT4/IDE signaling activity holds promise for preventing, reducing the risk of

developing or, at least, delaying the onset of AD, particularly in the high-risk APOE4 carriers, as well as for AD early intervention especially when addressed in the preclinical stages.

Title: Long term tolerance to human neural mesencephalic precursor transplant in a parkinson´s disease model

Authors: *C. A. SALAZAR-ALDRETE[1], H. GONZALEZ-SANCHEZ[1], V. RODRIGUEZ[2], C. CASTILLO[3]
[1]Bioquimica, Univ. Autonoma De San Luis Potosi.Bioquímica, San Luis Potosi, Mexico; [2]Univ. Nacional Autónoma de México, Juriquilla, Mexico; [3]Biochem., Univ. Autonoma De San Luis Potosi., San Luis Potosi, Mexico

Abstract: Striatal transplants of neural midbrain precursor cells improve drug-induced rotation in hemiparkinsonian rats (Courtois et al 2010). However, side effects caused by use of immunosuppressive drugs cut off behavioral test at three month after transplantation. This trouble limited the evaluation of maturity and integration of host tissue transplant to a short period of time. In the present study, we developed a long term tolerant model induced by early post-natal exposure to cells. METHODS. Wistar rats were randomly distributed in three groups (n= 8 per group): Group 1, rats that received an oral dose of 100 000 cel/μL (hVM1) on postnatal days 1-5 + Transplant of dopaminergic cells; Group 2, rats that received an oral dose of 100 000 cel/μL (hVM1) on postnatal days 1-5 but without transplant and Group 3, rats without tolerance treatment. Rats received a 6-OHDA injection in right medial forebrain bundle. Four week after

lesion, then movement asymmetry was corroborated by injection only rats exhibiting at least 4 contralateral rotation/min in response to apomorphine (0.25 mg/kg) were selected for further striatal transplantation studies (AP + 0.5,ML -3.3,DV -4.5). RESULTS: Animals of group 2 or group 3 showed an increasing of turning behavior while the tolerant model group displayed an improvement in drug-induced rotation evaluated after six months to tolerance induction. Our results are pointing to transplantation of dopamine-producing cells can produce long-term alleviation of behavioral turning asymmetry in an oral tolerant animal model able to generate changes enough to maintain the survival of the transplant into host without immunosuppression; however, cell engraftment and integration of transplanted cells remain to be elucidated.

Title: An *in vitro* experimental model of Parkinson’s disease: Effects of rotenone, neuroprotection by antioxidants and mechanisms of cell death

Authors: *A. J. FILHO[1,2], D. C. F. LOPES[3], C. S. MATSUBARA[3], M. N. SILVA[4], E. S. YAMADA[4], C. SCAVONE[3], C. D. MUNHOZ[3], E. T. COSTA[4]

Abstract: Despite different possible causes of Parkinson’s disease (PD), many studies have suggested important roles for mitochondrial impairment, oxidative processes as well as environmental factors in the pathogenesis of Parkinson's disease. In this context, one model to

study PD is the administration of the plant-derived pesticide rotenone which is a specific inhibitor of mitochondrial complex I, inducing apoptosis by generating mitochondrial reactive oxygen species and originating effects in rats which closely resemble PD. Therapeutic efforts aimed at removal of free radicals or prevention of their formation may be beneficial in PD. Regarding this point, natural products with antioxidant properties are an attractive source of potential cytoprotective compounds. The purpose of this study was: (1) to investigate the neuronal death induced by rotenone using mixed neuron/glia primary cultures from hippocampal and ventral mesencephalon of Wistar rats (*Rattus norvegicus*), (2) to investigate the role of calcium ions in this experimental model and (3) to investigate the potential cytoprotective effects of antioxidant-rich aqueous extract from mahogany leaves (*Swietenia macrophylla*). Neuronal death was analyzed with colorimetric assays for the production of MTT and lactate dehydrogenase enzyme activity (LDH). Our results showed significant concentration-dependent reduction in cell viability after exposure to rotenone both in cultures derived from hippocampus and ventral mesencephalon. We also demonstrate a discreet role of mitochondrial calcium in this rotenone-induced cell loss. Moreover, aqueous extract from mahogany leaves at non-toxic concentrations was not cytoprotective in this model. We also found that rotenone induced cell death by necrosis and apoptosis at the concentrations tested, as analyzed by MTT and LDH assays, as well as by Western blot analysis for specific necrosis and apoptosis markers. The results of this study should advance our knowledge on the mechanisms of action of environmental factors in the pathogenesis of Parkinson's disease. Further studies are still needed to elucidate the participation of calcium homeostasis in the mechanisms of cell death, as well as the use of antioxidant compounds as cytoprotective therapies in PD.

Abstract: Parkinson´s disease (PD) is mainly characterized by progressive loss of dopaminergic neurons in the substantia nigra causing dopamine depletion in the striatum. This triggers a succession of compensatory changes delaying the appearance of motor manifestations, leading to a prolonged pre-motor period of disease evolution. Here, we describe the metabolic pattern associated with progressive nigro-striatal lesion in the 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) monkey model. **Aim**: To define the metabolic changes associated with different states of striatal dopamine depletion. **Methods**: Twenty-four monkeys (*Macaca fascicularis*) were administrated MPTP using 0.5 mg/kg weekly to obtain different groups: *Baseline*, *asymptomatic*, *recovered, mild,* and *severe* parkinsonian, according to Kurlan scale assesments. An additional group (n=6) was studied at *baseline*, *severe* parkinsonian and after *L-Dopa* treatment for 14 weeks. PET imaging was performed using monoaminergic (^{11}C-dihydrotetrabenazine; ^{11}C-DTBZ) and metabolic (^{18}F-fluorodeoxyglucose; ^{18}F-FDG) radiotracers. Regions of interest (ROI) analysis were done for ^{11}C-DTBZ PET (striatum) and Statistical Parametric Mapping (SPM) analysis for ^{18}F-FDG studies (whole brain). **Results**: ^{11}C-DTBZ PET images showed a progressive decrease of Binding Potential (BP) values in the striatum throughout MPTP administration and the ensuing of parkinsonian signs. ^{18}F-FDG PET in the parkinsonian state was characterized by reductions in posterior parietal, temporal lobe, lateral premotor and frontal cortex, as well as increases in the thalamus, globus palidus and cerebellum. ^{18}F-FDG PET after L-Dopa administration revealed a metabolic pattern recognized by hypometabolism in posterior parietal-occipital region and hipermetabolism in post-comisural putamen, thalamus and midbrain. **Conclusions**: Progressive dopaminergic striatal depletion in this MPTP monkey model led to recognizable parkinsonian metabolic patterns that are homologous to the clinical changes observed on patients. Moreover, we report the first demonstration of metabolic brain networks at different DA depletion stages in a nonhuman primate model of parkinsonism. Supported by CIBERNED, UTE-FIMA.

Title: Mesolimbic system in Parkinson's disease: Degeneration of the medial forebrain bundle

Authors: S. SRITHARAN[1,2], E. A. PELZER[1], C. MELZER[1], *R. GRAF[1], L. TIMMERMANN[2], M. TITTGEMEYER[1]
[1]MPI Neurolog. Res., Koeln, Germany; [2]Neurol., Univ. Hosp. of Cologne, Cologne, Germany

Abstract: It is becoming increasingly clear that non-motor systems play a major role in Parkinson's disease. Many cognitive aspects such as learning, reward processing and memory are affected in PD and progress with disease duration. However, the underlying pathophysiology remains unclear. In this study we apply *in vivo* connectivity analysis following diffusion MRI and tractography to investigate pathological changes in an aspect of the medial forebrain bundle in PD connecting the substantia nigra and the nucleus accumbens. So far, 3 T diffusion and structural MRI images were acquired in 10 right-handed, non-demented male PD patients and 7 age-matched controls. All patients underwent L-Dopa-therapy. All MR-images were analysed with FSL 5.0.4 (http://fsl.fmrib.ox.ac.uk/fsl/). Masks of substantia nigra, caudate nucleus and nucleus accumbens were outlined in MNI standard space. Each mask was used as seed and target, respectively, for tractography; resulting connectivity values were statistically analysed in correlation to disease severity. In our preliminary analysis, we find that: (1) diffusion MRI offers the possibility for an *in vivo* quantification of this aspect of the medial forebrain bundle; (2) PD patients show a degeneration in the connectivity between substantia nigra and the nucleus accumbens with disease duration. In conclusion we hypothesize, that degeneration in this part of the medial forebrain bundle may contribute to the evolution of psychiatric, non-motor symptoms in PD.

Title: Characteristics of tremor related burst activity in the ventrolateral thalamus in patients with Parkinsonian rest tremor

Authors: ***P. ZHUANG**[1], M. HALLETT[2], T. LIU[1], Y. ZHANG[1], J. LI[1], Y. LI[1]
[1]Xuanwu Hosp, Capital Med. Uni, Beijing, China; [2]Human Motor Control Section, Med. Neurol. Br., NINDS, NIH, Bethesda, MD

Abstract: Objective: To characterize the tremor related oscillatory burst activity in the ventral oral posterior nucleus (the Vop, the pallidal relay nucleus) and the ventral intermediate nucleus (the Vim, the cerebellar relay nucleus) in patients with parkinsonian rest tremor. **Methods**: 26 PD patients with rest tremor who underwent thalamic surgery were studied. Microelectrode recordings in the Vop/Vim and EMG of contralateral limbs were performed during surgery. Single unit analysis and interspike interval (ISI) was used to assess neuronal mean firing rate (MSFR) and pattern. Bursts were detected by the "Surprise" method. The analysis includes: the temporal structure of peri-burst and burst segments; the pre-post burst length, the duration of burst and interburst intervals (IBI). The relationships between burst length, the duration of flanking ISIs and IBIs were performed. Power spectral analysis was performed to evaluate neuronal oscillation. Coherence analysis was used to study neuronal oscillatory activity in relation to limb EMG. Voluntary-responsive neurons and neurons located >3 mm anterior to the Vc border were presumed to be located in the Vop and kinesthetic-responsive neurons and those located <3 mm anterior to the Vc border were presumed to be located in Vim. **Results:** Of total 224 neurons identified, 68.3% (n=153) were oscillatory neurons. Of oscillatory neurons, 28.8% had β frequency (range of 8-30 Hz) and 71.2% (n=108) had tremor frequency (4-6 Hz) (TFB), of which, 91.7% (n=100) were coherent with limb tremor ($p<0.05$). The burst analysis showed that there were significant differences of burst characteristics between the Vop and Vim including: Intraburst rate (spikes/s): 108.4±29.2 vs 123.2±23.5; Burst duration: 41.4±9.3 ms vs 44.9±7.8

ms; Proportion of spikes in burst (%): 51.3±15.6 vs. 62.5±13.3; Proportion of time spent in burst (%):12.1± 6.0 vs 16.5± 5.3; IBI: 337.1±215.6 ms vs 203.1±67.8 ms. It was found that number spikes in burst significantly correlated with the length of pre- and post-burst ISI. However, no significant difference was reached between the Vop and Vim. Further analysis showed that the MSFR of oscillatory neurons in the Vop was lower than those neurons in the Vim (24.1±5.8 Hz vs 31.5±5.7 Hz, $p<0.05$). Similarly, the density of TFB oscillatory neurons in the Vop was significantly lower than those neurons in the Vim (0.31±0.29 /mm vs 0.68±0.7/mm). **Conclusion:** The data support the hypothesis that the altered interactions between the basal ganglia and the cerebellothalamic circuit seem to play an important role in resting tremor of PD.

Abstract: Parkinson's Disease (PD) is the second most common neurodegenerative disease in the world and affects 1-2% of the population over age 65. Pathologically, PD is marked by a loss of dopaminergic neurons in the substantia nigra pars compacta region of the brain. Because of lack of access to such tissue, or availability of good animal models of PD, iPSC-generated neurons hold promise in the development of model systems to study PD. Recently, biological links between LRRK2 mutation and PD have been reported. The most common mutant, G2019S, like some other LRRK2 mutations, has increased kinase activity, which correlates with increased neuronal cytotoxicity. We have generated iPSCs from patients harboring mutations in the PARKIN and LRRK2 genes, as well as a rare case with mutations in both the LRRK2 and GBA

genes, and a patient with Multiple Systems Atrophy (MSA)--a “Parkinson’s Plus Syndrome” disease with no known genetic determinants. To eliminate line-to-line variations due to genetic background, we have set out to generate a set of isogenic iPSC lines that differ at a single point in the genome using the Transcription Activator-Like (TAL) effector nuclease technology. For instance, we have deleted the -synuclein gene from the MSA line in order to understand the impact of Lewy bodies, and reverted the LRRK2 and GBA mutations back to wild type in order to better understand any synergies between these mutations. These iPSC lines have been differentiated to neural stem cells (NSCs), and further into dopaminergic neurons and glial cells. Using the NSCs, fluorescence-based, high-throughput compatible assays have been developed to monitor phenotypes that are associated with PD, such as oxidative stress, metabolic activity, apoptosis, mitochondrial function, and autophagy. The long-term goal is to use these optimized assays is to provide a platform that allows for the facile interrogation of small molecule compounds in “relieving” phenotypes associated with PD.

Title: Intrastriatal alpha synuclein preformed fibrils in macaque monkeys: neuronal transport, long-term imaging and neuropathologic changes

Authors: *J. H. KORDOWER[1], Y. CHU[1], S. MULLER[1], A. TAVARES[2], O. BARRET[2], D. ALAGILLE[2], J. SEIBYL[2], G. TAMAGNAN[2], K. MAREK[2], K. C. LUK[3], J. Q. TROJANOWSKI[3], V. M. Y. LEE[3]
[1]Dept Neurol Sci., Rush Univ. Med. Ctr., CHICAGO, IL; [2]Mol. NeuroImaging, LLC, New Haven, CT; [3]Pathology and Lab. Med., Univ. Pennsylvania Sch. Med., Philadelphia, PA

Abstract: Misfolded alpha synuclein (α-syn) is an integral pathology in a variety of neurodegenerative disorders including Parkinson's disease. Recent observations in the human brain, coupled with preclinical studies, demonstrated the templated conversion of normal α-syn to pathological α-syn by α-syn preformed fibrils (PFFs). This, as well as the transport and transfer of templated pathological α-syn in rodent models, supports the concept that α-syn has prion-like properties and the transfer of this protein could be responsible for disease progression. We injected thrice sonicated human α-syn PFFs fibrils unilaterally into the putamen of 9 cynomolgus monkeys. One animal died unexpectedly 3 months post-injection. Compared to baseline, PE2I SPECT imaging in the remaining 8 monkeys showed a bilateral increase in dopamine transporter (DAT) in the striatum beginning 3 months post-surgery. This effect was seen on multiple scans for up to 12 months post-surgery. At 12 months the mean increase was 71% with a range of 17% to 120%. We sacrificed 4 of the 8 monkeys at 12 months. An occasional Lewy body was seen in the monkey that died 3 months post-injection. In the monkeys sacrificed one year post-injection, each showed robust expression of α-syn as well as ser129-phosphorylated α-syn pathology within the area of the injection site. There was also a robust conversion of normal α-syn to pathological α-syn and transport of pathological α-syn to the ipsilateral substantia nigra (SN). Thioflavin S positive Lewy bodies and neurites were also seen within the ipsilateral SN. Dopaminergic SN neurons containing ser129-phosphorylated pathological α-syn displayed approximately 50% less tyrosine hydroxylase optical density relative to neighboring neurons that were ser129-phosphorylated α-syn immuno-negative or normal nigral neurons seen in control-injected monkeys. Studies are underway to assess spread or transport beyond the nigrostriatal system. These data support the concept that α-syn PFFs convert monkey α-syn into pathological α-syn that spreads, presumably by axonal transport, in the primate brain. These data will also be discussed within the context of additional experiments performed in these monkeys as well as the remaining ones that will be sacrificed at 18 months post-surgery.

Title: Rescue of the pathological phenotype in α-synuclein(1-120) transgenic mice

Authors: *L. CALO[1], M. WEGRZYNOWICZ[1], O. ANICHTCHIK[2], J. DALLY[1], J. XIA[1], B. SCHNEIDER[3], M. G. SPILLANTINI[1]
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Univ. of Plymouth, Plymouth, United Kingdom; [3]Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Abstract: Alpha synuclein is a 140- aa pre-synaptic protein associated to vesicles where it regulates release events by chaperoning the soluble NSF attachment protein receptor (SNARE) complex assembly and vesicle fusion (Nemani et al 2010; Burre' et al., 2010). Point mutations and duplication/triplications of α-synuclein cause familial forms of Parkinson's disease (PD), which is characterised by the aggregation of αsynuclein in the striatum in Lewy bodies (LB) (Ibanez et al., 2004; Spillantini et al., 1997, 1998). Part of the aggregated αsynuclein found in LBs of PD cases is C-terminally truncated and this post-translational modification increases the propensity of αsynuclein to aggregate and form toxic species although the mechanisms leading to αsynuclein aggregation are at present unclear (Baba et al., 1998; Tofaris et al., 2003; Burre' et al., 2012; Nakata et al., 2012; Janezic et al., 2013). Our previously described transgenic line containing C-terminally truncated αsynuclein, namely αsyn(1-120) is characterised by the presence of progressive formation of clumps of αsynuclein in the striatum, a re-distribution of SNARE proteins and defective dopamine release and by 12 months of age (Garcia-Reitbock et al., 2010). These features recapitulate several of the pathological hallmarks of early-onset PD and provide a valid model for the study of the molecular events that precede nigral degeneration Our hypothesis is that the presynaptic terminals are the initial site of neurodegeneration and therefore we focused on the study of the effect of key synaptic components on the ability to restore the synaptic deficit associated with α synuclein truncation. Here we show that the virally expressed co-chaperone of HSC70, CSPα not only rescues the DA release impairment but also reduces the pathophysiological "clumps" of αsynuclein in the striatum of αsyn(1-120) mice. Our results suggest that modulation of synaptic protein distribution represents a potential therapeutical target for restoring the deficit associated with the early stages of PD pathology thus slowing down or preventing nigral degeneration.

Title: Dopamine-mediated oxidation of methionine 127 in alpha-synuclein causes cytotoxicity and oligomerization of alpha-synuclein

Authors: *K. NAKASO[1], N. TAJIMA[1], Y. HORIKOSHI[1], S. ITO[2], T. MATSURA[1]

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder characterized by the selective loss of dopaminergic neurons and the presence of Lewy bodies. Many recent studies focused on the interaction between α-synuclein (α-syn) and dopamine in the pathogenesis of PD, and fluorescent anisotropy suggested that the C-terminal region of α-syn may be a target for modification by dopamine. However, it is not well understood why PD-related pathogenesis occurs selectively in dopaminergic neurons. We investigated the interaction between dopamine and α-syn with regard to cytotoxicity. A soluble oligomer was formed by co-incubating α-syn and dopamine *in vitro*. To clarify the effect of dopamine on α-syn in cells, we generated PC12 cells expressing human α-syn, as well as the α-syn mutants, M116A, Y125D, M127A, S129A, and M116A/M127A, in a tetracycline-inducible manner (PC12-TetOFF-α-syn). Overexpression of wildtype α-syn in catecholaminergic PC12 cells decreased cell viability in long-term cultures, while a competitive inhibitor of tyrosine hydroxylase blocked this vulnerability, suggesting that α-syn-related cytotoxicity is associated with dopamine metabolism. The vulnerabilities of all mutant cell lines were lower than that of wildtype α-syn-expressing cells. Moreover, α-syn containing dopamine-mediated oxidized methionine (Met(O)) was detected in PC12-TetOFF-α-syn. Met(O) was lower in methionine mutant cells, especially in the M127A or M116A/M127A mutants, but also in the Y125D and S129A mutants. Co-incubation of dopamine and the 125YEMPS129 peptide enhanced the production of H2O2, which may oxidize methionine residues and convert them to Met(O). Y125- or S129-lacking peptides did not enhance the dopamine-related production of H2O2. Our results suggest that M127 is the major target for oxidative modification by dopamine, and that Y125 and S129 may act as enhancers of this modification. These results may describe a mechanism of dopaminergic neuron-specific toxicity of α-syn in the pathogenesis of PD.

Title: Effect of oxidative stress on the glutathione system and the neuromelanin formation in substantia nigra of rats exposed to low doses of ozone

Authors: ***E. D. FERREIRA**, S. RIVAS-ARANCIBIA
Dept. de Fisiología, Facultad de Medicina, Univ. Nacional Autónoma de México, D.F., Mexico

Abstract: Oxidative stress is involved in various intracellular signaling. When the antioxidant species are insufficient to maintain the redox balance, a state of oxidative stress occurs which causes damage and loss of cellular functions, as seen in neurodegenerative disease such as Parkinson's disease (PD). Moreover the formation of neuromelanin, depend on the REDOX equilibrium during oxidative metabolism of dopamine. In PD, oxidized dopamine interacts cysteine wich is a precursor of glutathione. The aim of this work was to study the effect of oxidative stress on the relationship between the glutathione system and the formation of neuromelanin in the substantia nigra (SN) of rats chronically exposed to low ozone doses (O3). Method: sixty male Wistar rats with free access to food and water were randomly divided into the following 6 groups (n=10): group 1) control; group 2) O3 7 days; group 3) O3 15 days; group 4) O3 30 days; group 5) O3 60 days and group 6) O3 90 days. Ozone was daily administered for 4 h to 0.25 ppm. At the end of the treatment, the animals were anesthetized with sodium pentobarbital (50 mg/Kg) and each group was divided into 2 subgroups. In the first subgroup (n=6) animals were perfused and their brains were processed with histochemical techniques for neuromelanin (N). The second subgroup (n=4) rats were decapitated for obtaining fresh tissue of

SN and were processed with spectrophotometric techniques to measure the activity of glutathione peroxidase (GPX), glutathione reductase (GR), total glutathione (GT), glutathione reduced (GSH) and oxidized glutathione (GSSG). The results show an increase in GPX activity at 7 and 60 d and a decrease at 30 and 90 d ($p < 0.05$). The GR has a significant increase from 7 to 90 d compared to the control group. The GSSG presents a significant increase at 7, 15 and 60 d and a reduction at 30 and 90 d ($p<0.05$) compared to the control group. GSH showed a significant increase at 30 d and a decrease at 60 and 90 d ($p<0.05$) against control group. The neuromelanin shows a significant increase at 7 and 15 d and decreased at 60 and 90 d compared to the control group ($p < 0.05$). In conclusion exposure to O3 causes glutathione system alteration and block neuromelanine formation, which depends on the time of exposure to this gas. Therefore, oxidative stress caused by ozone exposure, contributes to the process of the progressive neurodegeneration in SN similar to what may be happening in PD.

Title: Characterization of Parkin expression in aged rhesus monkeys

Authors: *W. YANG[1], Z. TU[1], S. LI[2], X.-J. LI[2,1]
[1]State Key Lab. of Mol. Developmental Biol., IGDB, Chinese Acad. of Sci., Beijing, China; [2]Dept. of Human Genet., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Parkinson’s disease (PD) is an age-dependent neurodegenerative disorder that can be caused by genetic mutations. The loss of function of parkin caused by parkin gene mutations has been found to be associated with autosomal recessive early onset PD. Studies have suggested that parkin is capable of degrading the toxic forms of α-synuclein via its E3 ubiquitin ligase activity that targets proteins for proteasomal degradation, resulting in protecting neuronal cells from oxidative stressors. It remains to be investigated how parkin is expressed in the primate brain regions, especially in the aged substantia nigra that is particularly affected in PD. Here we examined the expression of parkin in the brain and peripheral tissues of rhesus macaque at 2, 8,

and 22 years of age. Western blot analysis showed that there are mainly two isoforms of parkin protein (52 kD and 45 kD) expressed in monkey tissues. While the expression of parkin is relatively stable in peripheral tissues at different ages, the level of parkin is markedly increased in the monkey brain regions from 2 to 8 years, suggesting that parkin function is important for neuronal function in the adult primate brain. Interestingly, there are varied expression levels of parkin in the substantia nigra in individual monkeys at 22 years of age. Our findings suggest that the different expression of parkin in the aged primate brain regions may contribute to the PD susceptibility during aging.

Title: Increased glutamate release in the dorsal striatum of a mitochondrial mouse model of parkinson's disease

Authors: *H. A. BOGER[1], A. FARRAND[1], R. GREGORY[2], K. HELKE[2]
[1]Neurosciences, [2]Comparative Med., Med. Univ. of South Carolina, Charleston, SC

Abstract: Mitochondrial dysfunction has been implicated in the degeneration of dopamine (DA) neurons in Parkinson's disease (PD). In addition, many animal models of PD utilizing neurotoxins, such as 6-OHDA and MPTP, have shown that these toxins disrupt mitochondrial respiration by targeting complex I of the electron transport chain, thereby impairing DA neurons in these models. The MitoPark mouse model was created to mimic the mitochondrial dysfunction observed in the DA system of PD. These mice display the same phenotypic characteristics as PD including, accelerated decline in motor function and DAergic systems with age. In addition, these mice respond to L-dopa treatment and with age, they also develop L-dopa dyskinesia, however the mechanism is unknown. A potential cause of L-dopa dyskinesia is corticostriatal glutamate excitotoxicity. Therefore, the focus of this study was to determine glutamate neurotransmission in the dorsal striatum of 28 week old MitoPark mice. At this age, MitoPark mice are displaying significant motor deficits. Using *in vivo* electrochemical detection of

glutamate, MitoPark mice have greater KCl-stimulated release of glutamate compared to control mice. In addition, PCR analysis of dorsal striatal tissue indicate that MitoPark mice have greater RNA expression of glutamate-specific receptors, including mGluR3, mGluR5, and NMDAR-2A. This increased expression pattern coupled with increase release suggests that MitoPark mice have a greater risk for glutamate-induced toxicity, as it has been shown that continuous activation of post-synaptic glutamate receptors increases intracellular levels of Ca2+ and cell death. Studies are ongoing to correlate the changes in glutamate release to DAergic markers. Future studies will be conducted to determine if blocking glutamate receptors or increasing glutamate uptake will reduce/prevent L-dopa induced dyskinesia as associated with DAergic mitochondrial dysfunction.

Title: Dynamics of neurodegeneration in a slow progressive MPTP marmoset model for idiopathic Parkinson's disease

Authors: *S. TOLBOOM[1,2], R. E. VAN KESTEREN[1], S. O. HOFMAN[2], J. A. M. WUBBEN[2], A. B. SMIT[1], I. H. C. H. PHILIPPENS[2]
[1]CNCR, VU Amsterdam, Amsterdam, Netherlands; [2]Neurodegeneration, BPRC, Rijswijk, Netherlands

Abstract: The current study investigates the dynamics and progression of neurodegeneration in a slow progressive model for idiopathic PD in marmoset monkeys (Callitrix jacchus). PD symptoms and pathology were elicited by intraperitoneal injections with a low dose of the neurotoxin MPTP on a weekly basis. Investigated were 1) the timing of symptom expression, 2) the individual variation of sensitivity towards MPTP, similar to the variation of disease severity in PD patients, and 3) the compensatory mechanisms after discontinuation of MPTP injections. Marmosets were selected from five different breeding families to obtain a genetically diverse group of animals for investigating familial aspects of PD. Animals were once weekly injected with MPTP (0.5 mg/kg, sc) and monitored over time using an extensive battery of behavioral assessments, including motor as well as non-motor related tests. In addition, we analyzed brain

tissue of animals from all disease stages using histology, to relate the disease symptoms to the pathological state, and with proteomics, which might reveal novel molecular targets in the development and progression of the disease. The slow induction of PD with low MPTP doses led to disturbances in both motor and non-motor-related behavior. As expected, motor-related behaviors were progressively impaired with disease progression. In addition, variation was observed in the onset and progression of parkinsonian symptoms, which correlated well with the animal's genetic background. These findings strongly suggest a genetic component, which will be further investigated using whole-genome sequencing. Strikingly, at the time of diagnosis, when only subtle parkinsonian symptoms were observed only mild degeneration was found in the substantia nigra. This suggests that degeneration starts in the axons of the affected neurons. Indeed, in the striatum a decline in levels of thyroxin hydroxylase, an enzyme necessary for the synthesis of dopamine, was found. In addition, all tested animals showed improvement of parkinsonian symptoms and motor related behavior after stopping MPTP treatment, which allowed us to uniquely address molecular and cellular mechanisms of compensatory processes. The slow progressive MPTP model for idiopathic PD provides a window of opportunity to test disease-modifying drugs on early progression and dynamics of PD. Moreover, this model allows us to study the recovery mechanism after MPTP discontinuation, leading to possible treatment options of PD. The integrative nature of the markers used and the human clinical validity of the marmoset model will contribute to a better understanding of the development and progression of the disease.

Abstract: Aging has been proposed as the major risk factor in the development of most neurodegenerative disorders, including Parkinson's disease (PD). Although it is likely that many systems are affected by aging, it is well recognized that during ageing there is a generalized increase in the oxidative stress state of the brain. Here, we examine the response of 3 strains of mice (C57BL/6, Swiss-Webster, GSTpi-/-) at three different ages (4 months, 12 months and 24 months) to an acute administration of a known inducer of oxidative stress, the parkinsonian toxin MPTP. We examined the SNpc for loss of SNpc DA neurons, induction of an inflammatory response by stereological assessment of resting and activated microglia as well as two measures of behavior: open field for general activity and rotorod for examination of motor coordination. We find that aging alone does not seem to have any significant effect on the number of SNpc DA neurons, astrocytes or microglia in C57B/6, Swiss-Webster or GSTpi-/- mice. Behaviorally, we observed that rotorod performance decreased as animal's age, but not difference was seen among genotypes; although there were noted differences between males and females. In open field, general activity was similar through 24 months in C57BL/6 and GSTpi-/- mice, but significantly increase in the Swiss-Webster. Exploratory behavior measured by rearing behavior was also stable in C57BL/6 and Swiss-Webster but declined in GSTpi-/- mice. Following MPTP, we find that as mice age, they do not increase their sensitivity to MPTP as measured by SNpc DA neuron number. In a similar manner ageing does not affect MPTP-induced changes in general activity.

and Sci., Univ. of South Florida, Tampa, FL; [6]Dept. of Psychiatry, Yale University, Sch. of Med., New Haven, CT

Abstract: MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) is a neurotoxin precursor to MPP+, which causes permanent symptoms of Parkinson's disease by destroying dopaminergic neurons in the substantia nigra of the brain. Monkeys exposed to low doses of MPTP may show cognitive deficits without motor abnormalities. Such cognitive deficits are similar to that observed in early Parkinson's Disease. The prefrontal cortex, which plays an important role in executive functions, receives a dense dopaminergic input. Dysregulation of dopamine (DA) circuitry may disrupt normal cognition. Using monkeys, the goal of this study was to assess the effects of MPTP neurotoxicity on dendritic circuitry in the monkey dorsolateral prefrontal cortex (DLPFC), a region critical to working memory performance. Young adult African Green monkeys were administered MPTP (2.25mg/kg) over 5 consecutive days. The animals were sacrificed 10 months after drug administration. Blocks of fixed brain tissue were Golgi impregnated and coded slides prepared. Randomly selected layer V and layer II-III pyramids were evaluated for amount of dendritic material and complexity of the dendritic arbors. Analysis of layer II-III pyramids showed a significant loss of arbor in the MPTP-treated monkeys (-22%) with a similar reduction in dendritic branching complexity. Layer V pyramids, by contrast, showed less disruption of circuitry with a 15% loss of dendritic branching and an 11% loss of neuronal complexity. These data support and extend previous findings on spine synapse changes following MPTP. The data is further consistent with a role for dopamine in regulating dendritic branching and spine changes on pyramidal neurons in the dorsolateral prefrontal cortex.

Title: The utilization of Engrailed 1 in developing neurons for cell replacement therapy in Parkinson's Disease

Authors: S. PARKER[1,2,4], R. WELCHKO[1,2,4], J. ROSSIGNOL[1,2,3,4], M. LU[1,4], *G. L. DUNBAR[1,2,4]
[1]Dept Psychol, Central Michigan Univ., MT PLEASANT, MI; [2]Program in Neurosci., Central Michigan Univ., Mt pleasant, MI; [3]Col. of Med., Central Michigan Univ., Mt. pleasant, MI; [4]Field Neurosciences Inst. Lab. for Restorative Neurol., Mt. pleasant, MI

Abstract: Parkinson's disease (PD) is a neurodegenerative disease with symptoms that include slowness in movement, tremors, depression and in some cases dementia. Cell replacement therapy (CRT) has shown potential to reverse the effects of PD. In PD patients there is a substantial loss of dopamine (DA) neurons in the substantia nigra pars compacta (SNpc). The aim of CRT is to transplant cells into the human brain that are able to survive for decades, behave similar to SNpc cells, and integrate within the striata. For CRT, finding a method that consistently produces cells with a greater survivability that will effectively replace the lost DA neurons would be invaluable. In this study, a gene involved in the survivability and development of DA neurons, Engrailed 1 (En1), was used in conjunction with three other genes to improve the transformation of mesenchymal stem cells (MSCs) into DA neurons. Previous studies have shown MSCs can be used as a source of DA neurons after exposure to certain genes. This study utilized an adenovirus and retrovirus recently developed in our lab. The adenovirus forces the polycistronic expression of the transcription factors Nurr1, Ascl1, and Lmx1a and the retrovirus forces expression of En1. This study focused on En1 as a candidate for improving the survivability of DA neurons transformed from MSCs. *In vivo* studies have shown En1 is involved in the development of the SNpc, in the generation of DA neurons in the brain, in addition to DA neuron survivability. To confirm that DA neurons were produced, expression levels of specific proteins were tested through RT-PCR and immunocytochemistry (ICC). Survivability of the DA neurons was quantified, plus the efficiency of DA production was quantitatively determined through a technique called high performance liquid chromatography (HPLC). Our results suggests that En1 has the potential for improving the survivability of DA neurons and that techniques to enhance this gene is worthy of further study.

Title: Glucocerebrosidase deficiency and glycolipid accumulation occurs in both normal aging and sporadic Parkinson's disease

Authors: *E. N. MANGANO[1], G. A. SMITH[1], E. PARK[2], H. CAO[2], E. BROWN[2], J. A. BEAGAN[1], Z. E. SCHNEIDER-LYNCH[1], D. A. AHMADI[1], P. J. HALLETT[1], O. ISACSON[1]
[1]Neuroregeneration Inst., McLean Hosp. /Harvard Med. Sch., Belmont, MA; [2]Shire, Lexington, MA

Abstract: Clinical and neuropathological evidence links GBA1, which encodes for the lysosomal hydrolase glucocerebrosidase (GCase) with sporadic PD. GCase is responsible for the conversion of the undegraded lipid substrates glucosylceramide (GluCer) and glucosylsphingosine (GluSph) into ceramide and sphingosine, respectively. A subset of sporadic PD-patients (~4-7%) has been identified as GBA1-mutation carriers, causing diminished activity (~30-40%) of GCase. PD-patients that carry a GBA1 mutation are often diagnosed younger and the symptoms are usually reported as more severe than PD-patients lacking a mutation. Identifying reliable biomarkers that closely associate with the pathogenic changes that occur during the early stages of PD may help increase the accuracy of early diagnosis. Diminished levels of GCase activity have been reported in the brains and CSF of sporadic PD patients, irrespective of whether they harbor GBA1 mutations. Therefore, we hypothesize that GCase activity and its associated glycolipids may be useful biomarkers to predict early stages of sporadic PD. We found widespread GluSph up-regulation in the putamen, cerebellum, hippocampus and frontal cortex, which coincided with reductions in GCase activity of non-GBA mutation carrying sporadic PD-patients in comparison to age-matched control patients. In addition to these changes, we also found age-dependent increases in GluSph, which correspond to a reduction in GCase activity. Moreover, we found age-dependent increases in GluCer and GluSph in wildtype and transgenic mice that overexpress human wildtype α-synuclein. Therefore, we hypothesize that age-dependent dysregulation in GCase activity and accumulation of glycolipids occurs with normal aging, which is further exacerbated with sporadic PD-patients.

Title: Quantification of postural stability in patients with Parkinson's disease using mobile technology

Authors: ***S. J. OZINGA**, A. G. MACHADO, A. B. ROSENFELDT, J. L. ALBERTS
Cleveland Clin., Cleveland, OH

Abstract: Patients with Parkinson's disease (PD) have declines in postural stability and exhibit gait dysfunction. Traditional biomechanical equipment has been used to identify these declines in stability. Unfortunately, the vast majority of clinical environments do not have access to biomechanical equipment to adequately assess postural stability. However, recent advances in processor speed and on-board electronics of mobile devices, present an opportunity to quantify postural stability. The aim of this project was to determine if kinematic data measured by the accelerometer and gyroscope within the iPad was of sufficient quantity and quality to accurately quantify postural stability in patients with PD. Seventeen patients with PD (8 males and 9 females; mean age 62±9) and seventeen healthy age-matched controls (7 males and 10 females; mean age 62±10) completed six different balance conditions under altered surface, stance, and vision. Simultaneous kinematic measurements were gathered from a three-dimensional motion analysis system and the iPad during balance testing. There was agreement between iPad and motion analysis systems in the overall assessment of postural stability for both the PD and older adult population. For each balance trial within the PD population, significant correlation between the two systems was present for: 1) three measures of postural sway from medial-lateral (ML) and anterior-posterior (AP) acceleration time-domain signals, including *peak-to-peak* (r values ranged from 0.75 to 0.97), *normalized path length* (0.49 to 0.99), and *root mean square* (0.71 to 0.98), 2) *95% ellipsoid volume*, combining ML, AP, and trunk rotation (TR) acceleration (0.98 to 1.00), and 3) *total power*, quantifying the magnitude of the ML, AP, and TR resultant acceleration in the frequency-domain (0.94 to 1.00). The tandem stance on firm and foam surfaces showed the greatest discrimination between PD and older adults, with 75% and 100% of significantly different sway measures for the firm and foam surfaces, respectively. Also, PD patients exhibited significantly more postural sway when standing in the tandem stance on a foam surface versus in the double-leg stance on a foam surface ($p<0.05$) as well as standing in the tandem stance on a foam surface versus a firm surface ($p<0.05$). Collectively, these results

indicate the accelerometer and gyroscope hardware within the iPad provide data of sufficient accuracy and quality to discriminate between populations and conditions during postural stability assessments. The objectivity, portability, and ease of use of this device make it ideal for use in clinical environments lacking sophisticated biomechanical systems.

Title: Quantifying the short-term effects of Subthalamic deep brain stimulation surgery on bradykinesia in Parkinson's disease patients

Authors: *M. DELROBAEI[1], G. GILMORE[2], K. OGNJANOVIC[2], F. RAHIMI[1], S. XIAN[1], S. TRAN[2], K. MCISAAC[2], M. JOG[1,2]
[1]Lawson Hlth. Res. Inst., London, ON, Canada; [2]Western Univ., London, ON, Canada

Abstract: Objective: Clinical scale based follow-up of patients undergoing Subthalamic deep brain stimulation (STN-DBS) has shown inconsistent effects on bradykinesia in Parkinson disease (PD) patients. However, quantitative assessment of STN-DBS effect on bradykinesia has not been done. Our group uses multisensory kinematic technologies to study long-term DBS effects on Parkinson disease. We present the kinematic analysis of the short term (3 month) effects of STN-DBS on bradykinesia in 5 PD patients. Method: 5 PD patients (age: 65±3.3, PD duration: 12.2±3.3) were recruited. All patients were eligible for STN-DBS procedure. Each patient was assessed at six time points with both the Unified Parkinson Disease Rating Scale (UPDRS) and a motion capture system: (0) preoperatively, (1) 1 week postoperatively, (2) 2 weeks postoperatively, (3) 1 month following surgery, on-DBS, (4) 2 months following surgery, on-DBS, and (5) 3 months following surgery, on-DBS. The participants performed a standard repetitive forearm pronation-supination task for 5 seconds for each arm while sitting. The angular displacement of forearm was quantified using an Animazoo IGS-180 suit. A set of quantitative measures of bradykinesia were extracted for both arms. The features include: the

root mean square (RMS), the standard deviation (STD), the range of motion (ROM), the dominant frequency (DFQ), and the peak power (PWR). Results: While the bradykinesia score (UPDRS Part III - Item 31) did not show any noticeable changes (0.2, 0.2, 0.2, 0.0, 0.0, and 0.2 on average from baseline to visit five after the surgery), the objective measures identified some improvements. On average, compared to baseline (pre-op), the RMS of forearm angular displacement increased by 23.1, 41.4, 36.6, 14.0, and 36.0% from visit one to visit five after the surgery. The STD increased by 23.9, 32.2, 45.9, 25.7, and 60.9% and the ROM increased by 21.7, 24.6, 23.3, 11.3, and 31.2% for the same duration. The results did not show any consistent increase for the DFQ which slightly increased in the first three visits (11.3, 4.1, 7.0%, respectively), but decreased afterwards (-6.1% at visit 4 and -12.9% at visit 5). Compared to other features, the PWR showed considerably more improvement, as increased by 52.6, 134.5, 155.3, 110.1, and 222.3%, respectively. Conclusions: Using a sensitive tool, our team was able to objectively monitor the immediate effects of STN-DBS on bradykinesia. The microlesion effects were quantified and showed improvements in the proposed features. Although the angular velocity (corresponding to the DFQ), which is clinically more observable, did not generally improve, the peak power showed maximal improvement.

Title: Persistent longitudinal alterations of neurotransmission in LRRK2 G2019S Knock-In mice

Authors: *D. A. BECCANO-KELLY[1], M. VOLTA[1], E. MITCHELL[1], D. SMITH[1], I. TATARNIKOV[1], S. BERGERON[1], K. CO[1], L. MUNSIE[1], H. L. MELROSE[3], M. J. FARRER[1], A. J. MILNERWOOD[2]
[1]Med. Genet., [2]Med., Univ. of British Columbia, Vancouver, BC, Canada; [3]Dept. of Neurosci., Mayo Clin. Jacksonville, Jacksonville, FL

Abstract: Parkinson's disease (PD) is the most prevalent neurodegenerative movement disorder in the world, affecting ~2% of the population. Mutations in the LRRK2 protein are a major cause of familial and sporadic PD. The protein is central to cytoskeletal dynamics and indirectly involved in autophagy, endosomal trafficking (linked to retromer recycling) and exo/endocytosis (synaptic transmission). Changes in neurotransmission appear to be important in PD with most recent studies illustrating that LRRK2 knock-down/knock out influences striatal glutamate signaling. LRRK2 overexpressor (OE) mice also illustrate alterations to short term striatal glutamatergic plasticity in addition to motor deficits and biochemical changes in the levels of key synaptic proteins such as dopamine D2 receptors. In order to investigate the effects of PD related LRRK2 mutations on neurotransmission, a longitudinal study assessing electrophysiological, behavioural and molecular changes was performed on knock-in mice carrying the G2019S mutation (accounting for ~2% of PD cases) in the LRRK2 murine homologue with endogenous control of expression. Whole-cell electrophysiological recordings in acute brain slices from 1, 3, 12 & 18 month old mice revealed varying alterations in glutamatergic transmission onto striatal medium spiny neurones of male heterozygous and homozygous knock-in animals in comparison to wild-type littermates. Concomitant motor phenotype is evident in the same genotypes. Interestingly, pharmacological agents significantly modulate the electrophysiological and behavioural effects of the wild type littermates, whilst having no effect on the animals heterozygous and homozygous for the G2019S mutation. Western blot analysis further revealed altered levels of numerous striatal receptors and signal transduction proteins pertinent to neurotransmission including LRRK2 itself. The data suggest another consequence of the G2019S mutation is altered LRRK2 auto-regulation. The data illustrates an ongoing effect on neurotransmission and behaviour caused by a single PD associated point mutation. These synaptic, motor and cognitive phenotypes are distinct from those observed in either OE or knock-out mice. This neither simplistic loss nor gain of function persists over the mammalian lifetime and represents an on-going effect that may be best tackled therapeutically during the early stage of aberrant neurotransmission alterations, therefore preventing the onset and progression of PD.

Title: Exogenous oligomeric alpha-synuclein in LRRK2 transgenic animals

Authors: *M. VOLTA, S. BERGERON, E. MITCHELL, L. MUNSIE, D. BECCANO-KELLY, A. MILNERWOOD, M. FARRER
Med. Genet., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Exogenous pathological forms of alpha-synuclein (aSyn) have been reported to seed the formation of intracellular aggregates in neuronal cultures, transgenic mice overexpressing A53T-aSyn and normal mice, through recruitment of endogenous soluble aSyn. *In vivo*, both recombinant aSyn fibrils and brain homogenates from symptomatic A53T-aSyn transgenic mice (exhibiting widespread synucleinopathy) induce progressive neuropathology, neurodegeneration and behavioral alterations. Along with genetic alterations in SNCA, mutations in the LRRK2 gene are amongst the main causes of familial Parkinson's disease (PD). The proteins are reported to interact at the molecular level and in Lewy body disease. However double transgenic mice led to conflicting results. Specifically some data shows LRRK2 overexpression accelerated mutant aSyn-induced pathology whereas other reports showed no additive effects. Thus, the relevance of LRRK2-aSyn interaction *in vivo* remains poorly understood. We sought to employ a more subtle approach, avoiding generalized protein overexpression. Hence, we unilaterally injected LRRK2 KO mice and non-transgenic littermates (NT LMs) into the dorsolateral striatum with either aSyn pre-formed fibrils (PFFs) or PBS vehicle. Animals were assessed before, 30 and 90 days after surgery in various behavioral tests analyzing locomotion, symmetry, anxiety and cognition. We observed a dramatic deficit in recognition memory in NT mice treated with PFFs and we are confirming the effect on KO animals. At the two post-injection time-points, the mice are transcardially perfused with PBS, the brains removed and embedded in paraffin. Immunohistochemistry was performed to assess the phosphorylation of aSyn at the Ser129 residue, the presence of aggregated forms of aSyn (through the use of the pathologic conformation-specific antibody Syn506) and tyrosine-hydroxylase expression in striatum and substantia nigra. To correlate the cognitive impairment with a neurophysiological mechanism, we are also assessing the efficacy of hippocampal plasticity in these animals. In an effort to further characterize the effects of exogenous aSyn, we are treating cortical neuron cultures prepared from LRRK2 KO mice and NT LMs with PFFs or PBS. We will assess pSer129-aSyn and aggregation, together with density of dendritic spines and synaptic markers. Our studies will expand current knowledge on the consequences of amyloid-like protein treatment and clarify the relative roles of LRRK2 and aSyn in neuronal physiology, neuropathology and behavior. These

data will form the basis of a more comprehensive approach on the molecular origins of late-onset PD.

Title: Drug screening for LRRK2 Parkinsonism: using the *Drosophila* dendritic arborization neurons as a model system

Authors: ***C.-H. LIN**[1], H.-I. LIN[2], R.-M. WU[2]
[1]Dept. of Neurology, Natl. Taiwan Universit, Taipei, Taiwan; [2]Dept. of Neurology, Natl. Taiwan Univ. Hosp., Taipei, Taiwan

Abstract: Background and Purpose: Parkinson's disease (PD) is a common neurodegenerative disorder, which is caused by the interplay between genetic and environmental factors. Mutations in Leucine-rich repeat kinase (LRRK2) are the most prevalent in both familial and sporadic PD, especially the non-synonymous G2019S mutation. We have previously created a transgenic LRRK2-G2019S *Drosophila* model and demonstrated loss of dopaminergic neurons, decreased longevity and behavioral deficits, which recapitulates several key features of human parkinsonism. Currently, there is no therapeutic treatment to slow or ameliorate the degeneration process in PD. We proposed to use the LRRK2-G2019S fly model to screen for a library with 640 FDA-approved drugs and identify potential compounds that could have a rescue effect of neurons in this fly model. Methods: An FDA-approved Drug Library consisting of 640 compounds were tested by using dendrite phenotype analysis of 3rd instar larva of LRRK2-G2019S transgenic flies in the first step of our analysis. We tested different concentrations of each compound and each experiment will be replicated for at least 3 times to get the mean value of number of dendritic arbors of each condition. After identifying the potential candidate drugs in the above first step, we will examine the potential beneficial effects on dopaminergic neurons in aging LRRK2-G2019S adult flies. We fed LRRK2-G2019S flies with candidate compounds

two weeks after egg laying and investigated the behavior, life-span and number of dopaminergic neurons of these aging LRRK2-G2019S flies. Results: Among the 640 screened drugs, 29 drugs with potential protective effects were identified using the dendrite phenotype analysis in the first step, with optimal concentration varied between 50 and 100 μM. It was found that 3 out of these 29 drugs demonstrated the most significant rescue effects of dendrite degeneration, those are Flufenamic acid, Lovastatin and Rifampicin. In the second part of the study, we found that treatment with Lovastatin and Rifampicin significantly improved the climbing speed of LRRK2-G2019S aging flies as compared to treatment with DMSO. Treatment with Flufenamic acid only showed some beneficial effect but not reach the significance level. Conclusions: Our results showed that Lovastatin and Rifampicin are potential neuroprotective agents for LRRK Parkinsonism. Future drug trial in patients with LRRK2-G2019S mutations are needed to confirm the beneficial effects of these two medications.

Title: Genetic and pharmacological evidence that G2019S LRRK2 confers hyperkinetic phenotype and prevents motor decline associated with aging

Authors: ***F. LONGO**[1], I. RUSSO[2], D. SHIMSHEK[3], E. GREGGIO[2], M. MORARI[4]

Degli Studi Di Ferrara, Ferrara, Italy; [2]Dept. of Biology, Univ. of Padova, Padova, Italy; [3]Dept. of Autoimmunity/Transplantation/Inflammation-Neuroinflammation-Novartis Inst. for BioMedical Research, Novartis Pharma AG, Basel, Switzerland; [4]Dept. of Med. Sciences, Section of Pharmacology, and Natl. Inst. of Neuroscience, Univ. of Ferrara, Ferrara, Italy

Abstract: The leucine-rich repeat kinase 2 mutation G2019S in the kinase domain is the most common genetic cause of Parkinson's disease. To investigate the impact of the G2019S mutation on motor activity *in vivo*, a longitudinal phenotyping approach was developed in knock-in (KI) mice bearing this kinase-enhancing mutation. Two cohorts of G2019S KI mice and wild-type littermates (WT) were subjected to behavioral tests, specific for akinesia, bradykinesia and

overall gait ability, at different ages (3, 6, 10, 15 and 19 months). The motor performance of G2019S KI mice remained stable up to the age of 19 months and did not show the typical age-related decline in immobility time and stepping activity of WT. Several lines of evidence suggest that enhanced LRRK2 kinase activity is the main contributor to the observed hyperkinetic phenotype of G2019S KI mice: i) KI mice carrying a LRRK2 kinase-dead mutation (D1994S KD) showed a similar progressive motor decline as WT; ii) two LRRK2 kinase inhibitors, H-1152 and Nov-LRRK2-11, acutely reversed the hyperkinetic phenotype of G2019S KI mice, while being ineffective in WT or D1994S KD animals. LRRK2 target engagement *in vivo* was further substantiated by LRRK2 de-phosphorylation at Ser935 in the striatum and cortex at efficacious doses of Nov-LRRK2-11, and in the striatum at efficacious doses of H-1152. In summary, expression of the G2019S mutation in the mouse LRRK2 gene has beneficial effect on motor function, likely via enhancement of LRRK2 kinase activity. This study provides an *in vivo* model to investigate motor effects of LRRK2 inhibitors.

Title: The Parkinsonian LRRK2*R1441G mutation modulates LPS-induced immune response in the brain and periphery

Authors: *E. A. KOZINA, Y. JIAO, Y. DOU, R. J. SMEYNE
St. Jude Children's Res. Hosp., Memphis, TN

Abstract: Mutations in the leucine-rich repeat kinase 2 gene (LRRK2) are the most frequent cause of familial late-onset Parkinson's disease (PD), with clinical and pathological phenotypes similar to that observed in sporadic PD. The highest level of LRRK2 protein expression is seen in cells of the immune system, particularly in B-cells and macrophages, suggesting that LRRK2 may play an important role in immune signaling pathways. This is supported by findings of genetic variations in LRRK2 in other immunological diseases, including Crohn’s disease and leprosy. Post-mortem human studies of PD brains support a critical role for neuroinflammation in its pathogenesis. Therefore, we compared how the immune system in the brain and periphery

responds in WT and transgenic mice carrying LRRK2*R1441G mutation. To stimulate the immune system, 3 month old transgenic LRRK2*R1441G and FVB/N (WT) mice were injected with saline or lipopolysaccharide (LPS, 5 mg/kg, i.p.). Blood, brain, and spleen tissue were collected at many time points ranging from 1 hour to 7 months after LPS exposure. In these brains we examined microglial activation, cytokine concentration, leukocyte infiltration as well as tyrosine hydroxylase (TH) and LRRK2 protein expression in the striatum and substantia nigra. In the periphery we examined serum cytokines and the number of innate and adaptive immune cells. In the LRRK2*R1441G mice we observed an up-regulation of LRRK2 protein expression in the substantia nigra and cortex after LPS exposure. We also observed a significant increase in the number of activated Iba-1 positive microglial cells in the substantia nigra in both WT and LRRK2*R1441G mice 24 hours after LPS injection. LPS administration also transiently reduced TH expression in the substantia nigra and striatum of LRRK2*R1441G mice but not WT mice. Examination of inflammatory cytokines and chemokines in the substantia nigra and striatum showed higher levels of IL-6, IFN-γ, TNF-α, KC, and MCP-1 in LRRK2*R1441G mice compared to WT. Additionally, the pro-inflammatory cytokine IL-1α was found to be elevated in transgenic LRRK2 mice 2 months after LPS exposure. LRRK2*R1441G mice also showed an infiltration of CD3-positive T-cells into the brain parenchyma. In blood serum, we found that LRRK2*R1441G mice have increased levels of IFN-γ, IP-10, KC, MIP-1α and MCP-1 after the LPS insult. This data suggests that LRRK2*R1441G mice have an enhanced inflammatory response to LPS, and this heightened immune response may contribute to the pathogenesis of R1441G mutation.

Late Discovery, West Point, PA

Abstract: Mutations in the Leucine-rich repeat kinase 2 (LRRK2) gene cause late-onset autosomal dominant Parkinson's disease (PD) and represents the most common known cause of familial PD. The potential mechanism(s) through which LRRK2 mutations precipitate selective neuronal dysfunction and neurodegeneration in PD is poorly understood. The observation that the most prevalent missense mutation, G2019S, leads to an increase in kinase activity has led to a concerted effort to identify LRRK2 kinase inhibitors as a potential disease modifying therapy for PD. Unfortunately, the ability to interrogate LRRK2 biology with many of the published LRRK2 kinase inhibitors has been limited due to their lack of selectivity over other kinases, poor brain penetration and/or failure to demonstrate CNS in-vivo activity. Here, we characterize the pharmacological properties of MLI-2 a structurally novel, highly potent and selective LRRK2 kinase inhibitor with CNS activity. MLI-2 exhibits single-digit nM potency in an *in vitro* purified LRRK2 kinase assay and a cellular assay monitoring dephosphorylation of LRRK2 pS935 or radioligand competition binding to LRRK2. MLI-2 has excellent kinase selectivity across a range of 308 kinases in addition to a diverse panel of receptors and ion channels. In rodents MLI-2 exhibits good oral bioavailability and is not a Pgp substrate. Acute oral and sub-chronic in-diet dosing with MLI-2 in mice resulted in dose-dependent central and peripheral target inhibition across the 24-hour period as measured by dephosphorylation of LRRK2 pS935. After 15 weeks treatment in mice, MLI-2 produced sustained central and peripheral target engagement (>90% de-phosphorylation of pS935) and was well-tolerated with no evidence of lung or kidney pathology that has been observed in LRRK2 knockout or kinase-dead animals. Together these data demonstrate the suitability of MLI-2 as a tool compound to explore the biology and tolerability of LRRK2 kinase inhibition and therapeutic potential of LRRK2 kinase inhibition in animal models of PD.

Title: Characterization of mitoNEET knock-out mice as Parkinson's disease model

Authors: *W. J. GELDENHUYS[1], L. LIN[1], D. SPEICHER[1], J. YUN[2], R. T. CARROLL[1]
[1]Northeast Ohio Med. Univ., ROOTSTOWN, OH; [2]Northeast Ohio Med. Univ., ROOTSTOWN, PA

Abstract: Parkinson's disease is an age-associated neurodegenerative disease which affects the dopaminergic neurons in the *substantia nigra*. The loss of the neurotransmitter dopamine leads to the characteristic movement symptoms seen in Parkinson's disease. Although the etiology is not fully known, the pathology of the neuronal cell death in Parkinson's disease is related to mitochondria dysfunction. The mitochondrial dysfunction leads to reactive oxygen species generation and oxidative stress. mitoNEET is a novel mitochondrial protein which belongs to a zinc-finger group of proteins that is conserved throughout evolution. mitoNEET is an iron-sulfur containing protein located on the outer mitochondrial membrane of mitochondria which regulates mitochondrial bioenergetics, and overexpression of mitoNEET leads to reduction in oxidative stress. Recently, the anti-diabetic drug pioglitazone (a thiazolidinedione) was found to be a ligand for mitoNEET, and has been also shown *in vivo* to be neuroprotective in the MPTP mouse model of Parkinson's disease. We hypothesized that a mitoNEET ligand would be neuroprotective against MPTP-Complex I mediated dopaminergic neuronal cell death. In this study, our goal was to evaluate a mitoNEET ligand NL-1, a derivative of pioglitazone, in the MPTP mouse model. In this study, C57BL/6 aged male mice as well as mitoNEET KO mice were treated with either vehicle, MPTP (35 mg/kg) NL-1 (10 mg/kg) or MPTP and NL-1 for 7 days. After 7 days, the dopamine was evaluated by HPLC-EC and biochemical markers evaluated by Western Blot. These results clearly demonstrated that mitoNEET ligand NL-1 was able to protect the dopaminergic neurons thus suggesting that mitoNEET could be a viable drug target in mitochondrial dysfunction related diseases such as Parkinson's.

Title: Transmission of human Lewy body disease prions to mice

Authors: ***D. R. JONES**[1], D. MARION[1], M. DETURE[1], A. BAINE[1], M. E. MURRAY[1], D. W. DICKSON[1,2], P. J. MCLEAN[1,2]
[1]Neurosci., Mayo Clin., Jacksonville, FL; [2]Mayo Grad. Sch., Jacksonville, FL

Abstract: The synucleinopathies are a group of neurodegenerative disorders characterized by the presence of neuronal inclusions called Lewy bodies and Lewy neurites, and include Parkinson's disease, multiple system atrophy and Lewy body disease (LBD). Recent data suggests that a pathogenic misfolding of the presynaptic protein, alpha-synuclein, and its subsequent aggregation and accumulation is fundamental to the disease process. It is hypothesized that the misfolded isoform is able to induce misfolding of normal endogenous alpha-synuclein, and that the disease propagates from cell-to-cell much like the prion diseases. In this study we performed intracerebral (i.c.) or intraperitoneal (i.p.) inoculations of sarkosyl insoluble or sarkosyl soluble human LBD brain homogenate and show that both non-transgenic mice and mice expressing wild-type human alpha-synuclein develop disease-associated immunopositive deposits at 4 months post-injection (i.c. cohort) or at 8 months post-injection (i.p. cohort). Transgenic mice inoculated i.c. (caudate putamen) displayed a marked increase in proteinase K-resistant LB509 positive deposits in the hippocampus and striatum, and phosphorylated alpha-synuclein positive deposits in the hippocampus, striatum and cortex, compared with transgenic mice inoculated with brain homogenate from an age-matched control having few to no Lewy bodies. Non-transgenic mice inoculated by the i.c. route displayed phosphorylated alpha-synuclein positive

deposits in the hippocampus, striatum and cortex, but no LB509 positive deposits were found. Non-transgenic mice inoculated i.p. had phosphorylated alpha-synuclein deposits in the cerebellum, pons and medulla only. There was no significant difference between the numbers of phosphorylated alpha-synuclein deposits in the rhombencephalon of peripherally inoculated transgenic mice versus control injected transgenic mice. These results provide insight into the mechanisms by which misfolded alpha-synuclein may spread from cell-to-cell, and support the hypothesis that disease-associated alpha-synuclein proteins are true prions.

Title: PARK14 Ex2(KO) mice as a novel model for age-dependent Parkinson's disease

Authors: Q. ZHOU[1], A. YEN[1], H. ASAI[2], T. IKEZU[2], B. WOLOZIN[2], *V. M. BOLOTINA[1]
[1]Med., [2]Pharmacol., Boston Univ. Sch. of Med., Boston, MA

Abstract: One of the major limitations in Parkinson's disease (PD) study is the absence of a mammalian model that closely mimics age-dependent progression of human PD. Recently, we created a new PARK14 $Ex2^{KO}$ mouse model in which the specific Ca^{2+} signaling function of PARK14 (PLA2g6) was genetically impaired, and discovered that ageing $Ex2^{KO}$ mice develop a strong PD-like phenotype. Here we validate PARK14 $Ex2^{KO}$ mice as a new model for age-dependent PD, and present *in vivo* and *in vitro* evidence for progressive loss of dopaminergic (DA) neurons in substantia nigra pars compacta (SNpc) and PD-like motor dysfunction in $Ex2^{KO}$ animals. Comparative analysis of ageing $Ex2^{KO}$ and WT male littermates (using balance beam, pole, rotarod, open field and other behavioral tests) uncovered the onset of ataxia and motor deficit at 10 months, which slowly progressed with age, and reached very severe motor dysfunction by 20 months. Balance beam test showed that the number of missteps in $Ex2^{KO}$

animals was 3±1, 4±1, 16±3 and 30±4 -fold higher than in WT animals at age of 10, 12, 16 and 20 months, respectively. Pole test showed 5±1 and 7±1 -fold reduction in performance of $Ex2^{KO}$ mice at 12 and 16 months, respectively. Open Field test revealed that $Ex2^{KO}$ mice display increased stereotypic movement, and decreased rearing. Importantly, L-DOPA reversed the motor deficits in KO^{Ex2} mice in dose and age-dependent manner: single injection of 5, 10, and 25 mg/kg L-DOPA improved motor coordination in 16 months old mice by 18%, 60%, and 80%, respectively. Lower doses of L-DOPA achieved similar effects in younger (12 months), while higher doses were needed for older (20 months) animals. It is important to mention that progressive ataxia and age-dependent motor dysfunction in $Ex2^{KO}$ animals were not a result of muscle or neuroaxonal dystrophy, as grip test showed no difference in $Ex2^{KO}$ and WT animals up to 20 months of age. Stereological analysis of TH-positive neurons in SNpc revealed progressive loss of dopaminergic neurons in ageing $Ex2^{KO}$, but not WT animals. However,no difference was observed in the number of TH+ neurons at 6-8 months, about 35% reduction could be seen in $Ex2^{KO}$ at 16 months, and more than 55% reduction at 24 months. Importantly, the number of degenerating PAS+ neurons in the SNpc was increased more than 10-fold, but no difference was found in the hippocampus or motor cortex of 16 months old $Ex2^{KO}$, compared to WT animals. Thus, $Ex2^{KO}$ mice develop age-dependent neurodegeneration with progressive loss of DA neurons in SNpc and specific motor dysfunction that closely mimic parkinsonism in humans. This mouse offers a novel mammalian model of age-dependent PD that can be used for testing new drugs and treatments.

Title: LRRK2-G2019S expression in the brains of BAC transgenic rats resembles the distribution of LRRK2 in humans and non-human primates

Authors: *J. BLACKBURN[1], R. COWELL[2], J. P. L. DAHER[2], M. S. MOEHLE[2], K. M. HINKLE[3], H. L. MELROSE[3], D. G. STANDAERT[2], A. B. WEST[2], L. A. VOLPICELLI-DALEY[2]

Abstract: A major percentage of late-onset Parkinson's Disease (PD) patients have mutations in leucine-rich repeat kinase 2 (LRRK2). Here, we utilize recently characterized monoclonal antibodies to evaluate rodent LRRK2 expression in the cortex, striatum, and substantia nigra pars compacta, brain regions relevant to PD. In both mice and rats, LRRK2 is highly expressed in the cortex and striatum, particularly in pyramidal neurons of layer V and in medium spiny neurons within striosomes. Nontrangenic rats express minimal to no LRRK2 in the SNpc. However, LRRK2-G2019S expression derived from human BAC constructs causes LRRK2 to be expressed in the substantia nigra pars compacta. In addition, unlike nontransgenic rats, BAC-LRRK2-G2019S rats express LRRK2 in striatal cholinergic interneurons. The distribution of LRRK2 from human BAC constructs more closely resembles descriptions of LRRK2 in humans and non-human primates. Computational analyses of DNA regulatory elements in LRRK2 show a primate-specific promoter sequence which may direct neuronal expression patterns. Together, these studies will aid in understanding the normal function of LRRK2 in the brain and will assist in model selection for future studies.

Abstract: Eukaryotic translation initiation factor gamma 1 (eIF4G1) is involved in protein translation. Recent studies identified point mutations in the EIF4G1 gene in autosomal dominant Parkinson's disease (PD), potentially linking eIF4G1 and protein translation with PD. Recent finding from our laboratory show that the alterations in protein translation plays a critical role in neurodegeneration in LRRK2 model of PD. To explore the role of eIF4G1 in PD, we generated conditional eIF4G1 transgenic mice expressing wild type and disease associated mutants (R1205H or A502V) eIF4G1. These mice express high levels of eIF4G1 in the olfactory bulb, cortex, hippocampus, substantia nigra pars compacta (SNpc) and striatum. When disease associated mutant eIF4G1 is expressed in brains of transgenic mice, they develop progressive degeneration of dopaminergic neurons in the SNpc, and exhibit behavioral deficits that are not observed in wild type eIF4G1 or littermate control mice. These data implicate these mutations in eIF4G1 play a role in the pathogenesis of PD, potentially through alterations in protein translation. Further characterization of these mice will reveal crucial roles of protein translation and eIF4G1 mutations in the pathogenesis and progression of PD.

Title: Parkin modulation by inflammation and mitochondrial impairment leading to caspase- and calpain-dependent cleavage: cAMP neuroprotection and relevance to Parkinson disease

Authors: *C. CORWIN[1], H. WANG[2], P. ROCKWELL[2], M. FIGUEIREDO-PEREIRA[2]
[1]Biol., [2]Biol. Sci., Hunter College, CUNY, New York, NY

Abstract: Parkin is an E3 ubiquitin ligase that provides neuroprotection by regulating proteasomal degradation of cytoplasmic proteins, mitochondrial dysfunction via mitophagy, and the targeting of specific mitochondrial proteins for proteasomal degradation. Parkin dysfunction due to mutations or to post-translational modifications is associated with Parkinson disease (PD). Using rat midbrain and cerebral cortical cultures, we investigated changes in Parkin induced by inflammation and mitochondrial impairment, as both are involved in the etiology of PD. As such, we found that the effects of the neurotoxic product of inflammation prostaglandin J2 (PGJ2) and the mitochondrial inhibitor oligomycin (Oligo) on Parkin integrity were similar with both types of cultures. PGJ2 induced Parkin cleavage by caspase, while Oligo induced calpain cleavage of Parkin. Whereas Parkin cleavage by caspase has been shown to result from different stress conditions, calpain cleavage of Parkin has not been reported. Our results show that calpain-cleaved Parkin migrates as a doublet with a size that differs from the caspase-cleaved fragment induced by PGJ2. The higher molecular weight form of the doublet may be due to phosphorylation. We also determined that full length (FL) Parkin is localized to mitochondria and the cytoplasm regardless of cellular conditions, while calpain or caspase-cleaved forms of Parkin are mostly detected in the mitochondrial fraction. The cleavage of Parkin by caspase and calpain seems to occur at a site that frees its UbL domain, to generate a fragment that could act as a proteasome inhibitor. Since PGJ2 and Oligo are neurotoxic and induce Parkin cleavage, we attempted to preserve Parkin integrity by raising intracellular cAMP with the lipophilic peptide PACAP27 (pituitary adenylate cyclase activating peptide). We chose this approach because the cAMP signaling pathway regulates the proteasome and is also known to mediate neuroprotection. We show that PACAP27 prevents the caspase- but not the calpain-dependent cleavage of Parkin. By using an alternate approach, we found that stabilizing intracellular ATP levels with the creatine analog cyclocreatine prevents Parkin cleavage by calpain. We also established that the phosphatase inhibitor okadaic acid stabilizes a higher molecular weight form

of FL Parkin and reduces its calpain-cleaved form. These findings suggest that stabilizing FL Parkin phosphorylation by phosphatase inhibition decreases its susceptibility to calpain-cleavage. Overall, characterizing mechanisms that stabilize Parkin integrity is important to provide novel therapeutic strategies for treating PD.

Abstract: Protein kinase C (PKC) has been implicated in the control of neurotransmitter release. The AS/AGU rat, which has a nonsense mutation in PKCγ shows Parkinsonian-like symptoms, including dopamine (DA) release impairment in the striatum. Here, we found that PKCγ protein was abolished in AS/AGU rat and that PKCγ-knockout(KO) mice showed Parkinsonian syndrome, suggesting that PKCγ-KO animals are possible models for Parkinsonian syndrome. To address this issue, we attempted to identify PKCγ substrates responsible for the regulated exocytosis of DA *in vivo*. For this purpose, we employed PKCγ-KO mice for phosphoproteome analysis by using Hydroxy Acid-Modified Metal Oxide Chromatography method. We found 10 candidates proteins with PKC phosphorylation motif that showed the decreased level of phosphorylation in the striatum of PKCγ-KO mice. Among them, we focused on Pak-interacting

exchange factor-β (βPIX), which is a Cdc42/Rac1 guanine nucleotide exchange factor, and found that PKCγ directly phosphorylates βPIX at Serine 583 and indirectly at Serine 340 in cell culture. We also found that PKC phosphorylated βPIX *in vivo*. Classical PKC inhibitors and βPIX knockdown (KD) significantly suppressed the Ca2+-evoked DA release in PC12 cells. The decreased level of DA release in βPIX KD cells was fully rescued by wild-type (WT) βPIX, but not βPIX mutants whose serine 340 or serine 583 was substituted by alanine (S340A or S583A). Double KD of Cdc42 and Rac1 decreased DA release of PC12 cells. Furthermore, the interaction of Cdc42/Rac1 with phospho-mimicking mutants of βPIX, S340E or S583E, was stronger than that with WT βPIX. These findings indicate that the phosphorylation of βPIX at Serine 340 and Serine 583 has pivotal roles in Ca2+-evoked DA release through interaction with Cdc42/Rac1 in the striatum. Thus, we propose that PKCγ positively modulates DA release through the β2PIX phosphorylation. The PKCγ-βPIX-Cdc42/Rac1 phosphorylation axis may provide a new therapeutic target for the treatment of Parkinsonian syndrome.

Title: Effect of buspirone on the subthalamic nucleus on an animal model of parkinson´s disease: An electrophysiological study

Authors: A. SAGARDUY[1], J. LLORENTE[1], C. MIGUELEZ[2,1], T. MORERA-HERRERAS[1], A. ARISTIETA[1], *J. RUIZ-ORTEGA[2,1], L. UGEDO[1]

Abstract: INTRODUCTION: L-DOPA is the most effective treatment for Parkinson's disease, but prolonged use induces motor complications including dyskinesia. Although the mechanisms underlying the development of L-DOPA-induced dyskinesia are not completely understood, prior studies demonstrated the implication of the subthalamic nucleus (STN). It has been described that buspirone, elicits an antidyskinetic effect. The aim of this study was to evaluate the effect of buspirone on STN neuron activity. METHODS: Single-unit extracellular recordings were performed *in vivo* on STN neurons from four different groups, i.e., control, chronically treated with L-DOPA, lesioned and lesioned chronically treated with L-DOPA (dyskinetic) rats. Also, preserving the STN-projections as intact as possible, *in vitro* cell-attached recordings were performed in 500 µm-thick, 3º angle parasagittal slices including the STN from naïve rats. RESULTS: In control rats buspirone administration decreased the firing rate in a dose-dependent manner (4 mg/kg i.p. 35% and 8 mg/kg i.p. 67%) and the coefficient of variation resulted increased. Similar results occurred in sham L-DOPA rats (8 mg/kg i.p. 58%). Buspirone (8 mg/kg i.p.) has not elicited any effect on STN neuron activity when was administered in rats with nigrostriatal degeneration. In addition, in control rats WAY-100635, a selective antagonist of 5HT1A receptors, and PD128907, a selective agonist of D3 receptors, blockaded the effect of buspirone and this effect was reversed by WAY-100635 but not by PD128907. Furthermore, the acute and chronic administration of L-DOPA (6 mg/kg plus benserazide 12 mg/kg i.p.) did not modify the inhibitory effect of buspirone (4 mg/kg i.p.). Conversely, in parasagittal slices containing the STN, buspirone induced excitatory, inhibitory and also biphasic responses being only the inhibitory effect prevented by WAY-100635. CONCLUSION: Buspirone administration *in vivo* induces a reduction on the firing rate of the STN neurons through 5HT1A and D3 receptors whereas *in vitro* buspirone seems to show a more variable effect. Moreover, effect of buspirone was abolished in 6-OHDA lesioned rats, suggesting that the STN may not be directly involved in its antidyskinetic effect.

Title: Investigating the dual effect of dopamine transporter over-expression and vesicular monoamine transporter 2 under-expression in genetically modified mice

Authors: *S. T. MASOUD[1], A. J. RAMSEY[1], G. W. MILLER[2], A. SALAHPOUR[1]
[1]Pharmacol. and Toxicology, Univ. of Toronto, Toronto, ON, Canada; [2]Emory Univ., Atlanta, GA

Abstract: The dopamine transporter (DAT) and vesicular monoamine transporter 2 (VMAT2) are two key proteins that regulate dopamine (DA) homeostasis. DAT takes up extracellular DA into the presynaptic neuron, while VMAT2 sequesters intracellular DA into vesicles. Both proteins play an important role in maintaining cytosolic levels of DA. Accumulation of cytosolic DA has been shown to propagate oxidative stress through metabolism, autoxidation and enzyme dependent reactions. Therefore, we hypothesized that any alteration in the transport and packaging of DA that leads to its cytosolic accumulation will result in neurotoxicity due to increased oxidative stress. Previously, we generated transgenic mice that selectively over-express DAT in DA neurons (DAT-tg mice). These animals display 36% loss of DA neurons, possibly as a result of increased DA reuptake. Additionally, we obtained VMAT2-knockdown (VMAT2-kd) mice that express only 5% of normal VMAT2 levels and show similar neurodegeneration as the DAT-tg mice. In this study, we intercrossed DAT-tg and VMAT2-kd mice to produce double transgenic DAT-tg/VMAT2-kd mice. These mice are hypothesized to display greater buildup of cytosolic DA than either genotype alone, due to the dual effect of higher DA reuptake (DAT over-expression) combined with impaired DA vesicular storage (VMAT2 knockdown). Preliminary characterization of DAT-tg/VMAT2-kd mice reveals low striatal DA tissue content and higher metabolite to DA ratios, which could reflect an increase in DA turnover. Interestingly, DAT-tg/VMAT2-Kd mice are 5 times more active than WT animals in open field locomotion. To evaluate if this hyperactivity is an indication of DA receptor supersensitivity, we treated these mice with apomorphine, a non-selective D1/ D2 receptor agonist. DAT-tg/VMAT2-kd mice showed increased stereotypic behavior in response to apomorphine, suggesting enhanced DA receptor function. Next, we treated the mice with different doses of amphetamine. At 1 mg/kg, DAT-tg/VMAT2-kd mice were hyperactive, however at 2 mg/kg, they displayed peculiar dyskinetic movements (tremor, jerking). These results suggest that DAT-tg/VMAT2-kd mice are highly sensitive to amphetamine. Future experiments with these mice include 1) stereology to determine the extent of neurodegeneration 2) radioligand binding to assess receptor levels and 3) response to other dopaminergic drugs (cocaine, L-DOPA). These studies will shed light on the role of DAT, VMAT2 and cytosolic DA in causing neurotoxicity *in vivo*. Since DA neurons are exceptionally vulnerable to damage in Parkinson's disease, it is possible that the mishandling of DA could act as a risk factor for these cells.

Title: Effects of overexpressed transcription factors in the locus coeruleus on dopamine phenotypes in the brain of Parkinson's mouse models

Authors: ***M.-Y. ZHU**, K. CUI, F. YANG, Y. FAN, D. PETERSON, B. CUMMINS, R. BROWN
East Tennessee State Universit, JOHNSON CITY, TN

Abstract: Dysfunction of the noradrenergic system is one of the pathogenetic alterations of Parkinson's disease, which may also influence the functional status of the dopamine system. However, their correlation remains to be elucidated. Phox2, Hand2 and Gata3 are the transcription factors that have been found to play a role in the maintenance of noradrenergic function in the mature brain. In the present study, we examine the possible effect of overexpression of these transcription factors in the locus coeruleus on the expression of the dopamine phenotypes in VMAT2 Lo mice, a mouse model of Parkinson's disease. cDNAs of mouse Phox2a/2b, Hand2 and Gata3, which have been constructed in the lentiviral vectors, were microinjected into the locus coeruleus, either alone or in combination, of 6 and 12 month-old model mice. The expression of these transcription factors as well as dopamine β-hydroxylase (DBH) and tyrosine hydroxylase (TH), along with behavioral performance on anxiety and cognition were measured. Results showed that overexpression of these transcription factors in the locus coeruleus significantly affected expression of TH and DBH in the striatum, substantia nigra, hippocampus or frontal cortex, respectively. Microinjection with Phox2a/2b, Gata3 Hand2 alone markedly increased TH protein levels in the striatum, substantial nigra and frontal cortex of 6 month-old model mice, as compared to non-treated VMAT2 Lo mice and age-matched wild-type littermates. Furthermore, injection with these transcription factors, alone or in combination, resulted in a very similar result in 12 month-old model mice. Moreover, injection with Phox2a/2b and Gata3, as well as combination injection of Phox2a/2b and gata3 or Phox2a/2b and Hand2 significantly alleviated cognitive deficits on the Morris water maze. Injection with Gata3 or Phox2b in combination of Gata3 significantly diminished latency to explore the open

arms on the elevated T-maze, a test of anxiety. The present study demonstrates an upregulatory effect of overexpression of transcription factors in the locus coeruleus on the functional status of central dopamine system, which may provide some clues for improving therapeutic strategy for Parkinson's disease. Sci., Northern Kentucky Univ., Highland Heights, KY; [6]Div. of Human Genet., Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH

Abstract: Mutations in the gene ATP13A2 are associated with Kufor-Rakeb Syndrome and Neuronal Ceroid Lipofuscinosis. The former is designated as a rare inherited form of Parkinson's disease (PD). The function of ATP13A2 is unclear but *in vitro* studies suggest that it is involved in the lysosomal degradation of proteins and in the homeostasis of manganese and zinc. We recently showed that ATP13A2-deficient (13a2) mice develop age-dependent sensorimotor deficits, and enhanced lipofuscinosis and accumulation of insoluble alpha-synuclein (aSyn) in the brain. The presynaptic protein aSyn abnormally accumulates in PD and is degraded through lysosomal-autophagy degradation pathways suggesting the relationship between ATP13A2 and aSyn may be important in PD. In the present study, we hypothesized that loss of ATP13A2

function combined with chronic manganese administration in mice would lead to alterations in sensorimotor function, increased and accelerated lipofuscin pathology and accumulation of insoluble aSyn in the brain. Wildtype (WT) and 13a2 mice received daily intraperitoneal injections of either vehicle or 5 mg/kg of a manganese solution for 45 days. Separate cohorts of WT and 13a2 mice were treated at 5-9 months (young) or at 12-19 months (old) of age. On day 30 all mice were tested on a battery of sensorimotor tests including the challenging beam traversal test, spontaneous activity in the cylinder, and gait. Lipofuscin autofluorescence was measured in multiple brain regions including the cortex, hippocampus, cerebellum, and substantia nigra. Soluble and insoluble aSyn protein levels were measured in the ventral midbrain. We found that older 13a2 mice receiving manganese displayed a significant increase in motor activity on the challenging beam and in spontaneous activity compared to 13a2 receiving vehicle. There were no significant differences in gait. Lipofuscin autofluorescence in the substantia nigra was significantly increased in older 13a2 mice receiving manganese compared to 13a2 mice treated with saline. In addition, insoluble aSyn was significantly increased in the ventral midbrain in older manganese-treated 13a2 mice compared to vehicle-treated 13a2 mice. These results indicate that loss of ATP13A2 function leads to an increased sensitivity to manganese *in vivo*.

Abstract: Improved animal models of Parkinsonism are essential to advance our understanding of disease pathophysiology and for eventual testing of potential therapeutics. To that end, the Michael J. Fox Foundation (MJFF) has funded the generation and characterization of novel animal models of Parkinsonism as part of its strategy to provide preclinical tools to the Parkinson's disease (PD) research and drug development community with minimal barriers. Various models expressing mutations in *SNCA, LRRK2, Park2, Park7* (DJ-1), and *Pink1* are available. One area of focus has been the creation of models with defects in pathways responsible for protein trafficking and degradation, as mutations in these pathways have been associated with PD incidence in patient populations. Human carriers of certain mutations in the *GBA* gene are at increased risk of developing PD. *GBA* encodes lysosomal glucocerebrosidase (GCase); mutations causing functional deficits in this lysosomal enzyme cause aberrant accumulations of glucosylceramide and glucosylsphingosine and are believed to also generally perturb lysosomal degradation pathways, potentially leading to toxic accumulation of α-synuclein, which is itself implicated both genetically and neuropathologically in PD. The GCase enzyme produced by the D409V mutation is catalytically active, but unstable. The novel homozygous *Gba* D409V knock-in mouse model described herein will be characterized for behavioral and pathological phenotype as well as for levels of α-synuclein and GCase activity at 4, 8, and 12 months of age. As part of the effort to the effort to understand the role of the *GBA* D409V point mutation, the mouse knock-in model crossed to a SNCA over-expressing transgenic line will be assayed for PD phenotypes. Other autophagy-deficient models relevant to PD include an *Atp13a2* knockout, which exhibits alpha-synuclein accumulation and sensorimotor deficits, and a new *Vps35* D620N knock-in which can be used to create a conditional knockout. These models, along with many others, are available with no licensing fees for basic research and therapy development efforts from The Jackson Laboratory PD mouse model resource. Availability and phenotypic characterization data will be presented at http://research.jax.org/grs/parkinsons.html .

Abstract: Alpha-synuclein is a 140 amino acid protein implicated both genetically and neuropathologically in Parkinson's disease (PD). Mutations in the *SNCA* gene that encodes the alpha-synuclein protein are associated with heritable PD. Increased levels of alpha-synuclein lead to neurodegeneration both *in vitro* and *in vivo* and aggregated alpha-synuclein is the primary component of Lewy bodies, the histopathological hallmark of PD. Thus, therapeutic strategies aimed at reducing alpha-synuclein and the development of *in vivo* models of alpha-synucleinopathy are areas of active interest in the PD field. The Michael J. Fox Foundation (MJFF) accelerates progress in PD research and therapeutic development by generating and rigorously characterizing preclinical tools and animal models and subsequently providing them to the research community with minimal barriers. Here we describe MJFF efforts to compare *in vivo* models of alpha-synucleinopathy. Data from a MJFF-sponsored side-by-side evaluation of five different transgenic alpha-synuclein mouse models for molecular, behavioral, neurochemical, and pathological phenotypes at three different ages (4, 8, and 12 months of age) will be presented. In addition, the MJFF supported a cross-validation study of the alpha-synuclein transmission mouse model of neuropathology (Luk K.C. et al., *Science* 2012). In this

validation study, behavioral and pathological phenotypes were examined at 30, 90, and 180 days post stereotaxic injection of alpha-synuclein fibrils into the dorsal neostriatum of mice. Moreover, the MJFF generated and characterized adeno-associated virus (AAV) vectors (serotypes 2 and 5) expressing human wild-type (WT) alpha-synuclein or GFP control. Here we report the *in vivo* characterization results for these alpha-synuclein AAV2 and AAV5 vectors in Sprague-Dawley rats, demonstrating efficient transduction within the rat substantia nigra and increased levels of human WT alpha-synuclein *in vivo*. Taken together, these data can help inform the PD community of the utility and reproducibility of various *in vivo* rodent models of alpha-synucleinopathy and may be of value to researchers seeking appropriate models in which to test potential therapeutics targeting alpha-synuclein. We are eager to share these data with the PD community and to facilitate additional characterization and distribution of these important preclinical models of parkinsonism.

Abstract: Heterozygous mutations in GBA represent one of the most frequent genetic risk factors for Parkinson's disease (PD) and Dementia with Lewy bodies (DLBs). Converging evidence suggests that reduced GBA enzyme stability, defective intrinsic enzyme activity, and compromised glucosylceramide metabolism may contribute to the degenerative process of sporadic PD. Neuropathological and clinical studies of PD patients with GBA mutations revealed that the mutations are strongly associated with α-synuclein accumulation, ultimately resulting in the degeneration of dopaminergic (DA) neurons and the presence of LB pathology. This suggests that biochemical defects caused by GBA mutations may play a pivotal role in pathogenesis of PD and DLBs. However, the specific mechanism underlying the interaction between α-synuclein and the pathogenic mutant forms of GBA remains elusive. To examine the pathological interaction between α-synuclein and GBA *in vivo*, we have generated bigenic mice by crossing D409H mutant GBA knock-in mice with the human A53T mutant α-synuclein transgenic (hA53T α-syn Tg) mice. Different genotype cohorts were collected, aged, and then assessed for their life-span, behavior, neuronanatomical and neurochemical changes. Based on the survival analysis, the life-span of the hA53T α-syn Tg with 29% enzyme deficiency due to the expression of a heterozygous D409H mutation in GBA was significantly shortened compared to that of the hA53T α-syn Tg. More dramatic reduction of the life-span was illustrated in hA53T α-syn Tg with the 61% enzyme deficiency caused by the expression of homozygous D409H GBA mutant. In addition, approximately 20% loss of DA neurons was shown in the D409H GBA-Het/hA53T α-syn Tg mice, which was exacerbated by the expression of homozygous D409H GBA in the hA53T α-syn Tg mice at 6 months of age. Ongoing experiments are designed to further assess the accumulation of detergent-insoluble A53T α-synuclein species and the behavior abnormalities. In part, our results suggest that deficiency of GBA due to D409H mutation plays a significant role in the pathogenesis of A53T α-synuclein-induced neurodegeneration, thus maintaining GBA in a catalytically active form may be an efficient therapeutic approach for the treatment of PD and α-synucleinopathies.

Abstract: Neuropore Therapies, Inc. is developing novel therapeutics for the treatment of Parkinson's disease and related neurodegenerative disorders by targeting the specific aberrant forms of α-synuclein (ASYN) that play a key role in the pathogenesis of these disorders. Candidate compounds such as NPT200-11, which are designed to stabilize conformations of ASYN incapable of propagating into toxic oligomers have been evaluated in animal models and shown to have beneficial effects, reducing the accumulation of ASYN, normalizing markers of neurodegeneration and improving motor function. In the current studies we utilized molecular modeling and simulation along with a variety of biophysical assessment tools including NMR spectroscopy, fluorescence polarization based aggregation assays and electron microscopic visualization of ASYN oligomers to more fully characterize the interaction of NPT200-11 with ASYN and the consequent effects on the formation of ASYN oligomers in lipid membranes. Data from these studies clearly demonstrate that NPT200-11 alters the aggregation of ASYN and prevents the formation of specific oligomeric structures believed to contribute to the neurotoxicity of misfolded oligomerized ASYN in Parkinson's disease.

Title: Live imaging of alpha-synuclein aggregates in the retina of alpha-synuclein-GFP transgenic mice as a marker of the alpha-synuclein pathology in the brain

Authors: *E. M. ROCKENSTEIN[1], D. L. PRICE[4], D. BONHAUS[4], M. MANTE[1], J. D. LINDSEY[2], E. MASLIAH[3]
[1]Neurosciences, [2]Opthamology, [3]Neurosciences and Pathology, Univ. Calif San Diego, LA JOLLA, CA; [4]Neuropore Therapies Inc, San Diego, CA

Abstract: Abnormal accumulation of alpha-synuclein has been reported to play an important role in neurodegeneration and synaptic dysfunctional in Parkinson's Disease (PD) and Dementia with Lewy Bodies (DLB). Real time visualization and monitoring of alpha-synuclein accumulation in the central nervous system (CNS) is critical in order to better understand the mechanisms of neurodegeneration. We have previously described a transgenic model expressing the alpha-synuclein-GFP fusion protein under the PDGF-beta promoter, and have shown that this model allows *in vivo* monitoring of the dynamics of alpha-synuclein accumulation in the brain utilizing two-photon microscopy. We have now expanded these studies to investigate whether the alpha-synuclein-GFP in these mice also accumulates in the retina and whether this accumulation mirrors that observed in the brain. Retinal imaging can provide a non-invasive means to evaluate optical pathology (retinal fundal maps and optical coherence tomography of vasculature and fluorescent-tagged proteins). For this purpose alpha-synuclein-GFP transgenic mice were imaged at various intervals with the Phoenix Micron III Retinal Imaging Microscope (Phoenix Research Labs, Pleasanton, CA). Mouse bright field image retinal maps (normal scan mode) were acquired followed by fluorescent images (progressive scans of 30) in the same orientation for each eye. Similar to the observations in the brain, in the retina of the tg mice we observed progressive accumulation of alpha-synuclein-GFP deposits in the perivascular region and in punctae around blood vessels likely associated with nerve terminals, retinal ganglion cells (RGC's) and glia. Double immunocytochemical studies are underway to more precisely identify the cells in the retina accumulating alpha-synuclein-GFP. In addition , imaging studies of RGC's by confocal scanning laser microscopy mode with a Spectralis imager (Heidelberg Engineering, Carlsbad, CA) with modified optics enabling us to focus on the mouse retina and by AlexaFluor594-conjugated cholera toxin B subunit (AFCTB) injected into the superior colliculus. These observations correlate with those reported in the CNS and support the relevance and utility of retinal imaging for *in vivo* characterization of transgenic mouse model phenotypes as well as therapeutic evaluations.

Abstract: Parkinson's disease (PD) is characterized by aberrant accumulation of oligomeric forms of alpha-synuclein (ASYN). It is hypothesized that these toxic forms of ASYN contribute to the neuronal dysfunction and cell death observed in PD and other synucleinopathies, in part, though the formation of pore-like structures in cell membranes. We have developed a novel compound, NPT200-11, designed to ameliorate PD-related symptoms and pathology by selectively blocking the formation and accumulation of these toxic species of ASYN. We evaluated the activity of this compound in a transgenic mouse model of PD overexpressing human wild-type ASYN under the Thy-1 promoter, by administering NPT200-11 at 0, 1 or 5mg/kg (IP) once daily (5 days per week) for 3 months and then assessing PD-relevant sensorimotor performance, biochemical alterations and neuropathological changes in ASYN and related proteins. We used the Round Beam Task to assess sensorimotor impairments, using number of slips as our primary outcome measure, and found that transgenic mice treated with NPT200-11 at both doses (1 & 5mg/kg) had statistically significantly reductions in slips

compared to vehicle-treated transgenic mice. Western Blot analysis of cerebral cortical and hippocampal brain homogenates revealed statistically significant reductions in transgenic ASYN protein levels. Similarly, neuropathological assessment found a significant reduction in ASYN immunolabeling in the cortical neuropil of mice treated with NPT200-11 at both concentrations (1 & 5mg/kg). Moreover, we found normalization of neurodegeneration-related markers including NEUN and GFAP. Together, these results demonstrate that NPT200-11 significantly improves sensorimotor, biochemical and neuropathological outcomes in a transgenic mouse model.

Abstract: Abnormal accumulation of a neuronal protein alpha-synuclein (ASYN) has been hypothesized to underlie neuronal cell death and synaptic dysfunctional in Parkinson's disease (PD) and Dementia with Lewy Bodies (DLB). Compounds that selectively interfere with alpha-synuclein protein-folding dynamics and prevent the formation of propagating dimers have been developed and further evaluated in animal models. One such compound, NPT200-11, has been shown to reverse motor deficits, and to normalize total alpha-synuclein levels and neurodegenerative markers in mThy1-ASYN transgenic mice overexpressing human ASYN. In addition to further characterizing the biological activity, safety and pharmacokinetics of NPT200-11 as a clinical candidate for the treatment of PD studies are underway to identify translatable secondary or surrogate markers for clinical evaluation. We previously demonstrated the feasibility of repeated longitudinal retinal imaging evaluations of e-GFP- ASYN in the PDNG78 transgenic mouse model of DLB/PD (Rockenstein et al., 2013), as a method to evaluate and track the progression of neurodegenerative changes in animal models of Parkinson's disease. Progressive pathological features in the PDNG78 retina were shown to mirror CNS pathology, thereby providing a means to non-invasively and repeatedly evaluate potential therapeutic interventions in a transgenic mouse model of PD/DLB. In the present study repeated longitudinal measures of eGFP-tagged ASYN in the retina demonstrated a robust, statistically significant time-dependent reduction in ASYN in the retina of NPT200-11-treated transgenic mice (5 mg/kg, IP, daily for up to 3 months).

Abstract: The pathological hallmark of Parkinson disease (PD) is the death of dopaminergic neurons in the substantia nigra and the intracellular accumulation of Lewy body and Lewy neurite, whose main component is the fibrillar form of alpha-synuclein (aSyn) with β-sheet structure. In the brain, polyunsaturated fatty acid (PUFA) is abundant and aSyn shows high affinity to the membrane enriched in PUFA chains and stabilizes conformation of αSyn in alpha-helical structure. Docosahexaenoic acid (DHA) is a major fatty acid composition of the neuronal membrane. DHA has been believed to be neuroprotective, by its anti-oxidative capacity and activating survival signaling. However, we found in rodents treated with CCl4 in addition to DHA, DHA-derived carboxylalkylamide adducts -modified proteins, were increased with marked necrosis of hepatic cells, but not in rodents fed with DHA-rich diet alone, or treated with CCl4 alone. In Parkinson disease, it is known that oxidative stress in increased in the dying neurons. Oxidation of membrane lipids, and modification of aSyn by ROS, RNS, and lipid radicals may decrease the affinity of aSyn to the membrane. In addition, oxidation of membrane-composing phospholipids should alter the physicochemical properties of the membrane, such as

membrane fluidity and permeability, and the fusion and fission of mitochondrion. Accumulation of aSyn with abnormal structure has been proposed to be associated with the pathogenesis of Parkinson disease. The cytotoxicity of αSyn depends on its higher structure, including momomeric, oligomeric and aggregated forms. This paper reports that DHA peroxidation modified αSyn and induced the oligomerization and facilitated the amyloidogenesis *in vitro*. In SH-SY5Y cells overexpressing aSyn, DHA induced cell death with increased aSyn adduct with N-acyl product from DHA peroxidation in the RIPA-soluble mitochondrial fraction and also in insoluble fraction. These results suggest that under oxidative stress, DHA-dependent modification of aSyn may initiate toxic ologomerization of aSyn even that in physiological condition, DHA functions as a lipophilic antioxidant. The biphasic function of DHA, either in a cytotoxic and protective way, is discussed in relation to the pathogenesis of PD.

Abstract: Presence of Lewy bodies and neurites is a hallmark of Parkinson's disease. Occurrence of its main component alpha-synuclein as a fibrillized, ubiquitinated and truncated constituent suggests that impaired protein clearance is an important event in aggregate formation. The A30P mutation is known for its fast oligomerization, but slow fibrillization rate. Despite its toxicity to neurons, mechanisms involved in either clearance or conversion of A30P alpha-synuclein from its soluble state into fibrils and their effects *in vivo* are poorly understood. We therefore triggered animals overexpressing A30P alpha-synuclein either with environmental neurotoxic factors, or by genetic crossings known to implicate in alpha-synuclein degradation pathways and analyzed its impact on protein clearance and phenotype progression. We observed that calpain-cleavage, induced by paraquat exposure, led to an increase in C-terminal truncation and aggregation pathology. Vice versa, overexpression of the calpain-inhibitor, calpastatin, reduced truncation and aggregation pathology. Interestingly co-overexpression of C-terminal interacting protein synphilin-1 reduced alpha-synuclein truncation and fibrillization, displaying an increase in the formation of autophagic-susceptible aggresomes. However, the lack of fibril pathology yet persistence of motor dysfunction in aged mice, supports the idea that fibrillized alpha-synuclein deposits are not solely linked to the phenotype progression.

Title: FABP3 promotes α-synuclein oligomerization in the dopaminergic neurons

Authors: K. FUKUNAGA[1], N. SHIODA[1], *M. MORIOKA[2], Y. OWADA[3]
[1]Pharmacol., Tohoku Univ. Grad Sch. Pharm Sci., Sedai, Japan; [2]Neurosurg., Kurume Med. Sch., Kurume/ Fukuoka, Japan; [3]Yamaguchi Univ. Grad. Sch. Med., Ube, Japan

Abstract: [Background] Fatty acid-binding protein 3 (FABP3) is highly expressed in the dopaminergic neurons, especially in the substantia nigra pars compacta (SNpc) (Shioda et al., J Neurosci, 2010;30:3146-55). FABP3 null mice exhibit hypo-dopaminergic phenotype in the extrapyramidal symptom. Notably, α-synuclein accumulation is critical to the pathogenesis of Parkinson's disease (PD) and is regulated by long-chain polyunsaturated fatty acids (LCPUFAs) such as arachidonic acid (AA) and docosahexaenoic acid (DHA). We have recently hypothesized that FABP3 triggers α-synuclein accumulation in the dopaminergic neurons. [Methods] MPTP-induced α-synuclein oligomerization was assessed in wild and FABP3 null mice. *In vitro* studies evaluated the promotion of α-synuclein oligomerization by making complexes with FABP3. [Results] MPTP-induced α-synuclein oligomerization in the SNpc was attenuated in the FABP3 null mice compared to wild mice. Immunohistochemical analyses revealed that MPTP-induced α-synuclein accumulation in the SNpc was also attenuated in FABP3 null mice. *In vitro* study confirmed that α-synuclein oligomerization with FABP3 was promoted by AA (100μM) treatment. [Conclusion] Taken together, complex of FABP3 with AA is risk factor for the formation of α-synuclein accumulation in the dopaminergic neurons of PD patients. The evidences propose a novel therapeutic strategy for PD. [Acknowledgements] This work was supported by KAKENHI 25293124 and 24102505 (KF).

Title: Characterization of the cellular uptake of α-synuclein oligomer/protofibril selective antibodies

Authors: *M. INGELSSON[1], G. GUSTAFSSON[1], F. ERIKSSON[2], E. NORDSTRÖM[2], C. MÖLLER[2], L. LANNFELT[1], J. BERGSTRÖM[1]

Abstract: Background Immunotherapy targeting α-synuclein has emerged as a potential therapeutic strategy against Parkinson's disease and other disorders with Lewy body brain pathology. We have developed oligomer/protofibril selective antibodies [1] and shown that administration of such antibodies can lower the levels of toxic α-synuclein oligomers/protofibrils both in human cell lines [2] and in the spinal cord of transgenic mice [3]. However, it is not known whether these antibodies can be taken up by cells and whether they exert their anti-oligomer effects intra- or extracellularly. **Objective** To investigate whether oligomer/protofibril selective α-synuclein antibodies can be internalized by cells in culture. **Methods** Native or α-synuclein:hemi-GFP BiFC overexpressing H4 human neuroglioma cells were subjected to the monoclonal oligomer/protofibril selective α-synuclein antibodies mAb47, mAb49/G and mAb38E2 or to the non-selective α-synuclein antibodies Syn-1 and mAb211. An anti-GAPDH antibody was used as isotype control. All antibodies were incubated at 2.5 μg/ml for different time lengths in regular growth media at 37°C. Next, the cells were fixed followed by incubation with a fluorescent anti-mouse secondary antibody. The levels of remaining antibodies in conditioned media were measured by indirect ELISA. Double immunocytochemistry against α-synuclein and various organelle markers was carried out to assess the intracellular localization of the antibodies. **Results** All antibodies investigated were internalized by the cells. The oligomer/protofibril selective α-synuclein antibody mAb47 showed the highest degree of intracellular presence. The uptake was seen already after 1 hour and reached a maximum after 4 hours of incubation. Cells overexpressing α-synuclein displayed a higher antibody uptake than non-transfected cells. After 24 hours of incubation the antibody signal had almost completely vanished and the corresponding extracellular antibody levels had decreased, as measured by ELISA. **Conclusions** The oligomer/protofibril selective α-synuclein antibody mAb47 was readily internalized by cultured human neuroglioma cells. Ongoing studies will elucidate by which mechanisms this and other α-synuclein antibodies are taken up by the cells. **References** 1) Fagerqvist, T. et al. Abstract: Parkinson's Disease (PD) is the neurodegenerative disease with high frequency next to Alzheimer Disease. It is characterized by loss of dopaminergic neurons in a substantia nigra and the appearance of Lewy bodies, therefore PD is a kind of progressive malignant disease to cause muscle rigidity and tremor. In the brain, spinal cord and olfactory bulb, the Lewy body is composed of the protein α-Synuclein, phosphorylated α-Synuclein and also including other proteins. Abnormal aggregation of α-Synuclein and phosphorylated α-Synuclein is accepted at high frequency in neuronal cells of PD patients. It is suspected that abnormal accumulations of α-Synuclein trigger neurodegeneration. To clarify where the Lewy bodies and phosphorylated α-Synuclein appear, it is necessary to establish the non-human primate model. In our laboratory, a novel non-human primate model of PD using mutated α-Synuclein (A30P) was established to explore the effect of mutated α-Synuclein. As for the common marmoset (Callithrix jacchus), a small New World primate, its structure of the brain evolves in comparison with rodents. Therefore, we expect that it is possible to link between an exercise dysfunction and a lesion part because the structure of the basal nuclei which are a main lesion part of PD is clear in marmoset. The transgene of mutated α-Synuclein (A30P) expression was evident in the brain of transgenic marmoset, moreover we found the abnormal protein aggregations in the liver. Thus we searched for a Lewy body in the all tissues and organs of transgenic marmoset including skin. In this presentation, we will show the recent results of searching Lewy body and also the exercise functional analysis.

Title: A53T mutation α-synuclein over-expression in rat brain show more toxic than wild-type via AAV injection

Authors: ***Y. DENG**, J. LU, H. QING, H. MA, R. WANG
Sch. of Life Sci., Beijing Inst. of Technol., Beijing, China

Abstract: There are many rodent models in Parkinson's disease, as 6-OHDA injection. AAV - mediated over-expression α-synuclein in rat brain is a newly developed technology in Parkinson's disease models. The gradually expression of α-synuclein in substantia nigra pars compact of rat after AAV injection accompany with loss of dopaminergic neurons is very similar to the clinical condition of Parkinson's disease. In this study, we used male wistar rats, and inject the AAV vectors which contain AAV-α-synuclein WT and its mutation A53T ,and EGFP to their substantia nigra pars compact by stereotaxic surgery, then keep them for 9weeks until take their brains. We found that when inject apomorphine i.p., the A53T group showed rotations but the other groups didn't show this. This data suggested that A53T α-synuclein is more toxic than WT. We use immunohistochemistry to identify that the AAV vectors expressed in substantia nigra and striatum. After that, the double- immunofluorescence method was used to find that the TH-positive cells were the cells which express α-synuclein/EGFP. Finally, the protease K digest method give us the result that A53T α-synuclein aggregate much more than WT. In summary, we establish a model to Parkinson's disease use AAV, and protein aggregation may play an important role in the cells loss progress. The mechanism of the A53T how to affect protein aggregation is still to be investigated.

Title: Both soluble and insoluble α-synuclein species are capable of inducing pathology in the mouse model of α-synucleinopathy transmission

Authors: *J. BARNES, J. MEINTS, H. A. MARTELL-MARTINEZ, M. K. LEE
Dept. of Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Pathological α-synuclein (αS) is implicated as a cause for neuronal dysfunction/neurodegeneration associated with Parkinson's disease (PD). Recent cell biological studies and extent human neuropathological studies suggest that αS pathology may spread from neuron to neuron. In particular, studies show that local injection of insoluble αS fibrils or crude brain lysates from tissues with severe α-synucleinopathy can induce global α-synucleinopathy in mouse brain. While previous work has explored possible mechanisms of *in vitro* neuronal αS release, uptake, and intracellular aggregation, little is known about such events *in vivo*. Specifically, the identity and toxicity of the transmissible αS species remain elusive. Moreover, the recently described intra-cortical/intra-striatal injection model of α-synucleinopathy demonstrates the spread of αS pathology in a direction counter to that proposed in humans. In order to establish a mouse model of αS transmission that more faithfully recapitulates the proposed spread in humans from the brain stem to anterior loci in the brain, we first established a model whereby αS pathology was initiated by injection of oligomeric/fibrillar forms of αS into the brain stem (dorsal motor nucleus of vagus, DMX) of young (3-4-month-old) mice overexpressing mutant HuA53TαS (line G2-3). Inoculation with *in vitro* pre-formed fibrils (PFFs) formed from recombinant αS or crude lysate (3000xg lysate) generated from end-stage HuA53TαS mouse tissue induced pathological αS alterations that spread in a highly reproducible spatial and temporal manner, reaching end-stage at ~70 days following inoculation. Because the crude brain lysates contain both soluble and insoluble αS species, the 3000xg lysate was further fractionated into highly soluble (S150) and insoluble (P150) fractions by centrifugation (150,000xg). Injection of S150 and P150 into the brain stem demonstrated that both fractions contain αS species sufficient to induce αS pathology that is subsequently transmitted anterogradely to the cortex. Conversely, neither saline nor 3000xg lysate from young asymptomatic HuA53TαS mice were capable of inducing αS pathology. Our results indicate that

distinct species of αS are sufficient to seed pathology in the brain stem that spreads in a predictable manner along known projection pathways in the brain. Further, this approach will allow us to identify the subcellular localization and biochemical nature of such toxic αS species.

Title: The effect of dietary ketosis on mitochondrial function and alpha-synuclein accumulation in alpha-synuclein overexpressing mice

Authors: *A. M. LEHMKUHL[1], M. J. IRWIN[2], J. D. PANDYA[5], S. S. KARKARE[1], B. LIOU[6], R. KRIKORIAN[3], P. G. SULLIVAN[5], Y. SUN[6], S. M. FLEMING[4,1]
[1]Psychology, [3]Psychiatry and Behavioral Neurosci., [4]Neurol., [2]Univ. of Cincinnati, Cincinnati, OH; [5]Spinal Cord and Brain Injury Res. Ctr., Univ. of Kentucky, Lexington, KY; [6]Human Genet., Cincinnati Children's Hosp. & Med. Ctr., Cincinnati, OH

Abstract: Parkinson's Disease (PD) is a progressive neurodegenerative disorder characterized by abnormal accumulation of the presynaptic protein alpha-synuclein (aSyn) and cell death. In addition to protein accumulation, mitochondrial impairment is well established in PD and thought to be an important contributor to cell loss. *In vitro* studies demonstrate an interaction between mitochondrial dysfunction and accumulation of aSyn, where alterations in either mitochondrial function or aSyn can lead to pathology and cell loss. It has been proposed that treatments that support mitochondrial function and/or reduce protein accumulation may have disease-modifying therapeutic potential in PD. Ketosis is a metabolic condition in which ketone bodies, as opposed to glucose, are utilized as the substrate for cerebral mitochondrial energy metabolism. The therapeutic potential of the ketone beta-hydroxybutyrate (BHB) on improving

mitochondrial bioenergetics is well documented. Additionally, BHB has been shown to stimulate lysosomal-autophagy degradation pathways in the liver, suggesting it may have therapeutic potential in PD by improving mitochondrial function and reducing aSyn accumulation. In the present study male wildtype (WT) and alpha-synuclein overexpressing (Thy1-aSyn) mice were fed either a control or ketogenic diet for 28 days starting at two months of age. Then, plasma BHB (*N*=21), mitochondrial bioenergetic parameters in the striatum (*N*=12), and soluble and insoluble aSyn in the ventral midbrain were measured (*N*=19). We found that while both WT and Thy1-aSyn mice fed a ketogenic diet showed increased plasma BHB levels compared to mice fed a control diet, Thy1-aSyn mice on the ketogenic diet exhibited a two-fold increase in plasma BHB levels compared to WT mice on the ketogenic diet. In addition, Thy1-aSyn mice fed a control diet show a reduced oxygen consumption rate compared to WT mice fed a control diet, while Thy1-aSyn mice on the ketogenic diet show significantly improved oxygen consumption and mitochondrial efficiency in the striatum compared to the Thy1-aSyn mice on the control diet. Soluble and insoluble aSyn protein levels were significantly increased in Thy1-aSyn mice fed the control diet compared to WT mice fed with the control diet. Taken together these findings suggest that by targeting mitochondrial bioenergetics as well as aSyn expression, BHB may have therapeutic, disease-modifying potential in PD.

Title: Alpha-synucleinopathy in Transgenic Mouse Model is associated with impaired autophagy and lysosome function

Authors: *R. KARIM[1], M. K. LEE[2]
[1]Univ. of Minnesota, MN; [2]Neurosci. Dept., Univ. of Minnesota, Minneapolis, MN

Abstract: Abnormal α-synuclein (αS) accumulation in neurons, as Lewy bodies/neurites, is likely contributor to neurodegeneration in Parkinson's disease and other related disorders. While the cause of αS aggregation is unresolved, studies show that αS accumulation and autophagy/lysosomal system (ALS) to reciprocally regulate each other. Thus, aberrant accumulation αS may cause ALS defects and further exacerbation of αS pathology. As an initial test of this hypothesis, we asked whether the presence of αS pathology *in vivo* is linked to ALS defects. Analysis of transgenic (Tg) mouse model of α-synucleinopathy (*A53TαS*) reveal that the presence of αS pathology is associated with impaired ALS. Specifically, increase in autophagic marker protein, LC3-II, was associated with increase in the levels of p62, indicating to defect in autophagic flux. The defect in autophagic flux occurs despite the increase in lysosomal content as indicated by the increases in the lysosomal marker proteins, lamp-1 and cathepsin D. Collectively, our data indicate that α-synucleinopathy *in vivo* may lead to impaired fusion of autophagosome with lysosomes, leading to aberrant expansion of both compartments. We propose that this cascade of events promotes further progression of αS pathology and increases vulnerability of neurons to αS pathology.

Title: Characterization of an α-synuclein rodent model of Parkinson's disease

Authors: *K. ALBERT[1], M. H. VOUTILAINEN[2], B. K. HARVEY[3], S. AHOLA[1], R. TUOMINEN[2], M. AIRAVAARA[1], M. SAARMA[1]
[1]Inst. of Biotech., [2]Div. of Pharmacol. and Pharmacotherapy, Univ. of Helsinki, Helsinki, Finland; [3]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Background: In Parkinson's disease (PD), the core motor symptoms are tremor, rigidity, slowness of movement, and difficulty with posture. It principally occurs through degeneration of dopamine neurons in the substantia nigra (SN). There are various methods of inducing Parkinsonian-like symptoms in rodents, such as the toxins 6-OHDA or MPTP models,

however these do not necessarily properly characterize the human condition. α-synuclein (α-syn) is mutated in familial forms of PD, and it is a major component of insoluble protein aggregates called Lewy bodies. Therefore, α-syn is strongly considered to be one of the major causes of dopamine neuron degeneration. α-syn pathology can be induced in rodents through injection of human WT or mutant α-syn into the SN, where it induces neurodeneraration and upregulates ER stress. This contributes to dysregulation of the unfolded protein response (UPR), and since α-synucleiopathies at least partially result from the misfolding of proteins, ER stress, UPR and their relation to α-syn are also important in PD and models of the disease. Objective: To create a rodent model of α-syn-induced PD that shows both α-syn overexpression as well as behavioral and molecular deficits for testing therapeutic efficacy of novel neurotrophic factors CDNF and MANF and mutants of GDNF family ligands. Methods: Stereotaxic injection of adeno-associated virus (AAV) vector carrying cDNA for human WT- α -syn or GFP in to one or two sites in the SN of rats. Both male Wistar rats as well as female SD rats were used, and tried commercial injection needles of different sizes as well as self-made coated glass capillaries. Amphetamine-induced rotations (2.5mg/kg, s.c.) and cylinder test were performed as behavioral assays. Immunohistochemistry of GFP, TH+ cells and α-syn+ cells in striatum (STR) and SN of the brains. Results: The behavior of male Wistar rats were followed for 5 to 7 months. We observed behavioral deficits only in the AAV-GFP injected animals. There was no difference in neurodegeneration between GFP and α-syn injected animals using a very thin, commercial needle, and a slow flow rate. In female SD rats, α-syn staining was found in SN after two sites of injections with commercial injection needles as well as by using glass capillaries. After 4 and 8 weeks, there is evidence of α-syn+ cells in both the STR and SN, and there is a decrease in TH fiber density in the STR. In both α-syn and GFP groups neurodegeneration was observed.

Abstract: Multiple commonly used transgenic animal lines exist for Parkinson's Disease (PD), with various approximations of an ideal Parkinsonian phenotype. However, success in creating a genetically altered animal line that shows a PD-like phenotype with robust and stable behavioral motor impairment, as well pathological tissue changes affecting the dopaminergic system, has proven to be a challenge. Also, many of the models do not express non-motor changes associated with PD, or they have not been investigated thoroughly. However, there is evidence that PD also affects various non-motor related changes in clinical disease, including disturbances in colon motility and fecal output. Targeted over-expression of human α-synuclein in a mouse model shows only a mild PD phenotype, even at 12 months of age. Therefore, we attempted to approach the disease model by using additional LPS challenges to enhance disease progression, and to assess by behavioral monitoring and nuclear imaging. In addition, we attempted to monitor colon motility as a non-motor endpoint over time. Twelve month-old A53T transgenic mice and corresponding wild type mice were tested for baseline behavior followed by LPS challenge over 3 consecutive weeks. During LPS injections and after a 16 week follow-up period, behavioral monitoring by beam balance test and beam traversing were performed. In addition, non-motor effects of the A53T transgene as well as additional challenge by LPS were monitored by a fecal output assay. Peripheral TSPO ligand (CLINDE) binding activity, which is an inflammatory marker, was analyzed by SPECT/CT imaging over time. Finally, at the endpoint, brains were collected and processed for dopamine and its metabolites from the striatum and histological evaluation of tyrosine hydroxylase and GAP 43 positive cells from substantia nigra (SN). Furthermore, expression of α-synuclein was monitored and evaluated between non-challenged and LPS-challenged A53T mice. This study focused on the validation of a previously published mouse model of PD in mice with novel endpoints and additional challenges. We present data about the progression of the PD phenotype up to 16 months of age, the effect of LPS on the phenotype, and whether biochemical, histopathological, and nuclear imaging markers correlate with behavioral changes.

Title: Tyrosine kinase inhibition regulates early systemic immune changes and modulates the neuroimmune response in α-Synucleinopathy

Authors: ***M. HEBRON**, I. LONSKAYA, S. SELBY, C. MOUSSA, F. PAGAN
Georgetown Univ., Washington, DC

Abstract: Objectives. Neuro-inflammation is common in α-Synucleinopathies and Tauopathies; and evidence suggests a link between the tyrosine kinase Abl and neurodegeneration. Abl upregulates α-Synuclein and promotes Tau hyper-phosphorylation (p-Tau), while Abl inhibitors facilitate autophagic clearance. Methods. A model of α-Synucleinopathy harboring human mutant A53T α-Synuclein and exhibits concomitant increase in murine p-Tau was used to determine the immunological response to Abl inhibition. Results. Age-dependent alterations of brain immunity, including loss of IL-10 and decreased levels of IL-2 and IL-3 were observed in old A53T mice. Brain CCL2 and CCL5 were decreased, but CX3CL1 remained constantly elevated. Young A53T mice exhibited differential systemic and central immune profiles in parallel with increased blood markers of adaptive immunity, suggesting an early systemic immune response. Tyrosine kinase inhibitors (TKIs), including nilotinib and bosutinib degraded brain and peripheral α-Synuclein and p-Tau and modulated blood immunological responses. TKIs did not affect brain IL-10, but they changed the levels of all measured blood immune markers, except CX3CL1. TKIs altered microglia morphology and reduced the number of astrocyte and dendritic cells, suggesting beneficial regulation of microglia. Conclusions. These data indicate that tyrosine kinase inhibition affects neuro-inflammation via early changes of peripheral immune profile, leading to modulation of neuro-immune response to α-Synuclein and p-Tau.

Title: Alterations in stimulation-evoked dopamine release and associated behaviors in mice lacking GSTpi and transgenic mice carrying the A53T alpha-synuclein mutation

Authors: *D. B. LESTER, K. J. SAMPLE, R. J. SMEYNE
Developmental Neurobio., St Jude Children's Res. Hosp., Memphis, TN

Abstract: Alpha-synuclein is a major constituent of Lewy bodies, the pathognomonic protein aggregate seen in both familial and sporadic Parkinson's disease (PD). Clinically, the A53T mutation within the alpha-synuclein gene results in dominantly inherited PD, thus we have made an effort to understand the pathophysiology of this mutation using transgenic mice. Previously we have shown that transgenic A53T mice have a slightly reduced number of SNpc dopaminergic neurons, but no alterations in basal dopamine (DA) content at 12 months old. Since PD patients with A53T alpha-synuclein polymorphisms show wide variations in symptom manifestation and severity, it has been suggested that other biological processes contribute to the detrimental effects of the mutation. One such process is oxidative stress. Previously we have shown that genetic deletion of the antioxidant protein glutathione S-transferase pi (GSTpi) in mice increases the sensitivity of SNpc dopaminergic neurons to exogenous parkinsonian toxins. Therefore, we set out to determine if loss of GSTpi could exacerbate the pathology of these A53T mice. However, as previously reported, loss of GSTpi had no effect on SNpc dopaminergic cell number, striatal DA content, or time on the rotarod in WT or A53T mice. To further analyze the neurochemical properties of the nigrostriatal DA system in these strains, the present study utilized *in vivo* fast scan cyclic voltammetry (FSCV) with carbon-fiber recording microelectrodes in anesthetized mice (12 months old) to measure changes in striatal DA release evoked by brief electrical stimulation of the medial forebrain bundle. GSTpi-/- mice showed reduced concentration of stimulated DA release as well as reduced DA half-life compared to WT mice. Loss of GSTpi did not reduce these properties in transgenic A53T mice; however, A53T mice already displayed reduced stimulated DA release and DA half-life. Administration of the DA transporter (DAT) blocker nomifensine (10mg/kg, ip) increased the DA half-life of GSTpi-/- mice (279%) to a significantly greater degree than that of the WT (208%), which may explain the large increase in locomotor activity observed in GSTpi-/- mice following nomifensine. Although loss of GSTpi does not alter the DA systems of A53T mice to the same extent, the measured properties (stimulated DA release, DA half-life, and locomotor activitiy following nomifensine) of A53T mice more closely resemble those of GSTpi-/- mice rather than the WT. The mechanism underlying this physiological change is unknown but may be related to differences in DAT densities or available DA supply. Further studies will be conducted to look at these possibilities as well as the impact of aging.

Abstract: Dopaminergic (DA) neurons in the substantia nigra pars compacta (SNc) degenerate in Parkinson's disease (PD). These neurons robustly express several nicotinic acetylcholine receptor (nAChR) subtypes. Smoking appears to produce neuroprotection against Parkinson's disease but the mechanism is unknown. To determine whether nicotine-induced changes in gene expression that contribute to the neuroprotective effects of smoking, we developed methods to measure the effect of prolonged nicotine exposure on the SNc neuronal transcriptome in an unbiased manner. Pools of twenty neurons were collected using laser-capture microscopy, and transcriptional changes were assessed using RNA deep sequencing. Overall, the expression of 129 genes was significantly affected by chronic nicotine, including genes involved in the ubiquitin-proteasome pathway, cell cycle regulation, chromatin modification, DNA binding, and RNA regulation. Using the same approach and an α- synuclein overexpression (Thy1-aSyn) mouse model, we measured the effects of α-synuclein expression on the SNc neuronal transcriptome. Our data show that DA neurons isolated from the α-synuclein Parkinson's disease mouse model display striking dysfunction of mitochondrial gene expression and have higher levels of oxidative stress. We also report preliminary transcriptome data for single-cell dopaminergic and GABAergic neurons isolated from midbrain cultures. In summary the results

show that nicotine can modulate expression of numerous genes in several pathways. The pathways modulated by nicotine are relevant to Parkinson's disease and may participate in the neuroprotective effects of smoking. Additionally, we show that over-expression of α-synuclein causes marked cellular stress relevant to PD within the DA neurons of the SNc. These novel techniques will facilitate advances in understanding the mechanisms taking place at the cellular level and will have applications elsewhere in the fields of neuroscience and molecular biology.

Abstract: Previous studies demonstrate that injections of pre-formed fibrillar (PFF) forms of alpha-synuclein (α-syn) into the mouse striatum can induce Parkinson's-like accumulation of aggregates in anatomically interconnected regions, which results in significant neurodegeneration. Our laboratory has replicated this finding in a rat, thereby inducing a progressive, neurodegenerative rat model of α-synucleinopathy. This model exhibits hyper-phosphorylated α-syn intraneuronal accumulations (i.e., diffuse Lewy neurite (LN)- and LB-like inclusions) as early as 30 days in several areas interconnected with the striatum, most prominently in the frontal and piriform cortices and the substantia nigra (SN). Furthermore, α-syn pathology in this model co-localizes with ubiquitin, indicating they share common properties with human LBs/LNs. While this model was established in young animals, one of the major risk

factors for PD is aging; therefore, we examined the effect of PFFs in aged animals. We are specifically interested in whether age influences the localization and accumulation of α-syn to the nucleus, which may increase the vulnerability of dopamine neurons. Additionally, we expect that age may impact the rate of α-syn propagation since reduced transport and protein synthesis are known to be impaired in older animals. To this end, young (2 month) and old (20 month) male Fischer rats received a single intrastriatal injection of either 8 or 12ug of mouse PFFs. Quantitative analysis of intraneuronal accumulations and dopamine degeneration within the SN of rats will determine whether aging impacts α-syn propagation and dopamine neuron vulnerability. Preliminary analysis of brain sections collected 60 days post-injection reveals substantially less LB-like inclusions in the aged rats compared to young rats, suggesting a less efficient spread of α-syn fibrils in aged brains. Stereological analyses are underway to determine whether the aged brain is more susceptible to α-syn-associated toxicity, resulting in more pronounced degeneration of SN dopamine neurons. Results from these studies will shed light on whether pathological forms of α-syn behave differently in an aged brain and provide further evidence that normal aging is an underappreciated factor in neurodegenerative disease.

Title: Glia, glutamate receptors and oligomeric alpha-synuclein

Authors: *E. DAVIS, K. CRADDOCK, K. CONANT, K. MAGUIRE-ZEISS
Neurosci., Georgetown Univ. Med. Ctr., Washington, DC

Abstract: The accumulation of oligomeric alpha-synuclein is a hallmark feature of a group of neurologic disorders called synucleinopathies. In addition to Parkinson’s disease, multiple system atrophy and diffuse Lewy body disease, synuclein is also evident in the substantia nigra of HIV-infected individuals. Glial activation is also present at both early and late stages of these

disorders, suggesting a role for glia in the progression of disease. Previously we demonstrated that oligomeric alpha-synuclein directly activates microglia leading to a complex inflammatory response via a toll-like receptor mediated pathway. Interestingly, monomeric alpha-synuclein did not incite a microglial inflammatory response, demonstrating a role for protein structure. Here we further characterize this glial activation by investigating the effect of oligomeric synuclein on glutamate receptors. Since glutamate receptor composition can modulate intracellular calcium levels, oligomeric synuclein-mediated alterations in these receptors would impact overall glial function. Here we also characterize the effect of oligomeric synuclein on astrocyte function; a glial cell type critical for calcium regulation. These studies investigate a novel role for oligomeric synuclein-induced glial activation.

Title: Pallidal deep brain stimulation in cortical-cortical and cortical-subcortical structures in the behaving 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine nonhuman primate hemi-Parkinson’s disease model

Authors: *C. M. HENDRIX, A. MURALIDHARAN, K. BAKER, J. VITEK
Neurol., Univ. of Minnesota, MINNEAPOLIS, MN

Abstract: Current hypotheses propose that therapeutic deep brain stimulation (DBS) improves motor signs in Parkinson’s disease (PD) by modifying abnormal patterns of neuronal activity in subcortical-cortical and cortical-cortical motor circuits. How motor improvements through therapeutic DBS correlates with the changes in neuronal activity remains unclear. This study examines this relationship through concurrent cortical-cortical single unit (SU) recordings in the premotor (PM), primary motor (M1), and supplemental motor (SMA) areas in the hemi-Parkinsonian 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) nonhuman primate undergoing pallidal DBS while performing a cued, center-out reaching task. Pallidal DBS

improved reaction times and reduced variability in reach behavior and periods of freezing. Beta and gamma band synchronization was more closely time locked to the task related go cue during DBS. Beta band desynchronization was time locked to reach onset under both DBS on/off conditions. Cortical SU peristimulus time histograms indicated a general inhibition of cortical activity while perievent time histograms aligned on task behaviors indicated an increase in the modulation of activity across epochs during DBS. Preparatory activity in SMA cells was present during DBS compared to little or no activity in the same cells while off-DBS. During DBS, peak coherence was more prevalent in the beta band for SUs across SMA-M1/PM structure while theta to alpha and gamma bands were more likely to appear within each cortical structure. Reduction of beta band activity has been linked to the development of bradykinesia. However, it is more likely that beta band activity is necessary and integral to normal movement; pallidal DBS acts to change the timing of such activity during motor behavior by facilitating time-locked beta band synchronization within the structure. An increase in time-locked modulation with DBS was also noted in/across gamma and theta-to-alpha bands suggesting that improvement in behavior may occur as the result of a combination of temporally correlated time locked changes across multiple power spectrums. DBS related inhibition and pattern changes in cortical activity with corresponding improvement in motor behavior is consistent with the hypothesis that pallidal DBS improves motor behavior through the suppression of non-selective firing patterns (noise), changes in selective firing patterns, and the temporal relationships of neural activity across frequency bands within the thalamo-cortical motor pathways.

Title: First evidence of neural mechanisms of Hebbian changes in white matter tracts induced by long-term deep brain stimulation

Authors: *T. J. VAN HARTEVELT[1,2], J. CABRAL[1,3], A. MØLLER[2], J. J. FITZGERALD[5], A. L. GREEN[5], T. Z. AZIZ[5], G. DECO[3,4], M. L. KRINGELBACH[1,2,5]

Catalana de la Recerca i Estudis Avançats, Univ. Pompeu Fabra, Barcelona, Spain; [5]Nuffield Dept. of Surgical Sci., John Radcliffe Hosp., Oxford, United Kingdom

Abstract: Hebbian learning has not been demonstrated at the macroscopic scale of long-range connections in humans, although behavioural changes from deep brain stimulation (DBS) suggest structural changes. It is not clear, however, which of the many connections from a given DBS target are most influential in providing the clinical benefit and if DBS creates long-term changes in brain connectivity. We used the rare opportunity of having preoperative and five-month postoperative diffusion tensor imaging (DTI) data from a patient with DBS of the subthalamic nucleus (STN) for Parkinson's disease which allowed us to reconstruct the spontaneous dynamics of the underlying pre and post connectivity measures. We used a whole-brain computational model to explain DBS-induced Hebbian long-term structural changes using simulated functional connectivity based on the pre- and postoperative DTI data. We calculated the difference between the pre-DBS and post-DBS structural connectivity (SC) and between the simulated functional connectivity (FC) matrices. The post-DBS FC matrix was calculated based on the pre-DBS SC matrix with a stimulation input in the STN included to simulate the DBS effects. The difference of the simulated functional and empirical structural connectivity matrices was compared to find the optimal stimulation factor through Hebbian learning. This stimulation factor was based on optimising the weights of the known connections from the STN so that the FC difference best fits the SC difference. Using rare pre- and post-DBS DTI data from Parkinson's disease, we showed significant changes in structural connectivity which led to significant functional alterations. Using a whole-brain computational model we showed that DBS appears to have its effect through changing the connectivity weights of the putamen and the thalamus, but not the caudate or STN. These functional changes led to clinical improvement as well as structural changes that improved towards normality. This is the first study providing evidence that DBS changes the functional weights of selective connectivity from the implanted electrode in the STN. This is highly suggestive of neural Hebbian changes in white matter tracts induced by long-term DBS. This novel approach allows us to determine the relative contributions of the connectivity of the DBS target and to track any long-term Hebbian changes induced by DBS.

Title: Randomized burst patterns of stimulation produce long-lasting, dose-dependent improvement in bradykinesia in the parkinsonian non-human primate

Authors: *J. WANG[1], A. MURALIDHARAN[1], L. VENKATESAN[2], C. VETRUBA[1], J. VITEK[1], K. BAKER[1]
[1]Neurol., Univ. of Minnesota, Minneapolis, MN; [2]St. Jude Med., Plano, TX

Abstract: Unconventional deep brain stimulation (DBS) paradigms are being explored for their potential to enhance therapeutic efficacy in patients with Parkinson's disease (PD). This includes stimulus patterns that may induce beneficial effects that outlast stimulus delivery, as previously demonstrated for akinesia by Tass and colleagues. The current study examined further the potential for randomized burst (RB) DBS patterns to mitigate parkinsonian motor signs as a function of dose duration using the MPTP monkey model of PD. Two rhesus macaque primates were operantly trained to allow passive limb manipulation and to perform a standard reaching task. Each was implanted with a scaled-down DBS lead in the STN region. A repeated-measures, block design was applied to evaluate and compare the effects of isochronal (2 hours/day; 130 Hz; 0.55 mA) DBS to RB stimulation, with the latter delivered for 2- (RB2) or 4-hours (RB4) per day at 0.2 mA. A chronically implanted Brio™ IPG (St. Jude Medical, Plano TX) with research software was used to randomly deliver bursts of stimulation to each of the three ventral-most contacts, with the most dorsal contact programmed as the anode. Each paradigm was applied for five days, followed by a DBS OFF block to characterize carry-over effects. Reaching data and modified UPDRS (mUPDRS) scores were collected daily, with the duration of each post-treatment, DBS OFF block extended until the mUPDRS score returned to baseline. mUPDRS scores and reach/retrieval velocity measures were improved by isochronal, RB2 and RB4 DBS, with therapeutic carryover observed for up to 3, 5, and 14 days, respectively. Post-DBS improvements of mUPDRS associated with isochronal and RB2 DBS were as high as 15%, while RB4 DBS yielded improvements of up to 29%. Reaching task behavior was marked by increased velocity at both the wrist and elbow, with post-DBS improvements at the wrist of up to 25%, 7% and 26%, and the elbow of up to 23%, 6%, and 43% for isochronal, RB2, and RB4 DBS, respectively. Our data are consistent with previous studies suggesting that both acute and long-term therapeutic benefit can be achieved using unconventional DBS patterns. Uniquely, our data suggest that carry-over of therapeutic benefit following discontinuation of DBS may be sensitive to dose duration, with enhancement of both the magnitude and endurance of after-effects achieved by increasing the dosing window. Moreover, these results underscore the need for further studies to understand the mechanism(s) underlying this therapeutic effect as a

potential means of deriving rationale for the development of novel stimulation paradigms to optimize further the magnitude and duration of therapeutic benefit.

Title: Developing closed-loop control of deep brain stimulation using oscillations in local field potentials

Authors: ***L. A. JOHNSON**[1], E. PARK[2], C. M. HENDRIX[1], K. B. BAKER[1], J. L. VITEK[1]
[1]Neurol., Univ. of Minnesota, Minneapolis, MN; [2]Dept. of Biomed. Engin., Hanyang Univ., Seoul, Korea, Republic of

Abstract: Deep brain stimulation (DBS) of the subthalamic nucleus (STN) or the globus pallidus internus (GPi) is an effective treatment option for many individuals with advanced Parkinson's disease (PD). Although patient's clinical symptoms may vary throughout the day, contemporary DBS systems deliver stimulation in a continuous fashion without regard for the patient's clinical state. A promising approach to improve DBS therapy is to modify stimulation parameters in real time based on measures of brain activity. In this study, we developed a closed-loop recording/stimulation system that extracts oscillatory activity from local field potentials (LFPs) recorded differentially from two DBS contacts to trigger stimulation at an adjacent contact. The system allowed for flexible, user-defined control of recording, real-time analysis, and stimulation parameters. For initial testing, we used the amplitude of beta oscillations (13-35Hz) to trigger DBS, as STN and GPi LFP beta power has been shown to be a biomarker of disease in PD patients and the non-human primate MPTP model of PD. The closed-loop system was first tested in-vitro to determine if stimulation artifacts would corrupt the signal of interest. A voltage waveform generator was used to create sinusoidal signals with amplitudes the same order of magnitude as those observed in-vivo at frequencies ranging from 10 to 40 Hz. Spectral analysis

confirmed that the power at each of the frequencies evaluated was unchanged between DBS in the ON (130Hz) and OFF conditions. The closed-loop system was also tested in-vivo, in a rhesus macaque rendered parkinsonian through intra-carotid injections of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and implanted in GPi with an 8-contact DBS lead. The DBS trigger threshold was established based on baseline beta amplitude measured in the resting DBS-off condition. Threshold was systematically varied (25, 50, 75 percentile of baseline); stimulation continued as long as the beta amplitude was above the trigger level. The behavioral effects of closed-loop DBS were assessed while the animal performed a center-out reach task and compared to open-loop (isochronal, 130Hz) and DBS-off conditions. In this study we developed a platform to evaluate real-time, closed-loop DBS in an awake, behaving animal model of PD, which will be useful to investigate the optimal parameters for feedback control of DBS and to understand the neural mechanisms underlying the therapeutic benefit of DBS.

Title: Changes in the phase-amplitude coupling of high-frequency oscillations as a biomarker of parkinsonian severity

Authors: *E. M. BELLO[1], A. T. CONNOLLY[1], K. B. BAKER[2], T. I. NETOFF[1], M. D. JOHNSON[1], J. L. VITEK[2]
[1]Biomed. Engin., [2]Neurol., Univ. of Minnesota, Minneapolis, MN

Abstract: Background: Previous studies have associated the presence of beta oscillations (10-35 Hz) in basal ganglia local field potentials (LFP) with Parkinson's disease (PD), but few have correlated the role of high-frequency oscillations (HFO, >100 Hz) to the severity of parkinsonian motor signs (Özkurt et al., 2011). Objective: To study changes in LFP phase-amplitude coupling associated with parkinsonian severity in a non-human primate model of PD. Methods: Spontaneous LFPs were recorded from three awake NHPs as a bipolar signal between two microelectrodes located in the globus pallidus interna or externa. Recordings were made pre-MPTP exposure as well as at each of three consecutive parkinsonian states (mild, moderate and severe) achieved through successive MPTP injections. Motor severity was indexed using a modified UPDRS. Each trial was labeled according to parkinsonian state and recording location and filtered into frequency bands ranging from 0.1-390 Hz. The phase-amplitude coupling (PAC) across bands was assessed according to a modulation index (MI) and compared to a set of 100 time-shuffled bootstrapped surrogates. PAC was considered significant if the MI was different from the noise floor with a $Z>3$. Results: In the naïve state, significant PAC was observed in 61% (202/333)(of recordings between the gamma phase (32-128 Hz) and the HFO amplitude (128-390 Hz). As parkinsonian symptoms worsened, the proportion of recordings with significant PAC in these bands remained constant 61% (101/165)in mild, 68% (126/184)in moderate, and 62% (68/109)in the severe state, Fisher's exact $p=0.2166$). In contrast, the HFO amplitude became significantly coupled with beta band phase (8-32 Hz) as severity increased 16% (53/333) in naïve, 39% (65/165)in mild, 42% (77/184) in moderate, and 59% (64/109)in the severe state, Fisher's exact $p<0.001$). Conclusions: Coupling between the phase of beta oscillations and the amplitude of high frequency oscillations in the globus pallidus was found to correlate with increasing severity of motor signs in the non-human primate model of PD. These data suggest that abnormal synchronization may impair normally independent neural processes through the basal ganglia necessary for normal movement.

Title: Effect of STN DBS on motor cortical activity in the resting state and during movement

Authors: A. MURALIDHARAN[1], J. ZHANG[1], F. AGNESI[2], S. NEBECK[3], *K. B. BAKER[1], J. L. VITEK[1]
[1]Dept. of Neurol., [2]Dept. of Biomed. Engin., [3]Col. of Biol. Sci., Univ. of Minnesota, Minneapolis, MN

Abstract: Introduction: Deep brain stimulation (DBS) of the subthalamic nucleus (STN) has been demonstrated to improve the cardinal motor signs of Parkinson's disease (PD). The relationship of these improvements to changes in motor cortical activity has not yet been characterized. In order to correlate the therapeutic effects of STN DBS on movement kinematics, changes in the activity and receptive field characteristics of neurons in the arm area of the motor cortex (M1) during passive-joint manipulation and a cued-reaching task were analyzed in this study. Methods: One female rhesus macaque was made parkinsonian by injecting the neurotoxin MPTP. The STN was mapped using microelectrode techniques and a scaled-down version of the human quadripolar-DBS lead was implanted in the right STN. Therapeutic stimulation parameters were assessed through behavioral testing and clinical examination. The effect of therapeutic DBS was determined by comparing single unit cortical activity before and during DBS while the animal was at rest, during passive manipulation of the joint corresponding to the unit's receptive field and the cued-movement task. Results: In the resting state, 54% of the neurons in the motor cortex were suppressed, 21% were activated and 12% showed no change during DBS. Sixty-seven per cent of the cells inhibited by DBS showed a tonic suppression, while a smaller percent (33%) expressed a bi-or poly- phasic discharge pattern. All of the units that were excited by DBS had bi- or poly- phasic response patterns. The distribution of DBS response types during passive-joint movement was similar to that seen at rest. Twenty-nine per cent of the cells were found to code for position, 24% to velocity and 46% to both in the pre-DBS interval. During DBS 28% changed their tuning characteristics, 32% lost tuning and 20% that did not respond to position or velocity were now tuned to one or both. In all the cells that exhibited responses to passive movements directional specificity was increased. During the cued-movement task, DBS increased the signal to noise ratio and rate of rise of neuronal activity. Conclusion: STN DBS affects multiple aspects of spontaneous and movement related activity in the motor cortex that occurs coincident with improvement in motor behavior. DBS appears to have a significant effect on information processing in the motor cortex reflected as an increase in the signal to noise ratio and directional specificity of M1 neurons during movement. The exact relationship between the improvement in motor control and associated changes in M1 neuronal activity (rate, pattern, directionality) remains unclear.

Title: A possible role of reward sensitivity and impulsivity in weight gain after deep brain stimulation

Authors: M. AIELLO[1], F. FORONI[1], R. ELEOPRA[2], G. PERGOLA[3], *R. RUMIATI[1]
[1]Area of Neurosci., Trieste, Italy; [2]AOUD "Santa Maria della Misericordia, Udine, Italy; [3]Univ. degli Studi, Bari, Italy

Abstract: Introduction: Deep brain stimulation of the subthalamic nucleus (STN-DBS) has acquired a relevant role in the treatment of Parkinson's disease (PD). Despite being a safe procedure, it may expose patients to an increased risk to experience non-motor effects. For instance, many studies have shown that after the implant, patients with PD suddenly increase in weight. However, the exact mechanism and the predisposing factors of this weight gain have not yet been identified. Objective: Since these aspects have been demonstrated to be modulated by STN stimulation surgery, we aimed at evaluating the role of reward sensitivity and impulsivity in weight gain after DBS. Methods: Patients with PD scheduled for undergoing STN-DBS were recruited. They were tested before surgery in an on medication condition and after surgery in an on medication/on stimulation condition, in a satiated state. All participants were asked to perform a self-report questionnaire about impulsiveness, a go-no-go experiment measuring the response inhibition to food items and finally, a task that evaluates both hedonic and motivational aspects of food processing (liking and wanting, respectively). Food stimuli varied across two dimensions: taste (sweet vs. non-sweet) and calorie density (high vs. low). The preoperative and postoperative body weights were recorded. Results: The mean body weight of patients increased post-operatively. After STN-DBS, patients exhibited higher level of impulsivity. The weight changes correlated positively with impulsivity, hedonic ratings of food items (liking) and salience/motivation towards food (wanting) in the on medication/on stimulation condition whether no correlations were found with tastiness ratings of food. Moreover, strong correlations were observed between weight changes and liking for high calorie density food (both sweet and non-sweet) in the on medication condition before surgery. Conclusion: Our results confirm that STN-DBS may expose patients to the risk of weight gain. They also suggest that both

impulsivity and higher sensitivity to reward may play a significant role in the regulation of food intake and weight after surgery.

Title: Deep brain stimulation: A new approach to programming for Parkinson's disease

Authors: ***G. GILMORE**[1], M. DELROBAEI[2], K. OGNJANOVIC[2], M. JOG[1], B. XIAN[2], F. RAHIMI[2]
[1]Clin. Neurolog. Sci., [2]Western Univ. Hosp., London, ON, Canada

Abstract: Objective: Out with the old and in with the new, technology is rapidly changing and it is essential clinical assessment tools keep pace. Deep brain stimulation (DBS) is a new treatment option provided to L-DOPA responsive Parkinson's disease (PD) patients who are not adequately controlled by their medication. DBS patients receive clinical scale based programming sessions for treatment of their gait. However this clinical scale based assessment for gait has shown inconsistent results. An objective, quantitative, assessment of DBS on gait has not been conducted. Our group uses a gait analysis carpet to track and assess the changes in gait following DBS parameter changes. Method: Three PD patients (age: 65±3.3, PD duration: 12.2±3.3) were recruited. All patients were eligible for STN-DBS procedure. The patients were assessed at five time points, once before surgery and four times post-surgery (at 1 month intervals). For the assessments the Unified Parkinsons Disease Rating Scale (UPDRS) and a gait capture carpet, using PKMAS software, were used. The patients performed Timed Up and Go task at both normal and fast speeds. Gait was assessed using functional ambulation profile (FAP) and stride length. The FAP score rates a patient's walk to a standardized data base (95-100 being normal). Results: The gait score (UPDRS Part III - Item 29) showed a fairly unchanged rating across visits (0.3, 0.3, 0.6, 1.0 and 0.3 on average), while the objective gait capture carpet tracked changes. The gait capture carpet showed a decrease in FAP scores from visit 1 to visit 5.

The changes in FAP scores were: patient E.V.: from 86.5 to 84.5 and patient L.M.: from 88.5 to 86.5. There was an improvement in FAP scores for patient F.Z.: from 73 to 78.5. Furthermore the stride length showed worsening in the patients (E.V.: from 102cm to 94.5cm; L.M.: from 105 to 100cm), and improvement in patient F.Z. (from 79.5 to 87). Conclusion: Our preliminary results show UPDRS was unable to track the worsening symptoms in two patients, which hindered their DBS programming. This illustrates that DBS programming will benefit from a more objective kinematic assessment tool that can track gait changes more specifically. The PKMAS carpet can give real-time feedback to the clinician to aid in more effective DBS programming.

Title: Data-driven statistical method for predicting the outcomes of combined pharmacologic and deep brain stimulation therapy for Parkinson’s disease

Authors: R. R. SHAMIR[1], T. DOLBER[1], A. M. NOECKER[1], A. M. FRANKEMOLLE[1], B. L. WALTER[1], *C. C. MCINTYRE[2]

Abstract: Deep brain stimulation (DBS) of the subthalamic region is an effective treatment for the motor symptoms of advanced Parkinson's disease (PD). Following the surgery, the neurologist is faced with the challenge of balancing both the patient’s pharmacologic and stimulation treatments to maximize therapeutic benefit and minimize side effects. This complex process is currently driven by clinical experience and intuition, typically incorporating guidelines based on previous empirical studies. Unfortunately, this treatment optimization process often requires time-consuming follow-up visits with the patient because of the extremely large treatment parameter space. In response to these limitations, clinical decision support systems (CDSS) that incorporate patient-specific computer models to help customize DBS parameter

settings to the patient have been developed, and the first generation of commercial DBS CDSS are now available in Europe. However, these current systems only provide guidance regarding electrical stimulation, ignoring the pharmacology side of patient management. Therefore, we set out to define the foundation for a comprehensive PD CDSS that couples both stimulation and medication variables. We developed a linear function that relates the DBS parameters, the levodopa dosage, and patient-specific preoperative clinical data with the actual treatment motor outcomes. Our novel CDSS also incorporates image-based patient-specific computer models of DBS activation volumes in a multi-linear regression analysis. The resulting predictor function was highly correlated with the actual motor outcomes ($r = 0.76$; $p<0.05$). These results demonstrate that the outcomes of a combined pharmacologic-DBS therapy can be predicted with a PD CDSS. Such data-driven statistical systems have potential to facilitate patient-specific treatment optimization.

Title: Long term-cortical and subcortical recordings in Parkinson’s disease patients using a totally implanted device

Authors: *C. DE HEMPTINNE[1], N. SWANN*[1], J. OSTREM[2], M. SAN LUCIANO[2], N. GALIFIANAKIS[2], P. STARR[1]

Abstract: * contributed equally Objectives: To assess the feasibility of chronic cortical and subcortical recording in humans with Parkinson’s disease (PD) using a novel bidirectional neural

interface, and to study chronic effects of deep brain stimulation (DBS) and antiparkinsonian medication on the motor network. Background: There is growing evidence for increased neuronal synchronization throughout the basal ganglia-thalamocortical loop in PD patients, especially in the beta band (13-30 Hz), that is reduced by medication and DBS. Most of this evidence has come from intraoperative studies or early postoperative recordings. Both these techniques are complicated by logistical constraints and cannot be dissociated from the acute brain physiology changes caused by edema around the recently inserted DBS electrodes. To overcome these limitations, we investigate the effect of antiparkinsonian therapies on cortical and subcortical signals using a novel fully implantable device, which has the capability of recording and storing data in addition to delivering therapeutic DBS. Methods: Three PD patients with severe motor fluctuations and minimal tremor have been each implanted with three electrodes; two DBS electrodes implanted bilaterally in the subthalamic nucleus (STN) and one subdural quadripolar strip electrode placed unilaterally over the primary motor cortex (M1). The cortical and ipsilateral STN electrodes were attached to an investigational, totally implanted neural interface capable of both recording and stimulation. Cortical and subcortical LFPs were recorded simultaneously in the outpatient clinic over multiple visits, on and off medication and on and off therapeutic stimulation. Signals were sampled at 800 Hz, stored internally and downloaded noninvasively by radiotelemetry. Results: Both cortical and subcortical signals were stable over time. In the STN, levodopa reduced low beta power (13-20 Hz), as previously described in acute recordings, but also reduced low gamma power (40 -70 Hz). In contrast levodopa did not modulate M1 beta power. Similarly, therapeutic DBS reduced beta and low gamma power in STN but did not affect M1 power. M1-STN coherence in the beta band was also reduced by levodopa. In one patient with prominent dyskinesias, a narrowband gamma peak (70 Hz) was consistently observed in M1 in the on but not in the off medication state. Discussion: These are the first chronic cortical and subcortical recordings in PD from a totally implanted device. They suggest that antiparkinsonian therapies have different effects on STN and cortical activities, decreasing beta oscillations in STN only, and decoupling STN-M1 interactions in the beta band.

Title: Electrocorticography reveals cortical characteristics of resting tremor in Parkinson's disease

Authors: *S. E. QASIM, C. DE HEMPTINNE, N. C. SWANN, P. A. STARR
UCSF, San Francisco, CA

Abstract: Introduction: Resting tremor of 4-8 Hz is one of the cardinal motor signs of Parkinson's disease (PD). Tremor is mysterious in that it fluctuates spontaneously, does not increase in severity with increased dopamine denervation (though some denervation is necessary for tremor to occur), and never occurs in 1/3 of PD patients. These observations have led to the hypothesis that tremor may act as a compensatory mechanism to reduce the excessive motor network synchronization that characterizes PD. Methods: We investigated the spontaneous onset of tremor by recording electrocorticography (ECoG) using a 6 contact subdural electrode strip temporarily placed over the precentral and postcentral gyrus of patients undergoing deep brain stimulation (DBS) surgery. Recordings were made while patients were awake and at rest with eyes open, off of antiparkinsonian medications. Tremor was identified using a combination of electromyography measurements from the bicep, wrist extensor, and wrist flexor muscles and wrist accelerometery. ECoG recordings were compared during nontremor versus tremor epochs using measures of power spectral density (PSD) and phase-amplitude coupling (PAC). Results: We analyzed 19 intraoperative recordings in 9 patients with PD that contained intermittent epochs of tremor. Within patient comparisons revealed significant difference only in the contact over primary motor cortex (M1). We found that average alpha (8-12 Hz) and low beta (13-31 Hz) log power decreased significantly during tremor. 8 out of 9 patients showed none to very little PAC at rest. In those patients we found that the coupling of phase in high beta (27-32 Hz) to the amplitude of high gamma (50-200 Hz) increased during epochs of tremor. One patient who did have significant coupling at rest, however, showed large decreases in beta phase to gamma amplitude coupling. Conclusions: We used ECoG in patients undergoing DBS surgery for PD, to measure changes in cortical activity between rest and tremor. Resting tremor modulated power in the alpha and beta bands of M1. It also increased the synchronization of high gamma amplitude to high beta phase, though this result was reversed in a patient who showed large PAC at rest.

Title: Parkinsonian and essential tremor pathophysiology

Authors: *H. CAGNAN[1], S. LITTLE[1], T. FOLTYNIE[2], P. LIMOUSIN[2], L. ZRINZO[2], M. HARIZ[2], B. CHEERAN[1], J. FITZGERALD[1], A. GREEN[1], T. AZIZ[1], P. BROWN[1]

Abstract: Tremor is central to a wide range of pathologies. However, the mechanisms underlying tremor generation remain largely unknown. In this study, we address two fundamental issues 1- the role of different deep brain stimulation targets in tremor generation, and 2- pathophysiological differences between Parkinsonian and essential tremor circuits. We hypothesised that stimulation delivered at certain parts of a tremor cycle should interact with oscillatory neural activity driving tremor, which would then be reflected as an instantaneous change in the temporal profile of tremor. Accordingly, we stimulated fifteen patients with Parkinson's disease with either thalamic or subthalamic electrodes (13 male and 2 female patients, age: 50-77 years) and ten patients with essential tremor with thalamic electrodes (9 male and 1 female patients, age: 34-74 years). We show that both thalamic and subthalamic stimulation significantly entrains tremor in patients with Parkinson's disease. Critically, though, there was no significant stimulation timing dependent change in instantaneous tremor amplitude when compared to tremor amplitude variability observed without stimulation. This is in stark contrast to essential tremor where thalamic deep brain stimulation at tremor frequency both entrained tremor and modulated instantaneous tremor amplitude depending on the tremor phase at which stimulation was applied. Parkinsonian and essential tremor also differed in the relative tolerance of their amplitudes (i.e. tremor severity) to spontaneous changes in instantaneous tremor frequency, with the amplitude of parkinsonian tremor demonstrating greater tolerance to spontaneous changes in instantaneous tremor frequency than in essential tremor. Based on these results we conclude that parkinsonian tremor is driven by a neural network, which includes the subthalamic nucleus and ventrolateral thalamus and has broad frequency-amplitude tolerance. We propose that it is this tolerance to changes in tremor frequency that dictates that Parkinsonian tremor may be significantly entrained by low frequency stimulation without amplitude modulation. In contrast, the neural circuits influenced by low frequency thalamic stimulation in

essential tremor have a narrower frequency-amplitude tolerance so that tremor entrainment through extrinsic driving is necessarily accompanied by amplitude modulation. Such differences in Parkinsonian and essential tremor will be important in selecting future strategies for closed loop deep brain stimulation for tremor control.

Title: Impedance reliability during neurostimulator replacement: Activa to activa vs. soletras to activa

Authors: ***E. L. HARGREAVES**[1], E. M. FEINSTEIN[2], R. J. DITOTA[1], S. WONG[2], S. F. DANISH[1]
[1]Neurosurg., [2]Neurol., Robert Wood Johnson Med. Sch., New Brunswick, NJ

Abstract: Deep Brain Stimulation (DBS) is an established adjunct neurosurgical treatment for movement disorders. At the heart of the DBS system is the neuromodulation device, which has a number of diagnostic capabilities to ensure the integrity of the DBS system. One of these capabilities is impedance testing. We have shown previously that Medtronic's most recent Activa (PC/SC) neurostimulators are more accurate in identifying the impedance of known resistors during bench tests than their Soletra predecessors. Further we have shown that the accuracy of all devices declines as the battery charge wears down. Here, we compare the difference between impedance assessments of Soletras to Activa SCs versus Activa PC/SCs to Activa PC/SCs during surgical generator replacement procedures. If the Activa family of devices is more accurate then there should be less of a difference and greater similarity moving from an Activa device to an Activa device then moving from a Soletra to an Activa SC. The Soletras were replaced in pairs (24 readable Soletras from 13 implanted individuals), and as such, a number of the devices were considered functioning at a normal battery charge (8/24), with only their contralateral counterparts failing. This is in contrast to the Activa generator replacements, where all 10 devices (9/10 dual channel PCs and 1/10 SC from 10 implanted individuals) were at

or near the “Elective Replacement Indicator” (ERI) thresholds. Analyses were performed on the monopolar impedances recorded immediately prior to deactivation and upon the intraoperative test of the new devices. Average time between Soletra to Activa SC assessments was 102min, which was not different from that between Activa to Activa assessments at 76min. Although the difference between monopolar impedance assessments for Soletras to Activa SCs (mean 63 Ohms) was similar to that of the Activa to Activa devices (mean 65 Ohms) the variability was statistically greater as analyzed by the absolute difference (mean 101 sem 12.4 Ohms compared to mean 76 sem 6.4 Ohms respectively). This was further supported by stronger correlations between impedance values before and during replacement procedures of the Activa to Activa devices (r=.93) over the Soletra to Activa SC devices (r=.73). Thus, these clinical results are consistent with our previous bench tests indicating that the Activa devices were more accurate then their predecessors, even when close to ERI thresholds. Differences in Soletra impedance as battery life declines may translate to degradations in clinical efficacy during this time and may necessitate compensatory programming changes, which may further need to be tempered upon replacement.

Abstract: Deep brain stimulation (DBS) of the subthalamic nucleus (STN) is a common and effective treatment for Parkinson disease (PD). Local field potentials (LFP) recorded from the STN in PD patients have revealed elevated power in the beta (13-30 Hz) band (for review, see Weinberger et al, 2009). Recent work suggests that clinical outcomes correlate with placement of a DBS electrode in relation to the region of highest beta oscillation in the dorsolateral STN (Zaidel et al, 2010). Here, we show the presence of distinct patterns of LFP phase-amplitude coupling within the STN. We obtained microelectrode recordings in 13 PD patients undergoing bilateral implantation of DBS electrodes in STN. For each patient, microelectrode recordings were obtained at different depths along a single trajectory aimed through dorsolateral STN (n = 26 electrode trajectories). All patients were awake and resting on the operating table with eyes open throughout recording. Data were analyzed using standard Fourier-based methods and phase-amplitude coupling techniques (Tort et al, 2010). Two distinct, significant ($P<0.01$) phase-amplitude coupling patterns were observed within the STN of the majority of patients (22/26 trajectories):(i) gamma frequency (>30 Hz) phase coupled to high frequency oscillation (HFO, > 200 Hz); and (ii) beta frequency (13-20Hz) phase coupled separately to activity centered at 150 Hz and 200 Hz, but spectrally distinct from HFO. We hypothesize that the HFO activity reflects action potentials manifesting in the LFP. Thus, the observed activity implies the rhythmic firing of neurons in multiple spectral bands in the STN, depending on spatial location. The differential spatiotemporal activity within the STN implicates sub-STN circuit mechanisms in the pathophysiology of PD. Such new spectral markers may help guide DBS electrode placement.

Title: Comparison of deep brain stimulation neural activation models developed with 7T MRI data

Authors: *K. GUNALAN[1], A. CHATURVEDI[1], Y. DUCHIN[2], G. SAPIRO[3], N. HAREL[2], C. C. MCINTYRE[1]
[1]Biomed. Engin., Case Western Reserve Univ., Cleveland, OH; [2]Radiology, Univ. of Minnesota, Minnesota, MN; [3]Electrical & Computer Engin., Duke Univ., Durham, NC

Abstract: Deep brain stimulation (DBS) has been shown to modulate axonal activity within the vicinity of the active electrode contact(s). Computational modeling provides for the ability to estimate the extent of axonal activation in response to extracellular stimulation, as first described by McNeal in 1976. In this study we compare two previously described methods of estimating axonal activation in the context of DBS: the McNeal-based approach and the activation volume predictor function. The McNeal-based approach couples DBS electric field modeling with multi-compartment cable axon models and thus provides the most detailed method of estimation. Activation volumes are based on classifiers that can approximate the spatial extent of axonal activation as a function of the stimulation parameter settings, which is computationally less intensive than the McNeal-based approach. We compared these models in a Parkinson's disease DBS patient using high-resolution (7T) magnetic resonance imaging data. We used probabilistic tractography to reconstruct the hyperdirect and subthalamopallidal pathways, which are believed to mediate the therapeutic benefit of subthalamic DBS, and the internal capsule, activation of which causes side effects. We modeled current controlled stimulation and, using the two methods, calculated the pathway activation patterns for clinically relevant stimulation parameter settings. The activation volume-based calculations were found to overestimate results compared to the McNeal-based approach. Despite this shortcoming, activation volumes provide for real-time visualization of the effects of stimulation parameters changes on the pathway activation patterns.

Title: Effects of low (60 Hz) and high (130/140 Hz) frequency STN DBS on upper extremity movement velocity and STN beta band power in Parkinson’s disease

Authors: ***Z. BLUMENFELD**[1], A. VELISAR[1], M. MILLER KOOP[1], L. SHREVE[1], E. QUINN[1], B. HILL[1], C. KILBANE[1], C. RODRIGUEZ[1], J. HENDERSON[2], H. BRONTE-STEWART[1]
[1]Neurol., [2]Neurosurg., Stanford Univ., Stanford, CA

Abstract: Objective: High frequency subthalamic nucleus deep brain stimulation (HF STN DBS) attenuates resting STN local field potential (LFP) power in the 13 - 30 Hz (beta) band and improves the cardinal motor signs of Parkinson’s disease (PD). Low frequency (60 Hz) STN DBS has not been useful clinically except for aspects of speech and gait. We have shown that 60 Hz DBS amplifies resting LFP peak power (Bronte-Stewart et al., SfN Abstract 2013). Therefore, we hypothesize that HF DBS, but not 60 Hz DBS, would improve limb bradykinesia. We report preliminary data on the effect of 60 Hz versus 140 Hz DBS on STN beta band power during movement. Methods: Five PD subjects (nine sides), off-medication at least one month

after DBS implantation surgery, performed a seated repetitive wrist flexion-extension (rWFE) task without DBS (baseline), and during randomized presentations of 60 Hz DBS, or HF (130 or 140 Hz) DBS (each either 2 or 3V). In three cases, STN LFPs were also recorded from electrodes 0 - 2 of the DBS lead (model 3389, Medtronic, Inc.) and from the investigational Activa® PC+S system via telemetry (FDA, IDE, IRB, and CA Medicare approved) while DBS was applied through electrode 1. Hand angular velocity was recorded using solid-state gyroscopic sensors (Motus Bioengineering, Inc.) and was acquired using Spike software (Cambridge Electronic Design, Inc.). Root-mean-square angular velocity (Vrms) was calculated in MATLAB (The MathWorks, Inc.). Results: Both HF DBS and 60 Hz DBS significantly increased Vrms compared to baseline, $p < 0.05$. There was no significant difference in the improvement during 60 Hz versus HF DBS. Preliminary results of movement-related STN LFPs recordings revealed no attenuation of baseline-movement-related beta band power during 60 Hz DBS and concomitant improvement in Vrms, whereas HF DBS attenuated baseline beta band power and improved Vrms (2/3 sides). For the third side, HF DBS improved Vrms to a greater extent than 60 Hz DBS, and there was attenuation of baseline-movement-related beta band power during both HF and 60 Hz DBS. Conclusions: Contrary to our hypothesis, both 60 Hz and HF DBS improved upper extremity bradykinesia to the same extent. Preliminary data suggests that improvement in Vrms during 60 Hz DBS may not be associated with attenuation of beta band power as it was during HF DBS. These results suggest that the attenuation of STN beta band power may not be causal to the improvement in bradykinesia and that 60 Hz DBS may be useful even for appendicular motor signs in PD.

Title: STN LFP recordings from the implanted Activa® PC+S neurostimulator system in freely moving PD subjects reveal conserved resting state profiles while lying, sitting or standing and voltage dependent beta band attenuation during 140 Hz DBS

Authors: *E. J. QUINN[1], Z. BLUMENFELD[1], L. SHREVE[1], A. VELISAR[1], M. KOOP[1], C. KILBANE[1], J. HENDERSON[2], C. RODRIGUEZ[1], B. HILL[1], H. BRONTE-STEWART[1]
[1]Neurol. and Neurolog. Sci., [2]Neurosurg., Stanford Univ., Stanford, CA

Abstract: Objective: To determine whether the resting state subthalamic nucleus (STN) alpha/beta band is similar lying, sitting or standing in PD subjects (PDs) with the implanted investigational Activa® PC+S neurostimulator system (Medtronic Inc.). Additionally, we investigated whether signal to noise characteristics of the implanted neurostimulator system with local field potential (LFP) sensing capability allowed discernable recordings during high frequency (HF) deep brain stimulation (DBS) at different voltages. Methods: STN LFPs were recorded from electrodes 0-2 from the DBS lead (model 3389, Medtronic, Inc.) using the Activa® PC+S system via telemetry (FDA IDE, IRB and CA Medicare approved) from five PDs (10 STNs) during lying, sitting, and standing (no DBS) and before, during and after randomized periods of 140 Hz (60 microsec) DBS at 1V and 3V through electrode 1 (while seated). PDs were off medication (>24/12 hours for long-acting/short-acting). Movement was monitored using angular velocity sensors, EMG, and continuous video, synchronized with LFPs. Data was carefully parsed to avoid any movement or electrical artifact during resting states. Alpha/beta (8-35 Hz) and beta band (13-30 Hz) power was calculated using previously published methods. Results: There was no difference in resting alpha/beta power during standing lying and sitting postures (P=0.967, 8-35 Hz) for the 10 sides. There was significant attenuation of beta band power during HF DBS at 3V but not at 1V (P=0.0002 at 3V, P= 0.116 at 1V, 13-30 Hz) in 6/10 sides where recording quality was acceptable. Electrical artifact limited the ability to discern neural signals during DBS in two sides and was worse at higher voltages. One subject was removed from unilateral stimulation analysis due to unconfirmed lead labelling. Conclusions: This is the first report to demonstrate concurrent and synchronized STN neural recordings and kinematic data in freely moving PDs from the implanted Activa® PC+S neurostimulator system in different resting postures and during HF DBS. We show that the LFP spectral profile is conserved during lying, sitting, and standing postures, and appears to be a robust property of the resting state in PD. We confirm our previous finding that beta band power is attenuated during HF DBS in a voltage dependent manner. Additionally, we will present details of the limitations encountered in our early experience with the Activa® PC+S neurostimulator system.

Abstract: We have developed an affordable device for the measurement of movement of easy access that can be used in clinical practice in the diagnosis, follow-up, and evaluation of Parkinson's patients. We are using this device in a pilot study with Parkinson's patients in the Hospital of Barrios Unidos in Bogota Colombia, which is part of the health network of hospitals of UROSARIO. Experimental Design. Our device consists of the accelerometer/gyroscope chip MPU-6050 mounted on a card with a serial I2C reading protocol. An ARDUINO UNO microcontroller with an ATMEL 380 chip for data acquisition and control and a Xbee Pro Series 2B for inalambric transmission. We use open source processing and python programs for signal conditioning and processing. Pilot Study. In all the patients with Parkinson's disease as well as the controls evaluated in this study we apply the miniBESTest (Balance Evaluation System Test) developed by Oregon Health Science University (www.bestest.us) to evaluate balance taking into account biomechanics, stability limits, postural responses, anticipatory postural adjustments, sensorial orientation and dynamic balance during walking. Balance and postural protocols. We use sit-stand-sit transitions, standing on a force-platform with eyes open and closed. We use an elastic belt located between L3-L5 where our device is placed. We also use a gripping protocol to assess isometric grip force, load force, acceleration in three dimensions, and grip tremor amplitude . In this case, we place the device in the wrists of the subjects. For the sit-stand-sit

transitions we are measuring time to peak, antero-posterior acceleration, amplitude, tilt and jerk. For the standing position we correlate the force measurement with mean velocity, F95% and jerk as an indication of the smoothness of postural changes. With these techniques we wish to contribute to the establishment of protocols of evaluation of kinetic and kinematic variables of movement in Parkinson's disease using affordable devices in processes of rehabilitation. .

Abstract: In Parkinson's disease (PD), the substantia nigra undergoes a loss of dopaminergic cells and cell function that, in part, manifests into the outward symptoms of PD. We have an ongoing clinical trial with the primary endpoint to examine the safety and feasibility of implanting an autologous peripheral nerve graft into the substantia nigra of PD patients undergoing deep brain stimulation (DBS) surgery. Schwann cells from the peripheral nervous system may serve as potential sources of neurotrophic factors including GDNF, NGF, BDNF, and NT-3, and peripheral nerve grafts to the CNS may provide an opportunity to directly deliver neurotrophic factors in areas affected by neurodegenerative diseases. Multi-stage, DBS surgery targeting the subthalamic nucleus was performed using standard procedures. After the DBS leads were implanted, a section of sural nerve (approximately 5mm in length) containing Schwann

cells was excised and unilaterally delivered, using a custom-designed cannula, into the area of the substantia nigra. Adverse events were continuously monitored. Our secondary aim was to measure changes in motor function through assessment of on a Unified Parkinson's Disease Rating Scale (UPDRS) evaluation before surgery and at 1, 3, 6, 9, and 12 months after surgery. We have successfully completed peripheral-nerve-graft surgery in 6 of 6 participants. Immediate, post-operative magnetic resonance scans have not indicated evidence of abnormal tissue disruption. Participants who completed nine months in the study reported comparable adverse effects to standard DBS surgery. In addition, UPDRS Part III scores off medication/off stimulation decreased after nine months (36 ± 8 baseline vs. 25 ± 13, mean ± SD; N=4). Meanwhile, scores on medication and on stimulation improved by 8 points (16 ± 11 baseline vs. 8 ± 6, nine months), and daily levodopa equivalents decreased from a mean of 844 ± 691 mg at baseline to zero after nine months. We have begun proteomic studies to examine expressions of neurotrophic-factor proteins in the peripheral nerve grafts. During the initial months of the study, we have observed a limited number of adverse events along with some improvements on UPDRS evaluations but on-going assessments will help gauge the safety and feasibility of implanting peripheral nerve tissue in conjunction with DBS surgery and the potential benefits these grafts may provide.

Title: Microelectrode recordings of the globus pallidus under sevoflurane anesthesia in Parkinson's disease patients

Authors: *J. E. QUINTERO[1], G. A. GERHARDT[1,2], C. G. VAN HORNE[1,2]
[1]Anat. & Neurobio., Univ. Kentucky, Lexington, KY; [2]Neurosurg., Univ. of Kentucky, Lexington, KY

Abstract: Recent reports have provided justification for using the internal globus pallidus (GPi) over the subthalamic nucleus (STN) as a target for implanting DBS leads. A consistent challenge for Parkinson's disease patients in DBS surgery is the awake portion of the surgery. An alternative would be to implant DBS leads in patients who are asleep. One concern for these types of surgeries is the ability to physiologically delineate the structures of the GPi and external globus pallidus (GPe) before securing the DBS lead. Our goal was to assess and characterize the electrophysiology of the GPe/GPi with microelectrode recordings and micro and macro stimulation during implantation in patients undergoing DBS surgery while under general anesthesia. We performed a retrospective study and comparison of dystonic and Parkinson's disease patients who underwent bilateral pallidal DBS placement with MER. Single-pass MER performed with tungsten-tipped microelectrodes to map GPe and GPi. MER recordings were performed on subjects who were either awake or under general anesthesia. We employed electrical micro and macro stimulations to obtain adverse effect profiles. We observed neuronal firing patters in the GPe/GPi of patients who were awake and under general anesthesia. Activation of the internal capsule was monitored with micro and macro stimulation. The identified firing patterns corresponded with palladial structures and borders, and the MER and stimulation results were used intraoperatively in deciding DBS lead placements. MER recordings of GPe/GPi along with micro/macro stimulation in asleep patients can help facilitate intraoperative DBS lead placement. Future studies will have to determine if palladial DBS lead placement, in patients under general anesthesia, can provide an effective means of avoiding the awake experience of DBS lead placement.

Abstract: Preclinical animal models are essential for successful development of safe and effective commercialized CNS therapies. Objective data from animal models establish proof of concept evidence and provide critical inputs to the design of later phase clinical studies. In medical device development, a large animal with an intact nervous system is preferred because it permits use of human-scaled devices and controlled testing that cannot be replicated with computer modeling or bench-testing. Therefore, we established an in-house sheep platform for early-phase testing of deep brain stimulation (DBS) therapy concepts and devices within the movement disorders space. In twelve animals commercial DBS leads with four active contacts were targeted to the subthalamic nucleus (STN), a common stimulation target in Parkinson disease. Overall, DBS lead implantation was not associated with remarkable neurological or histopathological complications. Assessments of targeting using standard comparisons of pre and post-operative brain images indicated that accuracy was comparable to clinical experience. Methods were developed to quantitatively assess motor behavior of chronically-implanted animals in the awake state. In open and blinded settings, we consistently found that motor behavior responses to STN stimulation significantly depended on the stimulation contact selected and parameters tested, including voltage, pulse width and frequency. Quantitative electromyographic assessments confirmed the motor behavior findings. This work establishes in-house capabilities for controlled testing of emerging DBS therapy concepts and device prototypes. Further work is ongoing to test prototype devices and develop additional objective physiological monitoring methods and biomarkers.

Title: Modelling α-synuclein aggregation in a cell system

Authors: *E. COLLA, V. LIVERANI, A. CATTANEO
Lab. of Neurobio., Scuola Normale Superiore, Pisa, Italy

Abstract: A better understanding of the cellular mechanisms involving the formation of α-synuclein (αS) aggregates, a pathological hallmark of α-synucleinopathies, is necessary to elucidate the underlying pathogenesis and develop effective therapeutic strategies. While animal models partially recapitulate the formation of αS fibrils in neurons as seen in humans, it has been very difficult to obtain reliable and reproducible data using cell models. Cell models would be more amenable for detailed mechanistic studies. Because of recent evidence that linked association of αS aggregates with the endoplasmic reticulum (ER)/microsomes vesicles to neurodegeneration in Prp A53T αS transgenic mice, we investigated if targeted expression of αS in the ER could lead to accumulation of ER-associated αS oligomers/aggregates in a cell culture system. Human wild-type or mutated (A53T or A30P) αS was cloned in the ER expression vector pCMV *myc*/ER in frame with an ER localization and retention signal. A Myc tag at the C-terminal of αS was also included. Transfection of SH-SY5Y neuroblastoma cell line with ER-targeted forms of αS led to expression of αS in the ER as shown by confocal colocalization with the ER marker grp94. While most of the transfected cells showed a dot-like staining typical of αS, a small percentage of cells also accumulated compact structures with a round shape, resembling aggregated species of αS and positive for antibodies against αS and Myc. αS staining was particularly intense at the periphery of the ring with a more opaque core at the center. These species colocalized with the ER and were seen in cell bodies as well as in processes. No major differences were seen by immunofluorescence, between the expression of wild-type and mutated forms of αS. At the same time, transfection with wild-type or mutated αS lacking the ER retention signal that leads to secretion of the protein failed to produce any αS staining or inclusions. Because of transient transfection did not provide a homogenous population of cells expressing αS in the ER and consequently forming ER-associated αS aggregates, we are now

developing inducible and stable cell lines expressing human wild-type, A53T and A30P mutated αS in the ER. We expect to be able to obtain several lines for each αS isoform with a different gradient of accumulation of αS aggregates. We plan to use this model to study cellular pathways affected by αS aggregation and to identify strategies to modify fibrils accumulation.

Title: Extracellular ATP induces intracellular alpha-synuclein accumulation via P2X1 receptor-mediated lysosomal dysfunction

Authors: *M. GAN[1], S. MOUSSAUD[1], P. JIANG[1], P. J. MCLEAN[1,2]
[1]Dept of Neurosci., Mayo Clin. Florida, Jacksonville, FL; [2]Mayo Grad. Sch., Mayo Col. of Med., Rochester, MN

Abstract: The pathological hallmark of Parkinson's disease (PD) is the accumulation of alpha-synuclein (αsyn) in susceptible neurons in the form of Lewy bodies and Lewy neurites. However, the etiology of PD remains unclear. Because brain injury has been suggested to facilitate αsyn aggregation, we investigated whether cellular breakdown products from damaged cells can act on neighboring healthy cells and cause intracellular αsyn accumulation/aggregation. Using two neuronal cell models we found that extracellular ATP-induced a 2-fold increase in intracellular αsyn levels between 24 to 48 hours after treatment. Further investigation revealed that the observed αsyn accumulation is a result of lysosome dysfunction caused by extracellular ATP-induced elevation of lysosomal pH. Interestingly, P2X1 receptor, a subtype of ATP-selective receptors that function as Ca^{2+} permeable, ligand-gated ion channels appear to mediate the cells' response to extracellular ATP. However, although Ca^{2+} influx via P2X1 receptors is necessary for αsyn accumulation, Ca^{2+} influx per se is not sufficient for increased αsyn accumulation. These findings provide new insight into our knowledge of the role of P2X receptors in PD pathogenesis and may be helpful in identifying new therapeutic targets for PD.

Title: The saturated free fatty acid palmitate increases alpha-synuclein expression levels-relevance to synucleinopathies

Authors: ***O. GHRIBI**[1], J. SCHOMMER[2], S. RAZA[2]
[1]Pharmacol, Physiol & Therapeut., UND Med. Sch., Grand Forks, ND; [2]Sch. of Med., Univ. of North Dakota, Grand Forks, ND

Abstract: Accumulation of the A-synuclein protein in Lewy body inclusions is a hallmark of a group of disorders collectively known as the synucleinopathies. These disorders include idiopathic Parkinson's disease, dementia with Lewy bodies, and multiple system atrophy. Lewy bodies-containing a-synuclein are also frequently found in Lewy body variants of Alzheimer's disease. Despite extensive research, no disease-modifying therapy is currently available for synucleinopathies and the search for diagnostic tests and biomarkers are still under development. The search for disease-modifying therapies or diagnostic markers would benefit from identification of factors that promote over-production of A-synuclein protein or from elucidation of cellular mechanisms that regulate the transcription of A-synuclein. Identification of such factors and underlying cellular mechanisms may help in understanding the pathogenesis of synucleinopathies and designing therapeutic agents that can prevent, reverse, or stop the over-production of a-synuclein and ultimately protect against synucleinopathies. In this study, we determined the effect of a diet rich in the saturated free fatty acid (sFFA) palmitate on a-synuclein *in vitro* and *in vivo*. We found that incubation of human neuroblastoma SH-SY5Y cells with palmitate increased expression levels of a-synuclein. We also fed wild type mice with a diet rich in palmitate for 3 months and found that this diet increases the expression levels of a-synuclein in hippocampus, cortex and substantia nigra. The etiology of synucleinopathies is not well defined but it is likely that the interplay between environmental (chemical and dietary) factors and genetic susceptibilities plays a key role in the pathogenesis of this disease. Our data

suggest that intake of diets with a high content of palmitate increase A-synuclein production and may promote synucleinopathies.

Title: The role of dopamine in generating toxic oligomeric conformers of alpha-synuclein

Authors: *D. E. MOR[1], E. TSIKA[2], J. R. MAZZULLI[3], J. H. WOLFE[1], H. ISCHIROPOULOS[1]
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland; [3]Northwestern Univ., Chicago, IL

Abstract: Parkinson's disease (PD) is defined by marked loss of dopamine (DA) producing neurons in the substantia nigra (SN) and an abundance of Lewy body inclusions comprised of aggregated α-synuclein (α-syn) protein. The role of α-syn in neurodegeneration remains a major research area. Growing evidence suggests oligomeric intermediates that form during aggregation of α-syn are neurotoxic. Kinetic stabilization of α-syn oligomers through a non-covalent interaction with oxidized DA may contribute to neurotoxicity. However, it remains unknown if DA interacts with α-syn oligomers *in vivo*, and if DA-stabilized species induce cellular injury. To investigate the role of DA in promoting α-syn toxicity, we are using an established mouse model of α-synucleinopathy expressing human α-syn with the A53T familial PD mutation. In this model, α-syn oligomers are formed in the SN without associated cell loss. Using a novel lentiviral approach to increase DA production in the SN of A53T mice, we are testing the effects on α-syn oligomers and cell viability. The virus carries the gene for tyrosine hydroxylase (TH), the rate-limiting enzyme in DA synthesis, with mutations at residues R37E, R38E (TH-RREE) such that feedback inhibition by DA is greatly reduced. Preliminary data indicate that TH-RREE significantly increases TH expression and striatal catecholamine levels compared with an empty vector control. Intriguingly, there is also an increase in steady-state levels of α-syn oligomers, and a shift in oligomer size towards larger Stokes radius. Formation of large intracellular aggregates of α-syn was not observed, consistent with DA-mediated stabilization of oligomers.

Moreover, the number of SN neurons is significantly reduced. Together, these data implicate DA and α-syn in a pathogenic mechanism that may underlie the selective loss of DA cells in PD.

Title: The interplay between atp13a2 and alpha-synuclein: mitochondria dysfunction via endoplasmic reticulum stress

Authors: *T. LOPES DA FONSECA, T. OUTEIRO
Abteilung Neurodegeneration, UMG, Göttingen, Germany

Abstract: A common pathological hallmark among several neurodegenerative diseases, including Parkinson's disease (PD), is the aberrant protein-protein interactions that result in disruption of several essential cellular functions. Misfolding and aggregation of α-synuclein (a-syn) has been extensively studied, as this is considered a central process in PD pathology. However, the interplay between a-syn and other PD-related proteins is still unclear. ATP13A2, a lysosomal transmembrane P5 ATPase, has been recently described to be part of the a-syn-interacting network, as it was able to rescue a-syn related toxicity in a yeast model. The physiological role of this protein is uncertain, but it is thought to play a role in metal homeostasis regulation, autophagy and mitochondrial function. One ATP13A2 PD-causative mutation consists in the duplication of residues 1632-1653 leading to a frameshift that shortens the protein size (ATP13A2 dup22). Here, we investigated the interplay between a-syn and ATP13A2, *in vitro*. A wide range of cellular effects was observed in human cells co-overexpressing a-syn and wild-type (WT) or ATP13A dup22. Briefly, cells displayed altered ER morphology, ER stress, and mitochondrial fragmentation. Interestingly, analysis of mitochondria bioenergetics showed that ATP13A2 dup22 reduces mitochondrial spare capacity and promotes the production of reactive oxygen species. Furthermore, in a cell-based a-syn aggregation paradigm, ATP13A2 dup22 significantly increased a-syn aggregation and promoted cytotoxicity. In total, our studies

identified a novel interplay between a-syn and ATP13A2, providing novel insights into the molecular basis of PD.

Title: Abnormal alpha-synuclein reduces nigral voltage-dependent anion channel 1 in sporadic and experimental Parkinson's disease

Authors: *Y. CHU, Y. HE, J. H. KORDOWER
Rush Univ. Med. Ctr., Chicago, IL

Abstract: Alpha-synuclein abnormality and mitochondrial dysfunction are considered as tow major contributors to Parkinson's disease. Their relationships are still unclear. The present study investigated alterations of voltage-dependent anion channel 1 (VDAC1) within remaining nigral dopaminergic neurons in patients with sporadic Parkinson's disease and rats with experimental Parkinson's disease as compared with controls. VDAC1 is a major component of the outer mitochondrial membrane known to regulate mitochondrial functions. Co-localization analyses revealed that VDAC1 immunoreactivity was severely reduced in the neuromelanin (NM)-laden neurons with alpha-synuclein inclusions in PD. Although there was cytoplasmic non-aggregative alpha-synuclein in age-matched controls, VDAC1 immunoreactivity in the alpha-synuclein positive nigral neurons was similar to the alpha-synuclein negative neurons. The VDAC1 existed in the fibers with fine granules alpha-synuclein but not in the fiber with accumulative and aggregative alpha-synuclein. Quantitative analyses revealed that the relative levels of VDAC1 were significantly decreased in PD nigral neurons when compared to age-matched controls. In PD, this decrease was significantly greater in nigral neurons with alpha-synuclein inclusions. In contrast, levels of MTC02, another general mitochondrial marker, was unchanged in neurons with alpha-synuclein aggregations that was similar to neurons without alpha-synuclein aggregations. Viral vector-mediated overexpression of mutant human alpha-synuclein (A30P) in rats resulted in significantly decreased VDAC1 in nigral neurons and striatal fibers. These results indicate that mitochondrial function associated with VDAC1 is decreased in sporadic and

experimental PD, and this decrease is associated with alpha-synuclein accumulation and aggregation.

Abstract: Human embryonic stem cells (HUES) and induced pluripotent stem cells (hiPS) are characterized by their ability to self-renew and their potential to differentiate into specialized cell types. The ability to generate large numbers of early precursors and stage-specific differentiated cells renders them a valuable source for studies in developmental biology, applications in regenerative medicine or for modeling human diseases. In particular, hiPS provide an unprecedented opportunity to study otherwise inaccessible human neurons and their precursors while the generation of patient-specific hiPS can significantly contribute in our understanding of the molecular mechanisms underlying neurodegenerative diseases. We have generated midbrain dopamine neurons by directed differentiation of hiPS derived from fibroblasts of healthy individuals and Parkinsonian patients harbouring an autosomal dominant and highly penetrant A53T mutation in alpha-synuclein (A53T-αSyn). To identify novel differentiation-related critical genes and regulatory networks as well as to discover A53T-dysregulated pathways, we have

launched whole transcriptome analysis of hiPS-derived cells by new generation sequencing of coding and non-coding RNAs (long non-coding RNAs and miRNAs) at specific stages of differentiation (iPS, neural precursors and neurons). We have complemented this analysis using HUES and HUES-derived differentiated cells. Total RNA was extracted and next generation sequencing was performed on polyA-selected transcripts (50nt, paired-end sequencing) and small-RNAs (50nt, signle-end sequencing) on Illumina HiSeq sequencer. More than 1.5 billion reads were generated. Small-RNA-Seq reads were aligned against mature miRNAs, precursors and relevant genomic loci whilst RNA-Seq reads were aligned against the genome using a spliced aligner. Both miRNA and mRNA differential expression analysis was performed using DESEQ and Pathways controlled by significantly differentially expressed miRNAs were identified using DIANA-miRPAth v2.0. Using integrated mRNA-miRNA functional analyses we aim to identify major regulatory networks during differentiation of human neurons and A53T-dysregulated pathways.

Abstract: Alpha-synuclein (aSyn), a common player in both sporadic and familiar forms of Parkinson's Disease (PD), was first described as a pre-synaptic and nuclear protein. While the role of aSyn in the pre-synaptic compartment has been widely studied, both the nuclear localization and the role of the protein in the nucleus are still unclear. Recent efforts revealed that nuclear aSyn binds histones and modulates their acetylation, suggesting a putative effect of aSyn on transcription. Here, we investigated both transcriptional changes in rapid and slow progressive PD patients and the role of aSyn in the nucleus. We analyzed the gene expression profiles of a large cohort of two clinically-distinguishable groups of PD patients, based on the rate of disease progression. By analyzing the transcriptional profiles in blood samples from those patients, we identified a subset of >200 differentially expressed genes whose function is linked to DNA repair, purine/pyrimidine biosynthesis, transcription regulation, ubiquitin-proteasome system and membrane trafficking. Selected genes were further validated by real-time PCR, in a subset of patients' blood cells. Importantly, some of the selected genes were also found to be significantly deregulated in differentiated Lund Human Mesencephalic cells that were either treated with MPP+, or over expressed aSyn. To investigate the presence of aSyn in the nucleus we used cell culture models, and transgenic mice expressing either wild type or A30P mutant aSyn. Our results demonstrated that aSyn is present in nuclear fractions of embryonic stage (E14) and in the midbrain region of adult A30P mice, as well as in human neuroblastoma cells. We also found that oxidative stress promoted the translocation of A30P and E46K aSyn mutants from the cytoplasm into the nucleus of cells 24h after H2O2 treatment. Next, to identify nuclear factors that interact with aSyn, we studied aSyn-DNA interactions by performing NMR experiments, genome-wide chromatin immunoprecipitation (ChIP)-sequencing and dual-luciferase assays. Our preliminary NMR results indicate that aSyn interacted with both DNA fragments and mononucleosomes. ChIP-sequencing experiments showed that aSyn can bind to the promoter regions of several genes, including NEDD4, CDC42 and SLC4A5. Furthermore, dual-luciferase assays confirmed that asyn overexpression increased SLC4A5 promoter activity. Altogether, our results suggest that transcriptional deregulation and nuclear aSyn might be important players in the pathophysiology of PD, and identify a panel of fingerprint genes that may serve as biomarkers in the prognosis of PD progression.

Title: Nutrient deprivation induces alpha-synuclein aggregation through ER stress response and SREBP2 pathway

Authors: *P. JIANG, M. GAN, W.-L. LIN, S.-H. YEN
Neurosci., Mayo Clin. Col. of Med., JACKSONVILLE, FL

Abstract: Abnormal accumulation of filamentous α-synuclein (α-syn) in neurons, regarded as Lewy bodies (LBs), are a hallmark of Parkinson disease (PD). Although the exact mechanism(s) underlying LBs formation remains unknown, autophagy and ER stress response have emerged as two important pathways affecting α-syn aggregation. In present study we tested whether cells with the tetracycline-off inducible overexpression of α-syn and accumulating α-syn aggregates can benefit from autophagy activation elicited by limited nutrient deprivation, since this approach was reported to effectively clear cellular polyglutamine aggregates. We found that limited nutrient deprivation of non-induced cells did not affect cell viability, but significantly activated autophagy reflected by increasing the level of autophagy marker LC3-II and autophagic flux and decrease of endogenous α-syn. Cells with induced α-syn expression alone displayed autophagy activation in an α-syn dose-dependent manner to reach a level comparable to that found in non-induced, nutrient deprived counterparts. Nutrient deprivation also activated autophagy further in α-syn induced cells, but the extent was decreased with increase of α-syn induction duration, indicating α-syn overexpression reduces the responsiveness of cells to nutrient deprivation. Moreover, the nutrient deprivation enhanced accumulation of α-syn aggregations concomitant with significant increase of apoptosis as well as ER stress response, SREBP2 activation and cholesterolgenesis. Importantly, the α-syn aggregate accumulation and other effects caused by nutrient deprivation were counteracted by knockdown of SREBP2, treatment with cholesterol lowering agent_lovastatin, or by GRP78 overexpression, which also caused decrease of SREBP2 activity. Similar results were obtained from studies of primary neuronal cultures with α-syn overexpression under nutrient deprivation. Together our findings suggested that down-regulation of SREBP2 activity might be a mean to prevent α-syn aggregates accumulation in PD via reducing cholesterol levels.

Title: α-Synuclein disrupts iron import in a yeast model of Parkinson's disease

Authors: *S. N. WITT[1], D. PATEL[2]
[1]LSU Hlth. Sci. Ctr. / Biochem., Shreveport, LA; [2]Biochem. & Mol. Biol., LSU Hlth. Sci. Ctr., Shreveport, LA

Abstract: We have been using a yeast model of PD to investigate the role of α-synuclein (α-syn) in controlling the intracellular trafficking of two proteins involved in iron uptake. Fet3-Ftr1 complexes, which reside in the plasma membrane, regulate high affinity iron uptake in yeast cells. Fet3 is homologous to ceruloplasmin and hephaestin, which are two human proteins involved in iron transport. A glycosylphosphatidylinositol-anchored form of ceruloplasmin is expressed in neurons. Under high iron conditions, Fet3-Ftr1 complexes are targeted to the vacuole/lysosome for degradation. In contrast, under low iron conditions, the Fet3-Ftr1 complexes shuttle back and forth between the plasma membrane and endocytic recycling vesicles. First, we determined that α-syn is extremely toxic to non-dividing stationary-phase yeast cells. The median lifetime of wild-type cells without α-syn is 13.5 ± 5 d and 4.0 ± 1 d with α-syn. In fet3Δ and ftr1Δ deletion strains, which should contain less iron than wild-type cells, the median lifetime is 7.0 ± 1.5 d, and this value does not change with α-syn expression. Second, we performed a colorimetric-based iron assay to determine the cellular iron content. We found that wild-type cells expressing α-syn have approximately 30% less iron than the same cells without α-syn expression; whereas, fet3Δ and ftr1Δ cells have approximately 20% less iron than identically treated wild-type cells. The combined results suggest that α-syn decreases the level of iron in wild-type cells, and the decrease in intracellular iron is responsible in part for the accelerated aging. Fet3 and Ftr1 form binary complexes in the endoplasmic reticulum. Under conditions of low iron, Fet3-Ftr1 complexes partition between the plasma membrane and recycling endocytic vesicles. α-Syn binds to vesicles, and at sufficient concentrations it can disrupt endocytosis. To determine whether α-syn disrupts the endocytic recycling of Fet3-Ftr1 complexes, we used strains with integrated copies of Fet3-GFP or Ftr1-GFP. Under low iron conditions, α-syn significantly decreases the number of Ftr1-GFP molecules on the plasma membrane compared to cells without α-syn. This result is consistent with α-syn disrupting

endocytic recycling of iron transporters, which causes a suboptimal number of Fet3-Ftr1 complexes to reach the plasma membrane. α-Syn thus decreases the amount of intracellular iron. We propose that the combination of decreased intracellular iron and stalled vesicles containing Fet3-Ftr1 complexes trigger cell death. Experiments are planned to test whether α-syn modulates the intracellular trafficking of iron transporters in neurons.

Title: DHA induced the dysfunction of cellular proteolysis system and the formation of α-synuclein aggregates in SH-SY5Y cells

Authors: *M. SHAMOTO-NAGAI[1], M. NAOI[2], T. OSAWA[2], N. MOTOYAMA[1], M. MINAMIYAMA[1], W. MARUYAMA[1]

Abstract: Intra-neuronal Lewy body (LB) is the pathological hallmark of Lewy body disease, Parkinson disease (PD), Lewy body dementia (DLB), and pure autonomic failure (PAF). Alpha-Synuclein (αS) is the major component of LB and under physiological conditions plays an important role in maintaining function of synapic vesicle and mitochondria, dopamine production and regulation of cellular redox state. Studies in familial and sporadic PD indicate that accumulation of αS with abnormal conformation is the causative factor. Dysfunction of proteolysis system, including ubiquitin proteasome system (UPS) and autophagy, is closely associated with the accumulation of abnormal proteins. Docosahexaenoic acid (22:6n-3, DHA) is one of the most common long chain polyunsaturated fatty acids (PUFA) and is highly enriched in the membrane of brain and retina. DHA is a potent antioxidant, but it is easily oxidized to produce lipid peroxides. In our previous study, we established human SH-SY5Y cells over-expressing αS (Syn-SH cells). After treatment of Syn-SH cells with DHA, cell death was caused

by mitochondrial dysfunction accompanied with accumulation of αS modified with DHA-derived lipid peroxides. In this paper, we analyzed the mechanism of oxidatively modified αS in concern to proteolysis system. Syn-SH cells were transfected with proteasome sensor vector (Syn-PSV-SH cells) to measure *in situ* proteasome activity. After incubated with 20 μM DHA for 3 days, the accumulation of the fluorescent protein was observed in Syn-PSV-SH cells, indicating the decreased proteasome activity *in situ*. The proteasome enzyme activity was measured using the cytosol fraction and synthetic peptide (Suc-Leu-Leu-Val-Tyr-MCA) as a fluorescent substrate, but the *in vitro* activity was not changed. Western blot analysis showed increased ubiquitinated proteins in Syn-SH cells treated with DHA for 1 day. These results indicated that DHA treatment impaired UPS in Syn-SH cells, but it was not due to the direct inhibition of the proteasome enzyme activity. Next, we examined the autophagy and lysosomal function in Syn-SH cells treated with DHA by fluorescence imaging using each specific fluorescent probes against autophagosome and lysosome. After DHA addition, it was detected that autophagosome increased continuously, even not markedly, and the lysosomal formation was inhibited in Syn-SH cells. These results suggest that DHA reduced the proteasome activity and inhibited the formation of mature autophagosome. The dysfunction of the proteolysis system is suggested to be involved in the accumulation of abnormal αS and cell death by DHA.

Title: Differential expression of alpha-synuclein *in vitro* and *in vivo*

Authors: ***K. TAGUCHI**, Y. WATANABE, A. TSUJIMURA, M. TANAKA
Kyoto Prefectural Univ. of Med., Kyoto, Japan

Abstract: α-Synuclein is the major pathological component of synucleinopathies including Parkinson's disease (PD) and dementia with Lewy bodies (DLB). Recent studies have demonstrated that α-synuclein also plays important roles in the release of synaptic vesicles and synaptic membrane recycling in healthy neurons. However, the precise relationship between the pathogenicity and physiological functions of α-synuclein remains to be elucidated. To address this issue, we investigated the subcellular localization of α-synuclein in normal and pathological conditions using primary mouse hippocampal neuronal cultures. While some neurons expressed high levels of α-synuclein in presynaptic boutons and cell bodies, other neurons either did not or only very weakly expressed the protein. These α-synuclein-negative cells were identified as inhibitory neurons by immunostaining with specific antibodies against glutamic acid decarboxylase (GAD), parvalbumin, and somatostatin. In contrast, α-synuclein-positive synapses were colocalized with the excitatory synapse marker vesicular glutamate transporter-1. This expression profile of α-synuclein was conserved in the hippocampus *in vivo*. In addition, we found that while presynaptic α-synuclein colocalizes with synapsin, a marker of presynaptic vesicles, it is not essential for activity-dependent membrane recycling induced by high potassium treatment. Exogenous supply of preformed fibrils generated by recombinant α-synuclein was shown to promote the formation of Lewy body (LB) -like intracellular aggregates involving endogenous α-synuclein. GAD-positive neurons did not form LB-like aggregates following treatment with preformed fibrils, however, exogenous expression of human α-synuclein allowed intracellular aggregate formation in these cells. Therefore, expression level of α-synuclein is one of the critical factors for the aggregate formation. Taken together, these results suggest the presence of a cell-type dependent mechanism for the regulation of the expression of α-synuclein. In other brain regions, the expression analysis is under progress. These findings will provide new insights for understanding the pathological conditions of neurodegenerative disorders including PD and DLB.

Title: NEDD4 regulation of the pro-apoptotic protein RTP801 in cellular models of Parkinson's disease

Authors: M. CANAL[1], J. ROMANÍ-AUMEDES[1], N. MARTÍN-FLORES[1], V. PÉREZ-FERNÁNDEZ[1], *C. MALAGELADA GRAU[2]
[1]Pathological Anatomy, Pharmacol. and Microbiology, [2]Univ. De Barcelona, Barcelona, Spain

Abstract: RTP801/REDD1 is elevated in cellular and animal models of Parkinson's disease (PD) and in affected neurons of PD patients. RTP801 over expression is sufficient to promote neuron death in cellular models of PD by a mechanism involving repression of mTOR kinase activity. RTP801 is a protein with a very short half-life (2-5 minutes), so its synthesis and degradation must be subject to a very fine-tuned regulation to precisely modulate mTOR pathway. Hence, elucidating which proteins mediate RTP801 degradation would be a stepping-stone to design new therapies to block neurodegeneration. NEDD4 (neural precursor cell-expressed, developmentally down-regulated 4) is one of the most abundant E3 ubiquitin ligases in mammalian neurons. It ubiquitinates proteins targeting them for proteasomal or endosomal/lysosomal degradation or for trafficking. In models of PD, NEDD4 is protective against alpha-synuclein toxicity. Here, we report that NEDD4 poly-ubiquitinated RTP801 in an *in vitro* cell free system. In cellular models NEDD4 and RTP801 interacted physically to each other. Furthermore, also in cellular models, both PD toxin 6-OHDA and the hypoxia inducer CoCl2 decreased levels of NEDD4, along with an increase in RTP801 protein. Interestingly, ectopic expression of NEDD4 protected from 6-OHDA-induced cell death and against ectopic RTP801-induced cell death, whereas the inactive mutant NEDD4-C867S abrogated this protective effect. To sum up, these findings show that NEDD4 is sensitive to oxidative stress associated to PD and that ectopic NEDD4 is protective by enhancing RTP801 degradation. This suggests that NEDD4 loss of function in PD could participate into neuronal death by elevating RTP801.

Title: Inhibition of the deubiquitinase UCH-L1 leads to autophagy activation and the clearance of alpha-synuclein aggregates in oligodendroglial cells

Authors: *K. PUKAß, C. RICHTER-LANDSBERG
Univ. of Oldenburg, Oldenburg, Germany

Abstract: UCH-L1 is an abundant protein in the brain. It is a member of the deubiquitinating enzyme (DUB) subfamily of ubiquitin carboxy-terminal hydrolases (UCHs). UCH-L1 is primarily expressed in neurons where it is required for maintaining the structure and function of synapses. As a monomer it has hydrolase activity for K48-linked ubiquitin chains and as a dimer it has ligase activity for K63 residues of the ubiquitin molecule. UCH-L1 transfers ubiquitin to alpha-synuclein (a-syn), a soluble, natively unfolded protein, which, as we have shown before, is expressed in oligodendrocytes (ODCs). A-syn and UCH-L1 colocalize in the presynaptic terminal. UCH-L1 is involved in the ubiquitination of tubulin and overexpression inhibits microtubule formation. Furthermore, UCH-L1 is detectable in Lewy bodies in Parkinson's disease, where it colocalizes with a-syn. The present study was undertaken to investigate whether UCH-L1 is present in cultured rat brain oligodendrocytes, the myelin forming cells of the CNS. RT-PCR, immunoblot analysis, and indirect immunofluorescence demonstrate that UCH-L1 is expressed in ODCs, increases during culture maturation, and is distributed throughout the cytoplasm and the cell processes. To test whether UCH-L1 is involved in protein aggregate formation, OLN-a-syn-GFP-LC3 cells, an oligodendroglial cell line stably expressing a-syn and GFP-LC3 was used. GFP-LC3 serves as a marker for the autophagic flux. Cells were incubated with the UCH-L1 specific inhibitor LDN-57444 (LDN). Indirect immunofluorescence demonstrates that small a-syn aggregates, which are observable in control cells, are removed by LDN treatment, while GFP-positive autophagic vesicles are increasingly formed. Western blot analysis shows an increase in free GFP and LC3 II, indicating activation of autophagy. Furthermore we tested whether UCH-L1 is a constituent of glial cytoplasmic inclusions (GCIs) in brains of patients with multiple system atrophy (MSA), which represents a neurodegenerative disease classified as a synucleinopathy with ODC pathology. Immunohistochemistry demonstrates that UCH-L1 is present in GCIs and colocalizes with a-syn. To summarize, UCH-

L1 is expressed in ODCs and its inhibition leads to activation of autophagy and the clearance of a-syn aggregates. Its presence in GCIs in MSA brains, which besides a-syn have been described to contain also cytoskeletal proteins and ubiquitin, indicates that it is involved in abnormal ubiquitination and MT formation during pathogenesis.

Title: Lysosomal abnormalities in Parkinson's disease brains

Authors: *M. CHENG[1], S. P. SARDI[2], A. CUERVO[3], D. SULZER[1], S.-H. KUO[1]
[1]Columbia Univ. Med. Ctr., New York, NY; [2]Genzyme, Boston, MA; [3]Albert Einstein Col. of Med., Bronx, NY

Abstract: Mutations in glucocerebrosidase (GBA) not only lead to Gaucher's disease (GD), known as the most common lysosomal storage disorder, but also increase the risk of Parkinson's disease (PD). We analyzed PD patient brains and found that GBA activity is gently reduced in PD/dementia with Lewy bodies (DLB) without GBA mutation cases, while GBA activity is significantly decreased in PD/DLB with severe or mild GBA mutation cases, accompanied by the accumulation of glucosylceramide (GluCer), a substrate of GBA, showing gain of toxicity. In addition, levels of lysosomal proteins LAMP1 and LAMP2A appear to be up-regulated in PD brains with heterozygous GBA mutations, suggesting general lysosomal dysfunction. Furthermore, another PD related protein - alpha-synuclein monomers and dimers are elevated in PD-GBA cases. In summary, our findings demonstrate a strong correlation between GBA mutations and lysosomal abnormalities, and provide insights into disease pathogenesis and potential therapeutic strategies for GD and PD.

Title: Decrease in UCH-L1 protein in the substantia nigra of neurotoxicant-treated mice is associated with reduced numbers of TH-IR neurons expressing UCH-L1

Authors: *B. M. WINNER[1,2], R. E. WELCH[1], Z. A. DERADE[1], K. J. LOOKINGLAND[1,2,3], J. L. GOUDREAU[1,2,3,4]
[1]Pharmacol. and Toxicology, [2]Ctr. for Integrative Toxicology, [3]Col. of Osteo. Med., [4]Neurol., Michigan State Univ., East Lansing, MI

Abstract: A significant proportion of the genes implicated in Parkinson disease (PD) are associated with protein degradation pathways. Ubiquitin carboxy-terminal hydrolase L1 (UCH-L1) is one such neuron-specific protein that has traditionally been described as a de-ubiquitinating (DUB) enzyme. UCH-L1 functions to replenish the pool of ubiquitin monomers to be tagged onto defective proteins. The DUB function of UCH-L1 is important for the ability of neurons to degrade misfolded proteins and deficits in misfolded protein processing is a key feature of PD molecular pathogenesis. Following neurotoxicant exposure, differential expression of UCH-L1 has been observed in brain regions containing dopamine (DA) neurons known to be susceptible in PD, nigrostriatal DA (NSDA) neurons and regions known to be resistant in PD, tuberoinfundibular DA (TIDA) neurons. UCH-L1 protein is increased in mice 24 h after an acute 20 mg/kg dose of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) in regions containing TIDA neurons, but not in regions containing NSDA neurons. UCH-L1 protein is decreased in brain regions containing NSDA neurons, suggesting decreased UCH-L1 expression could mechanistically linked with the susceptibility of these DA neuronal populations. That said, it is unclear if UCH-L1 protein levels change specifically within DA neurons with MPTP treatment. We sought to determine if these neurotoxicant-induced changes in UCH-L1 protein occur specifically within DA neurons in the MBH and ventral midbrain. To this end, transgenic mice expressing green fluorescent protein (GFP) driven by a tyrosine hydroxylase (TH) promoter were treated with saline (10 ml/kg) or MPTP (20 mg/kg, s.c.). Mice were anesthetized and perfusion fixed 24 h following treatment. 20 µm frontal brain sections were taken (100 µm intervals) and immunohistochemically stained for UCH-L1 using a Cy3-labelled secondary antibody. ImageJ software was used to count neurons containing Cy3, GFP or both fluorophores in a semi-

automated manner based on particle size and colour/intensity thresholds. The number of TH-GFP expressing neurons in the substantia nigra was unaltered 24 h following MPTP treatment. Decreased numbers of TH-GFP containing neurons immunoreactive for UCH-L1 were observed in the substantia nigra in MPTP-treated mice. Since the overall number of DA neurons appears unchanged in the NSDA neurons 24 h following MPTP exposure, the observed decrease in UCH-L1 immunoreactive TH-GFP neurons suggests that either UCH-L1 expression is decreased or that the turnover of UCH-L1 is increased in the DA neuronal population that is susceptible to neurotoxicant-induced injury and degenerate in PD.

Title: Gene expression profiling to identify Parkinson’s Disease associated transcripts

Authors: *L. LIN[1,2], L. W. STANTON[1,3,4]
[1]Genome Inst. of Singapore, Singapore, Singapore; [2]NUS Grad. Sch. for Integrative Sci. and Engin., [3]Dept. of Biol. Sci., Natl. Univ. of Singapore, Singapore, Singapore; [4]Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore

Abstract: Recent studies of Parkinson’s disease (PD) have taken advantage of patient-derived induced pluripotent stem cells (iPSCs) to recapitulate aspects of the disease *in vitro*. These studies have provided snapshots of the disease process in limited genetic backgrounds and have not interrogated transcriptome level changes associated with disease progression. In our study, multiple PD iPS cell lines carrying different genetic background were employed to identify common transcriptional alterations. In neural progenitors and midbrain dopaminergic neurons

(mDAs) derived from iPSCs, expression profiling studies were performed by microarray and RNA-seq. A number of transcripts were consistently differentially expressed among different PD cell lines, as compared with wild-type. RNA-seq results were further analyzed with a focus on the potential involvement of long non-coding RNAs (lncRNAs), which are functional transcripts known to be involved in neurogenesis and neurological disorders. Furthermore, electrophysiological tests and neurotoxicity assays also contribute to our understanding of disease phenotype *in vitro*, serving as a platform for functional study. Together, these data 1) further validate the iPSC model of PD; 2) uncover the abnormally regulated transcripts; 3) indicate an important role for lncRNAs in PD progression.

Title: Parkinson's disease linked park15 protein affects bmp signaling through proteasome independent nrage ubiquitination

Authors: *K. C. CHUNG[1], J. KANG[1], A. HONG[1], E. IM[1], Y. LEE[1], H. RHIM[2]
[1]Dept Systems Biol., Yonsei Univ., Seoul, Korea, Republic of; [2]2Center for Neuroscience, Brain Sci. Institute, Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Parkinson’s disease (PD) is characterized by progressive midbrain dopaminergic neuron degeneration and the formation of intracellular protein aggregates, referred to as Lewy

bodies. While defective ubiquitin-proteasome system, mitochondrial dysfunction, oxidative stress, and autophagy impairment have been suggested to play some roles in the PD pathogenesis, mutations in at least seven genes have also been individually linked to familial forms of PD. *F-box only protein 7* (*FBXO7;* also known as *PARK15*) gene mutations are closely associated with progression of the autosomal recessive form of familial PD. *FBXO7* encodes a component of Skp1, Cullin, F-box (SCF)-ubiquitin ligase complexes; however, its cellular targets, including substrates and regulators, are not yet clarified. To identify potential substrates of FBXO7, we performed a yeast two-hybrid screen of a human fetal brain library and identified neurotrophin receptor-interacting MAGE protein (NRAGE) as a novel FBXO7-binding partner. NRAGE is highly expressed during early corticogenesis, specifically in neural progenitors of ventricular zone and in differentiating neuroblasts of the cortex, concomitant with the spatial and temporal occurrence of bone morphogenetic protein (BMP)-mediated apoptosis. At the meeting, we will present the data demonstrating that FBXO7 affects BMP4-mediated signaling through proteasome- independent ubiquitination of NRAGE and augments the formation of downstream signaling components.

Title: Immunostaining of oxidized DJ-1 in human and mouse brain

Authors: *Y. SAITO[1], T. MIYASAKA[2], H. HATSUTA[3], K. TAKAHASHI-NIKI[4], H. ARIGA[4], S. MURAYAMA[3], Y. IHARA[2], N. NOGUCHI[1]

Abstract: DJ-1, the product of a causative gene of a familial form of Parkinson's disease (PD), undergoes preferential oxidation of cysteine residue at position 106 (Cys-106) under oxidative stress. Using specific antibodies against Cys-106-oxidized DJ-1, we examined oxidized DJ-1 immunoreactivity (oxDJ-1 IR) in wild type and DJ-1 knockout mouse brain sections as well as human brain sections from cases classified into different Lewy body (LB) stages of PD and PD with dementia. In mouse brain, the oxDJ-1 IR was particularly enriched in the olfactory bulb, cerebellum, cortex, and hippocampus (Fig. 1A). The oxDJ-1 IR was evident in the substantia nigra of the midbrain of mouse and human (Fig. 1A and 1B). In neuromelanin-containing neurons and nerve fibers of the substantia nigra of human brain section, oxDJ-1 IR was prominently observed, and the LBs also showed oxDJ-1 IR (Fig. 2). OxDJ-1 was detected in the astrocytes of the striatum. In addition, neurons and glias in the red nucleus of the midbrain and the inferior olivary nucleus of the medulla oblongata, which is related to the regulation of movement, showed clear oxDJ-1 IR. Our observations suggest the relevance of DJ-1 oxidation to the homeostasis in multiple sites of brain, including neuromelanin-containing neurons of the ubstantia nigra.

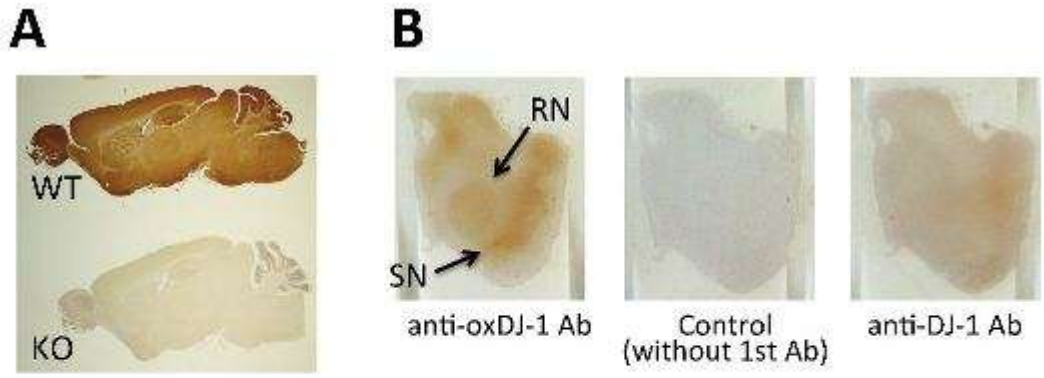

Fig. **1**
A: Sagittal sections from the WT and DJ-1 KO mice brains were stained with anti-oxDJ-1 mAbs.
B: The immunoreactivity of the anti-oxDJ-1 mAb was present throughout the midbrain of human, particularly high levels of oxDJ-1 were observed in the substantia nigra (SN) and red nucleus (RN).

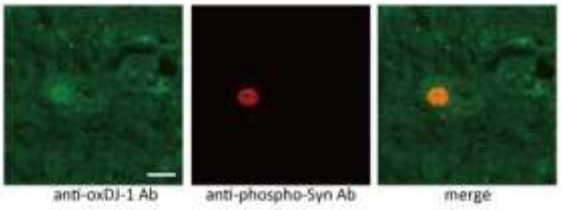

Fig. 2
The areas labeled with oxDJ-1 and phosphorylated α-synuclein (indicative of LBs) antibodies colocalized.

Title: Expression and protease activity of mouse legumain are regulated by DJ-1 and secretion of mouse prolegumain into serum is increased in DJ-1-knockout mice

Authors: ***T. YAMANE**[1], I. OHKUBO[2], H. ARIGA[1]
[1]Grad. Sch. of Pharmaceut. Sci., Hokkaido Univ., Sapporo, Japan; [2]Dept. of Nutrition, Sch. of Nursing and Nutr., Tenshi Col., Sapporo, Japan

Abstract: Legumain (EC 3.4.22.34) is an asparaginyl endopeptidase. Legumain is highly expressed in tumors and highly activated in Alzheimer disease brains. Recently, we found that transcription of the legumain gene is regulated by p53 tumor suppressor in HCT116 cells. We and others reported that DJ-1/PARK7, a cancer- and Parkinson's disease-associated protein, works as a coactivator to various transcription factors, including the androgen receptor, p53, PSF, Nrf2, SREBP and RREB1. In this study, we found that expression levels of legumain mRNA and protein and legumain activity were increased in DJ-1-knockout cells. Furthermore, we found that the p53-binding site is present on intron 1 of the mouse legumain gene, that the dot

structure of legumain was increased in DJ-1-knockout cells, and that secretion of prolegumain into the conditional medium and serum was increased in DJ-1-knockout cells and DJ-1-knockout mice, respectively. These results suggest that legumain expression, activation and secretion are regulated by DJ-1.

Abstract: Gene mutations in PINK1, a mitochondrial serine/threonine kinase, result in autosomal recessive Parkinson's disease (PD). The tight regulation of PINK1 levels in the mitochondria has been proposed to play an important role in mitochondria quality control via mitophagy. However, the mechanisms by which the steady state level of PINK1 are regulated, are poorly understood. Here we show that the parkin substrate, AIMP2, functions as a novel

regulator for PINK1 ubiquitin-proteasome dependent degradation. AIMP2 interacts with both PINK1 and the 26S proteasome subunits to promote the ubiquitin proteasomal degradation of PINK1. Overexpression of AIMP2 decreases PINK1 levels, whereas depletion of AIMP2 increases PINK1 levels both *in vitro* and *in vivo*. Moreover, AIMP2-mediated PINK1 regulation leads to differential kinetics of parkin recruitment to CCCP-damaged mitochondria. These results suggest that AIMP2 serves as a key regulator of PINK1 expression and functions in a mechanism to identify damaged mitochondria for autophagic removal through regulation of PINK1 steady state levels.

Title: Parkinsonism, mutant VPS35, and novel retromer functions in neurons

Authors: *L. N. MUNSIE[1], A. MILNERWOOD[2], P. SIEBLER[3], D. BECCANO-KELLY[1], M. VOLTA[1], C. KLEIN[3], M. FARRER[1]
[1]Med. Genet., [2]Neurol., Univ. of British Columbia, Vancouver, BC, Canada; [3]Neurogenetics, University of Lübeck, Germany

Abstract: Vacuolar protein sorting 35 (VPS35) is a core component of the retromer complex, crucial to endosomal protein sorting and intracellular trafficking. Little is known about retromer function in neurons but we recently linked a VPS35 mutation (p.D620N) to familial parkinsonism. Here we show that VPS35 is involved in the trafficking of excitatory AMPA-type neurotransmitter receptors (AMPARs). We examined the affect of the p.D620N mutation on neuronal function. While some measures are unaffected by the p.D620N mutation, we found altered intracellular trafficking and subcellular localization of mutant VPS35, in addition to altered synaptic transmission, AMPAR surface expression, and AMPAR recycling. Perturbations

to synaptic function in the presence of the p.D620N mutation may produce chronic pathophysiological stress and subsequent neurodegeneration

Title: Differential glutamate release from synaptoneurosomes prepared from Parkinson's and Huntington's disease mouse models

Authors: ***J. B. WATSON**[1], C. C. FERNANDEZ[1], E. MASLIAH[2], T. A. SARAFIAN[1]

Abstract: Alterations in glutamate release have been implicated in the synaptic pathology of multiple neurodegenerative diseases including Parkinson's Disease (PD) and Huntington's Disease (HD). Here a micro-method for preparing synaptoneurosomes (SN) enriched in presynaptic and postsynaptic elements [see JW Chang et al (2012) Neurosci Methods 211:289-295] was used to examine glutamate release from SNs prepared from both an α-synuclein overexpressing PD mouse model (ASOTg or Thy-1 αSyn) and an HD mouse model with expanded glutamine repeats in the mutant huntingtin protein (R6/2 BHD/150). Initially a glutamate oxidase assay coupled to Amplex Red® fluorimetry (Life Technologies/Invitrogen) was optimized over 30 minutes in 96 well plates containing glutamate standards either alone or in the presence of SNs prepared from freshly dissected wildtype (WT) mouse forebrain. SNs receiving multiple drug treatments (4 mM EGTA, 40 mM KCl ± 2 mM $CaCl_2$ or 100 μM $CdCl_2$) confirmed both depolarization- and Ca^{2+}-dependent glutamate release from WT control SNs. Inclusion of TBOA (50 μM) confirmed functional glutamate transporters for synaptic reuptake. Glutamate release (KCl/Ca^{2+}-dependent, mean±SEM pmole/μg protein) was subsequently measured in fresh cortex and striatum SNs prepared from both PD and HD mouse models. Only SNs prepared from ASOTg cortex (male, 2-4 months) showed an increase in glutamate release relative to WT controls (P=0.027). Conversely glutamate release from R6/2 striatum SNs (60-65 days old) was decreased versus WT controls (P=0.033). Future experiments will utilize both

pharmacological treatments and recombinant protein manipulations of PD and HD mouse model SNs to sort out the relevant presynaptic signaling pathways that mediate altered glutamate release.

Title: Is the presence of perforated synapses after dopamine depletion a sign of maladaptive brain plasticity?

Authors: *M. AVILA-COSTA[1], V. ANAYA-MARTÍNEZ[1], A. GUTIERREZ-VALDEZ[1], J. ORDOÑEZ-LIBRADO[1], J. SANCHEZ-BETANCOURT[1], E. MONTIEL-FLORES[1], J. ESPINOSA-VILLANUEVA[1], P. ALEY-MEDINA[1], L. REYNOSO-ERAZO[2], J. MACHADO-SALAS[2]
[1]UNAM, Neuromorphology Lab., Tlalnepantla Edo Mex, Mexico; [2]UNAM, Tlalnepantla Edo Mex, Mexico

Abstract: Synaptic plasticity is the process by which long-lasting changes take place at synaptic connections. The phenomenon itself is complex and can involve many levels of organization. Some authors separate forms into adaptations that have positive or negative consequences for the individual. It has been hypothesized that an increase in the number of synapses may represent a structural basis for the enduring expression of synaptic plasticity during some events that involve memory and learning; also, it has been suggested that perforated synapses increase in number after some disease and experimental situations. The aim of this study was to analyze whether dopamine depletion induces changes in the synaptology of the striatum of rats after the unilateral injection of 6-OHDA. The findings suggest that after the lesion, both contralateral and ipsilateral striata exhibit an increased length of the synaptic ending in ipsilateral (since 3rd day) and

contralateral striatum (since day 20), loss of axospinous synapses in ipsilateral striatum and a significant increment in the number of perforated synapses, suggesting brain plasticity that might be deleterious for the spines, because this type of synaptic contacts are presumably excitatory, and in the absence of the modulatory effects of dopamine, the neuron could die by excitotoxic mechanisms. Thus, we can conclude that the presence of perforated synapses after striatal dopamine depletion might be a form of maladaptive synaptic plasticity.

Title: Gender differences on the chronic effect of L-dopa and melatonin in the motor performance in a Parkinson disease model

Authors: ***A. GUTIERREZ VALDEZ**, V. ANAYA-MARTINEZ, J. T. SÁNCHEZ BETANCOURT, J. L. ORDOÑEZ-LIBRADO, E. MONTIEL-FLORES, J. ESPINOSA-VILLANUEVA, S. A. SÁNCHEZ -SORIA, A. TRUJILLO-MARTÍNEZ, F. HUERTA-OLIVAREZ, T. IBARRA-GUTIÉRREZ, M. R. AVILA-COSTA
UNAM, TLALNEPANTLA, Mexico

Abstract: Parkinson disease is a neurodegenerative disorder that affects movement due to the progressive degeneration of dopaminergic neurons of the Substantia nigra pars compacta (SNc). In the last years, it has been observed a greater incidence in men than in women, setting out that this difference is due to the action of sexual hormones. L-dopa is the most common drug for the treatment of PD because of its clinical efficacy; however, long-term L-dopa treatment induces involuntary abnormal movements, several evidences suggest that L-dopa can increase the

oxidative stress pre-existing condition, for that reason we decided to add melatonin as a potent antioxidant. We conducted this study to determine the ability of melatonin alone or in combination with L-dopa to protect nigro-striatal dopaminergic loss induced by 6-OHDA, comparing the results with L-DOPA-only treated rats, as well as determine differences between genders. The experiments were carried out in male, intact female (with estrogen) and ovariectomized (ovx) female rats underwent 6-OHDA-induced lesion in the medial forebrain bundle. The drugs were administered orally daily for 6 months; the motor behaviors were assessed by skilled forelimb use in a staircase test and stepping ability while walking on beams. At the cellular level, the numbers of TH-positive immune cells were evaluated. Surprisingly our results show that independently of the sex, the rats treated with the co-administration of L-dopa/melatonin had the best performance in the motor tasks and increase in the number of dopaminergic cells, which in turn imply the well-preserved synaptology of a less denervated striatum. In addition, we observed differences between sex, showing that intact female rats treated with L-dopa or melatonin had a significantly better recovery than male and ovx female and exhibited conservation of dopaminergic cells, showing that estrogens have neuroprotective effect. Our results suggest that co-administration of L-dopa/melatonin could be a possible candidate for the treatment of PD to prevent or slow the damage caused by L-dopa treatment. Also, the estrogens may exert beneficial effect against the development and progression of the disease and this could be used like in adjunct treatment of PD.

Title: The effect of electrical stimulation of the subthalamic nucleus or internal part of the globus pallidus to primate striatal interneurons

Authors: *Y. SHIMO[1], A. NAKAJIMA[1], T. UKA[2], N. HATTORI[1]
[1]Neurol., [2]Physiol., Juntendo Univ., Bunkyo-ku/Tokyo, Japan

Abstract: Background: Deep brain stimulation (DBS) of the subthalamic nucleuse (STN) or internal segment of the globus pallidus (GPi) is an established therapy for advanced motor symptoms in Parkinson's disease (PD). Previous studies showed that stimulation of the STN or GPi affects GPi neuron or thalamic neuron activity, however, the effect on the striatal neuron activity by STN or GPi DBS is still unclear.To investigate the effect of STN or GPi stimulation on the activity of striatal neurons, we recorded neuronal activity of the interneurons of primate putamen during high-frequency electrical stimulation of STN or GPi. Methods: Neuronal activity of the interneurons in the putamen (tonically active neurons: TANs) was recorded extracellularly during electrical stimulation of the STN or GPi (frequency: 130Hz, pulse width 60 micro seconds, stimulus current 0.4mA or 0.1mA for 30 seconds) in two normal monkeys. TANs were identified by a characteristic firing pattern (Shimo and Hikosaka 2001). Results: We examined 72 TANs activity during STN (55 neurons) or GPi (17 neurons) stimulation. Many TANs reduced their activity during STN or GPi stimulation (88% of recorded neurons during STN stimulation, 74% of recorded neurons in GPi stimulation, $p<0.05$ Mann-Whitney U test). Inhibitory responses of TANs during STN stimulation were diminished after local injection of sulpiride (10 μg/μl, total 1.2 μl). Moreover, many of the GPi neurons were inhibited by STN stimulation (11/17 neurons, $p<0.05$ Mann-Whitney U test). Conclusion: TANs are considered to be cholinergic interneurons. This study showed that electrical stimulation of the STN or GPi influences the activity of neurons which are located in the upstream structure of the basal ganglia, and dopamine may play an important role in the response. These results indicate that modulating of TANs activity may be one possible therapeutic mechanism of the STN or GPi DBS.

Title: Physiological patterns of optogenetic stimulation in the motor thalamus restore reaching in parkinsonian rats

Authors: *S. SEEGER-ARMBRUSTER[1,2], C. BOSCH-BOUJU[3,5,2], S. T. C. LITTLE[3,2], R. A. SMITHER[1,2], S. M. HUGHES[4,2], B. I. HYLAND[1,2], L. C. PARR-BROWNLIE[3,2]
[1]Dept. of Physiol., [2]Brain Hlth. Res. Ctr., [3]Dept. of Anat., [4]Dept. of Biochem., Univ. of Otago, Dunedin, New Zealand; [5]Nutr. and Integrative Neurobio., INRA, Univ. of Bordeaux, Bordeaux, France

Abstract: High frequency deep brain stimulation (DBS) of the subthalamic nucleus or globus pallidus internus is a standard treatment option in advanced Parkinson's disease (PD) to reduce akinesia and rigidity, whereas DBS and thalamotomy of the motor thalamus (Mthal) improves tremor. The primary aim of this study was to investigate if there are better ways to stimulate the Mthal to improve akinesia. Specifically, we explored if neural activity previously recorded in the Mthal of a behaving control rat and played into the brain of parkinsonian rats might restore reaching movements. We used a chronically implanted fibreoptic probe in the Mthal of adult male Wistar rats to selectively stimulate glutamatergic neurons transduced with channelrhodopsin-2 by injection of lentiviral vector (pLenti.CamKII.hChR2(H134R).mCherry). Rats performed a reach-to-grasp task for food pellets, homologous to human reaching, and we recorded the number of reaches per 5 min before, during and after optogenetic stimulation. We induced acute parkinsonism by injecting the dopamine antagonist haloperidol (0.03-0.07 mg/kg, s.c.) so each rat could act as its own control (vehicle injection). Control rats typically executed over 150 reaches per 5 min period, whereas parkinsonian rats displayed marked akinesia, executing less than 20 reaches per 5 min period. We compared the effect of DBS using complex physiological patterns previously recorded in the Mthal during reaching behaviour, with tonic DBS delivering the same number of stimuli per unit time (rate-control 6.2 Hz) and with stimulation patterns commonly used for DBS in other brain regions (tonic 130 Hz, continuous theta burst (cTBS), and tonic 15 Hz rate-control for TBS). Blue light (473 nm) stimulation with the physiological reaching pattern significantly restored reaching in parkinsonian rats (two-way ANOVA; time $p = 0.0095$; pattern $p = 0.0092$), which was dependent on pattern and not rate as tonic 6.2 Hz stimulation did not improve reaching. In addition, standard patterns of stimulation failed to improve reaching in parkinsonian rats, although cTBS showed a strong trend ($p = 0.0562$) to increase the number of executed reaches. In contrast, blue light stimulation did not alter reaching in control rats for any of the patterns (time $p = 0.1496$; pattern $p = 0.3906$). Additionally, stimulation with yellow light (561 nm) did not alter reaching performance in control or parkinsonian experiments for any of the stimulation patterns (all: $p > 0.19$). These data indicate that the pattern of stimulation in the Mthal is critical to improve reaching in parkinsonian rats and that Mthal may be an effective site to treat the akinesia of parkinsonism.

Title: Optogenetics mapping of the dynamic properties of the Hyperdirect and Indirect Pathways

Authors: *B. DE LA CROMPE[1], N. MALLET[1,2], F. GONON[1,2], T. BORAUD[1,2]
[1]Univ. De Bordeaux, IMN UMR 5293, Bordeaux, France; [2]CNRS, IMN, UMR 5293, Bordeaux, France

Abstract: The cortico-basal-ganglia (CBG) loop is a complex network involved in action selection and decision making. The appropriate control of CBG's dynamic states is necessary to ensure normal locomotion as attested by the emergence of hyper-synchronized β-oscillations condition in Parkinson's disease (PD). The origin of exacerbated β-oscillations (15-30 Hz) is correlated with the degree of akinesia/bradykinesia which is one of the major symptoms of PD. For now, the emergence and the maintenance of these exacerbated oscillations in motor CBG are still debated. However some computational studies proposed a role of the hyperdirect pathways and Globus pallidus-Subthalamic nucleus (GP-STN) network on the establishment of this state. By receiving GP and motor cortex (mCx) projections, STN forms a bottleneck between two major pathways of CBG (indirect and hyperdirect pathways). Thus the STN is an appropriate target to manipulate the dynamic of CBG loops. The goal of this study is to unravel the role of the mCx and GP inputs in the emergence and the maintenance of β-oscillation using optogenetic and electrophysiological approaches. We used optogenetics toolboxes to selectively modulate GP and mCx neurons and study their involvement in the emergence/maintenance of β-oscillation in controls or parkinsonian rat. Our electrophysiological data show how selective manipulation of mCx and GP inputs impact on the maintenance, the genesis and the propagation of β-oscillation in the CBG loop.

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disease, characterized by motor dysfunction resulting from dopamine deficiency-induced functional changes in basal ganglia networks. The basal ganglia, which are composed of multiple subcortical nuclei, are known to regulate movements and emotions through a precise balance of direct and indirect pathways. Within the basal ganglia, a key circuit is the reciprocal network between the GPe and the STN. Deep brain stimulation (DBS) of STN has been shown to relieve symptoms of the patients with advanced PD and is considered to be an effective treatment for various neurological and psychotic diseases including movement disorders. However, the mechanism underlying the effects of DBS remains unknown, and even fundamental characteristics such as the functional anatomy and synaptic profiles of these circuits are unclear. In fact, the complexity of neuronal circuit organization in the GPe-STN network (such as its heterogeneous neuronal population and complex patterns of cell type-specific convergence and divergence) has long been underappreciated. In this study, we perform a fine-scale synaptic mapping of the GPe-STN connection using a newly developed synapse labeling tool, mammalian GFP reconstitution across synaptic partners (mGRASP). In MPTP-induced PD model, we observed a significant decrease in tyrosine hydroxylase (TH)-positive neurons in SN, which resulted in a significant decrease in TH-positive axonal projections in the striatum, and notable PD-like motor dysfunction assessed by the vertical grid test. To dissect cell-type specific synaptic mappings, we then introduced presynaptic mGRASP in parvalbumin (PV)-positive neurons of the GPe and postsynaptic mGRASP in the STN of the PD mouse model. Our preliminary results suggest that mGRASP fluorescence signals indicating the presence of

synapses were evident on the soma and dendrites of STN neurons and further that synapses are decreased in the PD mouse model. We are presently conducting detailed analyses of synaptic changes together with a fundamental characterization of the GPe-STN network in healthy and PD model mice. A clear understanding of connectivity characteristics associated with PD will guide us to understand the relationship between these circuits and behavior, mechanisms of DBS effects, and to develop more effective treatments for the patients with PD.

Title: Correlation of synchronized dynamics in cortical and basal ganglia networks in Parkinson's disease

Authors: S. AHN[1], S. E. ZAUBER[2], T. WITT[3], R. M. WORTH[3], *L. L. RUBCHINSKY[4]
[1]Dept. of Mathematical Sci., Indiana University-Purdue Univ. Indianapolis, Indianapolis, IN; [2]Neurol., [3]Neurosurg., Indiana Univ. Sch. of Med., Indianapolis, IN; [4]IUPUI & Indiana Univ. Sch. Med., INDIANAPOLIS, IN

Abstract: Increased oscillatory power and synchrony in the beta band in cortico-basal ganglia circuits is well described in patients with Parkinson's disease. The synchrony between basal ganglia and the cortex has been observed and described. Synchronized dynamics within cortical networks and within the basal ganglia has being studied too (such as synchronization between spikes and Local Field Potentials, LFPs). Given the presumed relevance of both cortical and basal ganglia neurodynamics to the symptoms of Parkinson's disease, it is interesting to explore not only synchrony between cortex and basal ganglia, but also the correlations between synchronous dynamics within the cortical networks and in the basal ganglia networks. In the present study, we consider correlations of cortical and basal ganglia synchronized dynamics at the beta band in parkinsonian patients. We record neuronal unit (spikes) and LFP from subthalamic nucleus (STN) simultaneously with scalp EEGs recordings from motor and

prefrontal areas during microelecrtrode-guided implantation of deep brain stimulation (DBS) electrodes. We then analyze the correlation of the phase synchronies between the synchronous activity of spike-LFP pairs and the synchronous activity between EEG electrode pairs. We first study the phase synchrony during relatively short temporal running windows, and then study the temporal correlations between these synchronous activities to explore the temporal correlations of cortical and basal ganglia networks at the beta band. We found that intrahemispheric phase synchronization between motor EEG electrode is significantly correlated (with some time-delay) with the spiking unit-LFP phase synchronization as they develop in time. This suggests that the change in the degree of synchrony in cortical motor networks is related with (and, perhaps, induces) the change in the coherence of oscillatory interactions within basal ganglia circuits. The correlations between dynamic activities in cortical and subcortical networks points to the complex interconnectedness of the cortical and subcortical circuits in the pathophysiology of Parkinson's disease and signifies further study of cortico-subcortical interactions on different time-scales. We also consider a predictive aspect of the relationship between synchronization of EEG oscillations (which can be obtained noninvasively) and spiking unit-LFP synchrony in STN (which may be recorded only during invasive surgical procedures).

Title: Increased interhemispherical synchronization in the hemiparkinsonian rat: A multielectrode approach

Authors: B. N. JAVOR-DURAY[1], M. VAN DER ROEST[1], C. J. STAM[2], H. W. BERENDSE[3], M. VINCK[4], *P. VOORN[1]

Abstract: Increased synchronization patterns are detected in a wide range of cortical regions and basal ganglia in parkinsonism. However, it is not known how dopamine depletion in basal ganglia affects different cortical areas, their synchronization to each other and to basal ganglia. In the current study, we performed multielectrode recordings in a freely moving rat model of parkinsonism to explore local and interregional changes. Local field potentials were recorded from 12 cortical (motor and sensory areas) and 2 striatal (sensori-motor sector) sites. Serial recordings were performed of behaving rats before and after a unilateral 6-hydroxydopamine injection into the medial forebrain bundle. We computed spectral power and interregional synchronization (Phase Lag Index) before and after the dopaminergic cell lesion in the substantia nigra. Our recordings revealed an elevated beta peak in the power spectrum solely in the motor-related brain regions of the lesioned hemisphere, viz. motor cortical areas and striatum. Moreover, these areas showed enhanced coupling in the beta band compared to the pre-lesion condition. Interhemispherical synchronization was increased between motor cortical areas in the two hemispheres. Cortico-striatal beta synchronization was increased between striatum in the lesioned hemisphere and multiple cortical areas (on both sides of the brain). The contralateral striatum did not show such changes. Our findings indicate that the investigated cortico-striatal system shows widespread synchronization changes in response to the dopaminergic cell depletion in substantia nigra. These changes involve both hemispheres, unlike the observed power spectral alterations.

Title: Disrupted connectivity of motor loops within the basal ganglia in atypical parkinsonism

Authors: *T. TANIWAKI, A. YORITA, H. KIDA, K.-I. YAMASHITA, S. MIURA
Dept Med, Kurume Univ., Fukuoka 830-0011, Japan

Abstract: Atypical Parkinsonism (AP) reportedly includes altered connectivity of neural loops involving the basal ganglia. Little is known of any changes in the connectivity of motor loops. The goal of this study was to further understand the connectivity within the basal ganglia-thalamo-motor (BGTM) loop in AP. Eight AP patients and eight patients with Parkinson disease (PD) performed a protocol involving self-initiated (SI) finger movements while being scanned with functional magnetic resonance imaging (fMRI). In the mapping, there was no difference between the groups. Analysis using structural equation modeling (SEM) revealed significant positive interactions within the right BGTM loop during the SI task. PD patients showed reduced connectivity from the thalamus to the motor cortices, while there was decreased connectivity within the basal ganglia in the AP group, which is the first demonstration of this phenomenon. These results suggest different pathophysiology of the two entities involving different loci in the BGTM loop, and illustrate the utility of SEM for network analysis.

Abstract: Neural oscillations are thought to underlie coupling of spatially remote neurons and gating of information within the human sensorimotor system. Different frequency ranges have been associated with different movements and neurological diseases. In dystonia, a prominent low frequency peak has been found at rest in the globus pallidus (GP). Little is known about neural oscillations at the network level in other subcortical parts of the motor system. The

thalamus is particularly interesting since it links subcortical structures like the cerebellum and the GP with cortex, and is known from tracing studies in animals to show differential connectivity to these structures. Thus, we here investigated the electrophysiological profile of the ventrolateral thalamus in dystonic patients undergoing surgery for deep brain stimulation at rest and during voluntary movement; we compared these findings to tractography-based connectivity distributions of cerebellar and pallidal projections in healthy human subjects. Local field potential (LFP) activity in the beta frequency band significantly increased from anterodorsal to posteroventral direction ($p < 0.05$), while alpha activity decreased -i.e. posteroventral areas showed less alpha and more beta activity than more anterodorsal areas. Regarding tractography results, posterior regions were significantly represented by dentate projections; more anterior regions, however, showed a stronger pallidal connectivity. Electrophysiological recordings and connectivity analysis had both a territory specific accentuation within the motor thalamus. These findings let to assume that the basal-ganglia-thalamo-cortical loops are not only anatomically separated from the cerebello-thalamo-cortical loop, but also functionally segregated through distinct oscillatory frequencies. Further studies are needed to elucidate the exact nature of this anatomical-functional relationship and their interaction.

Title: Investigation of subthalamic and peripheral motor unit activity in Parkinson disease during an isometric grip task

Authors: *K. G. HAMMOND[1], C. L. GONZALEZ[2], H. C. WALKER[2]
[1]Physical Therapy, Univ. of Alabama At Birmingham, Birmingham, AL; [2]Neurol., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Relatively little is known about how subthalamic activity is modulated by movement in awake, behaving humans with idiopathic Parkinson disease (PD). METHODS: In patients undergoing subthalamic deep brain stimulation for routine care, we evaluated single unit discharges in the hand region of the subthalamic nucleus with parallel measurement of peripheral motor unit activity at five different levels of submaximal isometric grip force. RESULTS: We studied 22 neurons from 6 PD subjects, and participants readily performed the behavioral task. Subthalamic units showed heterogeneous responses, with individual units showing increased activity, decreased activity, or selective responses during the dynamic versus the static phase of the isometric force. At the group level, the discharge frequency of subthalamic units increased during the dynamic but not the static component of the grip force ($p=0.001$, pairwise comparison $p=0.03$, repeated measures ANOVA). With increasing levels of static force, there were corresponding increases in motor unit activity measured by both surface and intramuscular EMG, yet there was no corresponding change in subthalamic nucleus discharge rate at our level of statistical power ($p=0.83$). CONCLUSIONS: During an isometric grip task, subthalamic hand units in humans with PD discharge preferentially during dynamic versus static force conditions. Subthalamic activity did not decrease with increasing levels of static force. Better defining the role of the subthalamic region in specific motor behaviors could improve our understanding of basal ganglia physiology and ultimately guide new approaches to therapy.

Title: Role of pedunculopontine cholinergic neurons in gait

Authors: *N. FARHANI[1], R. RAJAKUMAR[2], M. S. JOG[3]
[2]Anat. and Cell Biol., [3]Neurol., [1]Univ. of Western Ontario, London, ON, Canada

Abstract: Parkinson's disease (PD) patients suffer from tremor, rigidity and bradykinesia, and these symptoms are associated with severe dopaminergic nigrostriatal denervation. These symptoms are responsive to L-DOPA treatment and/or deep brain stimulation. In advanced stages of PD, other symptoms that are unresponsive to these treatments, including gait and balance abnormalities and impaired control of complex movements, emerge. The later symptoms are not prominent at early stage of PD when there is a significant dopaminergic neuronal loss and they are also not responsive to levodopa. Therefore, the postural and gait abnormalities are believed to be not a consequence of dopaminergic cell loss. Pedunculopontine nucleus (PPN) is located in the caudal midbrain and contains neurons possessing either acetylcholine or GABA, dispersed throughout the nucleus. PPN sends direct projections to the groups of the reticulospinal neurons that in turn send descending commands to spinal networks referred to as central pattern generator, which is involved in synergistic activation of muscles responsible for gait and locomotion. PPN also sends cholinergic projections to a group of neurons in the brainstem that in turn send projections to the reticulospinal neurons and regulate their activity. Determining topographical organization of cholinergic neurons within the PPN that are involved in different aspects of gait and efferent circuitry involved in mediating PPN's role in gait may facilitate in studying gait abnormalities in PD. In the present study, an anterograde neuronal tracer (e.g., BDA) that labels the axonal projection sites of PPN neurons are microinjected into each of the topographical areas of the PPN, and target sites of cholinergic neurons that mediate different aspects of gait will be determined. The same rats will also receive a retrograde tracer (e.g., Flurogold) into the lumbar spinal cord to label reticulospinal neurons projecting to the lumber spinal segments. Sections will then be immunolabeled for vesicular choline transporter, GAD67 or VgluT2 to identify cholinergic terminals. Those neurons containing Flurogold and receiving cholinergic terminals from the PPN will be deemed as the possible neurons involved in mediating efferent circuitry involved in mediating PPN's role in controlling lumbar spinal neurons. Our results will identify the topographical areas and neuronal circuitry and future pharmacological studies to identify the role of PPN in gait and locomotion.

Abstract: Introduction The pathophysiological basis of freezing of gait (FOG) in Parkinson's disease (PD) is incompletely understood. Cortical processing conflicts may play an important role in provoking FOG for example, when gait is interfered with a cognitive task (dual tasking). Freezing phenomena are not restricted to gait but may also occur during repetitive finger movement. In this study, we characterized the cortical correlates of dual tasking during repetitive finger movement in healthy controls (HC) and gait freezers. Methods We included 12 PD patients with STN-DBS and FOG (9 male, age 60.5 ± 12.6 years) and 12 age- and sex matched healthy controls (7 male, age 61.9 ± 10.1 years). They were instructed to perform internally generated continuous tapping with the right index finger with and without dual task. The interference task was a phonemic verbal fluency task. Subsequently, we analyzed the activity and synchronization (coherence) of the cortex by calculating the corticocortical coherence and phase synchronization index. Results The performance of the interference task did not differ between healthy controls and PD patients. The cortical activity did not change during single and dual task in both healthy controls and PD patients. Healthy controls showed alpha band synchronization in the bilateral centro-parietal areas in the single task that desychronized during dual tasking. PD patients showed similar synchronization in both single- and dual task. Instead, healthy controls demonstrated an increase of synchronization in the frontal areas during dual tasking unlike PD patients. Discussion PD patients demonstrate during dual tasking i) absent desynchronization in the bilateral centro-parietal areas and ii) absence of synchronization in the frontal areas. Abnormal fronto-centro-parietal synchronization patterns may parallel the cortical processing deficits in gait freezers.

Title: Dopamine depletion results in frequency-dependent disinhibition of corticostriatal transmission *in vivo*: Role of local GABAergic function

Authors: *V. R. JAYASINGHE[1], A. R. WEST[2], K. Y. TSENG[3]
[2]Neurosci., [3]Cell. & Mol. Pharmacol., [1]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Parkinson's disease is strongly associated with the emergence of increased beta oscillations within the basal ganglia, which is thought to reflect a disruption of corticostriatal transmission, and thereby exacerbate motor deficits associated with this disease. The mechanisms underlying the elevated synchronization at beta frequencies observed following dopamine lesion remain unclear. However, dysfunction of local GABAergic interneurons may play a key role as these cells provide robust feed-forward inhibition to striatal projection neurons, and this inhibition is impaired in the dopamine-depleted, parkinsonian striatum. Therefore, the goal of this study was to determine if impaired GABAergic function could underlie the increased synchrony within the corticostriatal pathway at specific frequencies observed in the parkinsonian state. *In vivo* electrophysiological recordings performed in the dorsal striatum of rats revealed a progressive increase in the inhibitory modulation of the local field response evoked via motor cortex train stimulation at 10 (alpha), 20 (beta), and 40 Hz (gamma). Interestingly, this frequency-dependent striatal inhibition evoked during cortical stimulation was lacking in the dopamine-depleted striatum of rats that received the unilateral 6-OHDA lesion. We next asked whether local GABAergic transmission controls striatal responsivity to cortical drive in a frequency dependent manner. Local infusion of the GABA-AR antagonist picrotoxin into the dopamine-intact striatum revealed a frequency-dependent disinhibition of corticostriatal transmission which was similar to that seen in the dopamine-

depleted striatum. Importantly, infusion of picrotoxin into the dopamine-depleted striatum failed to further disrupt the disinhibitory corticostriatal response. Together, these results highlight the possibility of an impaired striatal GABAergic inhibitory control of cortical inputs in the dopamine-depleted striatum that enables the augmented cortico-basal ganglia synchronization that spreads beyond the beta oscillation range.

Title: Modulating dopamine and glutamate signaling in the primary motor cortex alters the motor symptoms of Parkinson's disease and L-DOPA-induced dyskinesia in rats

Authors: *D. LINDENBACH, C. BISHOP
Psychology, Binghamton Univ., Binghamton, NY

Abstract: The most effective treatment for Parkinson's disease (PD) is the dopamine precursor L-DOPA, but long-term use typically results in the development of debilitating involuntary movements known as L-DOPA-induced dyskinesia. Recent research suggests that dopamine and glutamate signaling in the primary motor cortex (M1) is abnormal in PD and after L-DOPA treatment. To this end, we sought to determine if local M1 delivery of a D1 receptor antagonist (SCH23390) or an NMDA receptor antagonist (MK-801) would modify the behavioral and molecular response to a DA lesion and L-DOPA treatment. Adult male Sprague-Dawley rats were given a unilateral nigrostriatal dopamine lesion with 6-hydroxydopamine, affixed with bilateral M1 microinjection cannulae, and treated with daily L-DOPA (6 mg/kg) for 2 weeks. Subsequently, we microinjected SCH23390 (0, 3 and 18 nmol) or MK-801 (0, 3 and 18 nmol) into M1 and then delivered systemic L-DOPA (6 mg/kg). Rats were then rated on behavioral measurements of dyskinesia and PD disability. A separate cohort of rats was given the same treatments and sacrificed 1 h later for immunohistological examination of c-Fos in the motor

striatum. Initial results suggest that M1 blockade of D1 receptors reduces dyskinesia while antagonism of M1 NMDA receptors exacerbates L-DOPA-induced dyskinesia. Research linking these behavioral effects with striatal c-Fos expression is ongoing. Our data suggest that modulating aberrant M1 neurotransmitter signaling may provide therapeutic benefit for PD and dyskinesia.

Title: Optimized temporal patterns of stimulation suppress oscillatory neuronal activity in a computational model of Parkinson's disease and in hemi-parkinsonian rats

Authors: *D. T. BROCKER[1], W. M. GRILL[1,2,3]
[1]Dept. of Biomed. Engin., [2]Dept. of Neurobio., [3]Dept. of Surgery, Duke Univ., Durham, NC

Abstract: Non-regular temporal patterns of deep brain stimulation (DBS) are an exciting and relatively unexplored parameter space for improving therapeutic efficacy and/or efficiency. Using a computational model of the parkinsonian basal ganglia, we developed a novel temporal pattern of DBS with a low average frequency (45 Hz) for testing in hemi-parkinsonian rats and human subjects with Parkinson's disease (PD). The pattern was developed using a genetic algorithm—an engineering optimization approach—that incentivized simultaneously maximization of pattern efficacy and efficiency. Our previous work showed that the optimized pattern of stimulation suppressed PD motor symptoms in hemi-parkinsonian rats and human subjects with PD more effectively than frequency-matched regular DBS at 45 Hz. Here, we explored possible mechanisms for the differential efficacy between the optimized pattern and regular 45 Hz control DBS. We found that the optimized pattern more effectively suppressed synchronous oscillation in both a computational model of PD and in hemi-parkinsonian rats. In the computational model, the optimized pattern of stimulation suppressed oscillations in the beta range more effectively than did regular 45 Hz stimulation. In the hemi-parkinsonian rats, field potential recordings were collected from the globus pallidus and motor cortex ipsilateral to

dopaminergic lesion in awake, freely behaving rats under the different subthalamic DBS conditions. The optimized pattern of stimulation and high frequency regular DBS both significantly reduced low frequency oscillations compared to regular 45 Hz stimulation. Abnormal synchronous oscillations are thought to be related to parkinsonian symptoms, and temporal-pattern dependent suppression provides a possible mechanism of action for effective temporal patterns of DBS.

Title: Relationship between oscillatory activity and tremor in rats

Authors: *C. S. OZA[1], D. T. BROCKER[1], C. E. BEHREND[1,2], W. M. GRILL[1,3,4]
[1]Biomed. Engin., [2]Sch. of Med., [3]Neurobio., [4]Surgery, Duke Univ., Durham, NC

Abstract: Abnormal oscillatory activity within and across cortical - basal ganglia - thalamic network is associated with motor symptoms in movement disorders (e.g. beta oscillations in Parkinson’s and theta oscillations in Essential Tremor). While pharmacological or deep brain stimulation treatment that alleviates motor symptoms may suppress these abnormal oscillations, whether such oscillatory activity is causal of motor deficits such as tremor remains unclear. Our goal was to characterize the role of abnormal oscillatory activity in motor deficits in awake and behaving healthy rats. We first focused on the so-called high voltage spindle (HVS) oscillations (5-13 Hz) that are present in the cortex – basal ganglia network in normal rats and are exaggerated with dopamine depletion. We recorded local field potentials in the motor cortex and the globus pallidus along with behavioral recordings through an accelerometer connected to the

head cap and video recordings. We observed a significant increase in spectral power and coherence between motor structures and acceleration in 7-12 Hz band during a large number of HVS episodes implying a relationship between oscillatory activity and tremulous head motion. Next, we used a computational model of the basal ganglia and a genetic algorithm optimization technique to design a novel temporal pattern of subthalamic nucleus stimulation that increased oscillatory power in the 7-12 Hz band in the basal ganglia. We then tested this pattern in normal rats and compared its effects with regular 50 Hz (the average frequency of the designed pattern), 4.5 Hz, and 9 Hz stimulation to test the hypothesis that novel stimulation pattern that increased power in the 7-12 Hz band would induce tremor in healthy rats. The optimized pattern of stimulation induced significant head and paw tremor in majority of the rats tested and severity was related to stimulation amplitude. While regular 50 Hz stimulation also induced minor motor deficits, the total number of tremulous paw movements and head tremor severity were often exacerbated by our novel stimulation pattern. While increasing stimulation amplitude of the optimized stimulation pattern exacerbated motor deficits, 4.5 or 9 Hz stimulation did not induce motor deficits even at higher amplitudes. These results suggest that when a healthy motor network is subjected to abnormal oscillatory activity through a novel stimulation pattern, the imposed activity manifests as tremor. Additionally, our results reinforce that the temporal pattern of stimulation is an important parameter that can induce selective motor deficits in a healthy animal.

Title: Neuronal basis of deep brain stimulation of the substantia nigra pars reticulata to treat gait

Authors: *G. C. MCCONNELL, W. M. GRILL
Duke Univ., Durham, NC

Abstract: Deep brain stimulation (DBS) of the subthalamic nucleus improves the distal motor symptoms of Parkinson's disease (PD), but long-term improvements in gait and postural instability are inconsistent. Due to the substantial impact of gait and postural instability on quality of life, alternative targets for DBS are under investigation, including the substantia nigra pars reticulata (SNr). The effects of stimulation location within the large nuclear region of the SNr and stimulation parameters on improvement in gait are unclear, and this lack of foundational knowledge hinders the application and optimization of SNr DBS. We hypothesized that the location of stimulation within the SNr (medial *vs.* lateral) differentially treats gait and investigated the neuronal basis for these differential effects by characterizing the neuronal response to SNr DBS using immunomapping of markers for neuronal activity and plasticity. Rats were implanted with platinum iridium stimulating electrodes in either the medial or lateral SNr and a cannula in the medial forebrain bundle for administration of 6-hydroxydopamine to render rats hemiparkinsonian. Gait was quantified using a motorized treadmill. Immunohistochemistry was used to determine the extent of the 6-hydroxydopamine lesion, the location of the electrodes, and recent neuronal activity and plasticity as indicated by expression of c-Fos and phosphorylated extracellular signal-regulated kinase (pERK). Hemiparkinsonian rats, in contrast to healthy rats, were unable to maintain walking speed on a motorized treadmill and spent most of the time at the back of the treadmill. High frequency DBS of the medial SNr, but not lateral SNr, improved the rat's ability to maintain walking speed on the treadmill. Immunomapping showed that stimulation of the medial SNr, but not lateral SNr or non-stimulated controls, induced expression of cFos and pERK in the midbrain locomotor region (MLR), comprised of the cuneiform nucleus and pedunculopontine nucleus. These results suggest that improvement in gait depends on the location of the electrodes (medial *vs.* lateral SNr). Further, immunomapping results suggest that medial SNr DBS improves gait through modulating MLR activity and thereby shed light on the neuronal basis of SNr DBS for the treatment of PD.

Title: Dysfunctional GABAB transmission at striatonigral synapses drives motor sensitization in parkinsonian mice

Authors: *A. BORGKVIST[1], M. KHEIRBEK[2], R. HEN[3], D. SULZER[1]
[1]Dept. of Neurol., Columbia Univ. Med. Ctr., New York, NY; [2]Neurosci. and Psychiatry, [3]Neurobio. and Behavior, Columbia Univ., New York, NY

Abstract: Degeneration of dopamine (DA) neurons in Parkinson's disease (PD) causes hypokinesia, and subsequent DA re-administration produces highly sensitized motor behaviors in PD models. This feature is classically attributed to adaptive responses in DA receptor signaling within striatal medium spiny neurons (MSN). However, the sensitization may, in addition, reflect changes in MSN excitability due to prolonged absence of DA. Indeed, here we show that optogenetic activation of striatonigral afferents within the substantia nigra reticulata (SNr) of hemiparkinsonian mice directly produces a sensitized motor response. With patch-clamp electrophysiology and live 2-photon imaging of vesicular fusion we found increased striatonigral synaptic activity on the lesioned side, which resulted from the loss of normal GABAB mediated presynaptic inhibition. Thus, heterosynaptic sensitization of GABA release within the SNr of the parkinsonian brain is a DA receptor independent mechanism, which we propose may contribute to the sensitized motor response observed upon DA re-administration in PD.

Title: Chemogenetic inhibition of the subthalamic region of parkinsonian mice improves motor function

Authors: *L. BROOM[1], T. SAMARDZIC[1], A. WORLEY[1], J. CLARK[1], Y. OISHI[2], D. K. SIMON[3], C. B. SAPER[3], V. VANDERHORST[3]

Abstract: Deep brain stimulation is an effective treatment of motor symptoms in Parkinson's disease (PD). However, the presence of hardware and unintended stimulation of fiber tracts are limitations of this technology. Chemogenetic approaches provide an alternative without these limitations. One such approach makes use of Ivermectin (IVM) channels, which are mutated nematode glutamate gated chloride channels that can be delivered locally via microinjection of an adeno-associated viral vector (AAV). IVM channels are inert in mammals due to a mutation, but can be specifically and reversibly targeted by the drug Ivermectin, leading to inhibition of transfected neurons. In this study, we apply this strategy to the subthalamic region (STN), which is overactive in PD, to assess the feasibility of this approach to ameliorate motor function in an acute parkinsonian mouse model. We placed micro-injections of AAV10-CMV-IVM-GFP (Patrick Fuller) into the STN region of male C57Bl6J mice. Following transfection, we assessed the effect of inhibition of the STN region on motor function in the intact CNS following i.p. injections of vehicle or Ivermectin. To study whether the treatment effects were reversible, treatments were repeated after a wash-out period. Motor tests included high speed gait and kinematic analysis, and assessment of complex motor behavior using rotarod, balance beam, horizontal ladder, open field testing, and grip strength. To determine the effects of STN inhibition in an acute parkinsonian model, we injected 6-hydroxydopamine (6OHDA) into the substantia nigra (SN), and repeated the motor tests with vehicle and Ivermectin treatments. After the behavioral tests, we used immunohistochemistry to visualize GFP+ transfected neurons in the STN region and tyrosine hydroxylase (TH) neurons in the SN. Behavioral test results were correlated with the injection sites, and the loss of TH staining. The results show that chemogenetic inhibition of the STN region in non-lesioned mice induces small enhancements of motor performance such as an increase in gait speed and latency to drop off an accelerating rotarod. Following 6OHDA-induced dopaminergic cell loss and subsequent worsening of motor performance, inhibition of the STN region results in marked improvements of motor function. For some of the motor tests, these effects surpass pre-lesion performance. The effects are reversible and dose dependent. These findings represent a proof of concept for this novel

technology to ameliorate motor function in a parkinsonian mouse model. The results demonstrate its potential as a treatment in PD and other neurological conditions that involve an imbalance in neural circuitries.

Title: Spinal cord stimulation alleviates motor symptoms and decreases beta oscillatory activity in bilateral 6-OHDA marmosets

Authors: *R. A. FUENTES[1], M. SANTANA[2], P. HALJE[3], H. SIMPLICIO[2], U. RICHTER[3], M. FREIRE[2], P. PETERSSON[3], M. NICOLELIS[4]

Abstract: Although deep brain electrical stimulation can alleviate the motor symptoms of Parkinson's disease (PD), a small fraction of PD patients can take advantage of this procedure due to its invasive nature. A significantly less invasive method - epidural spinal cord stimulation (SCS) - has been recently suggested as an alternative approach for symptomatic treatment of PD. However, the mechanisms underlying motor improvements through SCS are unknown. Here, we show that SCS reproducibly alleviates motor symptoms in a primate model of PD. Simultaneous neuronal recordings from multiple structures of the cortico-basal ganglia-thalamic loop in PD

monkeys revealed abnormal highly synchronized neuronal activity within each of these structures and excessive functional coupling among them. SCS disrupted this pathological circuit behavior in a manner that mimics the effects caused by pharmacological dopamine replacement therapy or deep brain stimulation. These results suggest that SCS should be considered as an additional treatment option for PD-patients.

Title: Phase amplitude coupling in Parkinson's Disease detected with scalp electroencephalography

Authors: *N. C. SWANN[1], C. DE HEMPTINNE[2], J. OSTREM[3], R. KNIGHT[4], P. STARR[2]
[1]Neurolog. Surgery, Univ. of California, San Francisco, San Francisco, CA; [2]Neurolog. Surgery, [3]Neurol., Univ. of California San Francisco, San Francisco, CA; [4]Helen Wills Neurosci. Inst., Univ. of California Berkeley, Berkeley, CA

Abstract: Introduction: Emerging theories of Parkinson's Disease (PD) suggest that it is characterized by excessive synchronization in the beta frequency band (~20 Hz) throughout basal ganglia-thalamo-cortical loops. Recently we showed that one robust measure of this synchronization is the coupling of beta phase to broad-band gamma amplitude, thought to reflect spiking activity (i.e. phase amplitude coupling, or PAC). Invasive electrocorticography recorded during deep brain stimulation (DBS) surgery revealed that PAC over primary motor cortex (M1) was elevated in PD compared to patients without PD. Other recent work suggests high frequency (>70 Hz) activity may be detectable at the scalp using electroencephalograhy (EEG), under some circumstances. We tested whether PAC (beta phase to broad-band gamma amplitude) over M1, recorded non-invasively with EEG, differs between medicated, unmedicated PD patients, and healthy control subjects and whether it is sensitive to therapeutic basal ganglia DBS. Methods: We examined an archival data set of 15 PD patients and 16 age-matched healthy control subjects. All EEG data were collected at rest. PD patients were tested on two different days, once on and once off medications, in a counterbalanced order between patients. We also collected preliminary

data from 2 PD patients with DBS. These patients were tested on and off DBS in the off medication state. For each dataset we calculated PAC using a Kullback–Liebler based method after standard pre-processing and artifact rejection. Results: For the group analyses we observed significantly greater PAC for the patients off compared to on medication ($p<0.0067$, using a two-tailed, paired, non-parametric Wilcoxon sign rank test.) The difference between patients off medication and healthy controls trended towards significance ($p<0.0604$, two-tailed, unpaired, non-parametric Wilcoxon rank sum test). The difference between patients on medication and healthy controls was not significant. DBS stimulation was associated with a suppression of PAC that rebounded once DBS is turned off. Conclusion: These preliminary findings suggest that PAC is a neurophysiological biomarker for PD in the off-medication state, and is detectable at the scalp. Future studies will investigate the reliability of the signal over-time and its relation to specific symptoms.

Neurology, Natl. Taiwan Univ. Hospital, Col. of Med., Taipei, Taiwan; [3]Dept. of Neurology, Natl. Taiwan Univ. Hosp., Taipei, Taiwan; [4]Ctr. for Optoelectronic Medicine, Col. of Medicine, Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Introduction: Pain is a disturbing non-motor symptom involving more than 40% of Parkinson's disease patients. Given that central mechanism of PD related pain remains unclear, we presume the cause of rising pain to be the intrinsic cerebral network change, and resting state functional MRI is adopted to investigate cerebral functional network. Method and result: Three groups of subjects are collected, including 12 healthy controls (HC group), 12 PD patients with pain (whose average painful VAS score >40/100) (PD-P group), and 10 PD patients without pain (PD-NP group). Demographically, the PD-P and the PD-NP groups share similar disease duration, age and sex, while the PD-P group has significantly higher UPDRS motor score, higher depression and anxiety scores. We performed seed-based analysis using substantia nigra (SN) and lentiform nucleus (LN) as seeds. Comparing to the PD-NP group, the PD-P group demonstrates significantly higher resting functional connectivity (rFC) between left LN and bilateral insula, lower rFC between right LN and left striatum, and also between left LN and right striatum. Interestingly, comparing to PD-P subjects and HC group, the PD-NP subjects have the highest rFC between LN and the opposite site striatum. In those PD subjects with initial motor symptoms onset on the left side, the PD-P subjects have higher rFC between right SN and right middle cingulate cortex (MCC). After taking UPDRS motor score, depression and anxiety scores into analysis of covariance, the rFC between right SN and right MCC is significantly higher in PD-P group, and is also positively correlated to the VAS pain scale. Discussion: We found that PD related pain closely correlates to anxiety and depression, indicating that the affective component of pain processing that is relevant to PD pain. Further evidence is provided by the resting state functional connectivity study, which shows the relationship between PD related pain and the increased rFC between SN and limbic system. Also, the increment of rFC between bilateral basal ganglia in PD-NP subjects shows a compensatory mechanism which protects the PD-NP group from having pain, and further suggests a modulatory role of basal ganglia in pain processing.

Title: Acute effect of lead insertion into the basal ganglia on primary motor cortex in patients with Parkinson's disease

Authors: *N. C. ROWLAND[1], C. DE HEMPTINNE[2], N. SWANN[2], R. KNIGHT[3], P. STARR[2]
[1]Dept Biol, Univ. of California, San Francisco, SAN FRANCISCO, CA; [2]Univ. of California, San Francisco, San Francisco, CA; [3]Univ. of California Berkeley, Berkeley, CA

Abstract: Objectives An emerging hypothesis regarding akinesia and rigidity in Parkinson's disease (PD) posits that abnormal coupling of low-frequency beta (13-30 Hz) phase and broadband gamma (BBG) amplitude (70-200 Hz) within the cortico-basal ganglia (BG) loop prevents normal processing of motor control signals. Following surgical insertion of BG deep brain stimulation (DBS) electrodes in awake patients, there is often a temporary reduction in motor symptoms due to acute disruption of BG activity, termed the "microlesion effect". This effect should be associated with changes in motor cortex physiology. **Methods** We analyzed high-density electrocorticographic (ECOG) activity from 28-contact subdural strips placed directly over premotor, primary motor and primary sensory cortices during surgery for DBS lead placement in 10 patients with PD. Patients performed reach-and-point movements to a touchscreen tablet during a cyclical 'rest'-'prepare'-'move' sequence timed with visual cues. We compared our findings to five patients with essential tremor (ET) also undergoing DBS surgery. **Results** We found that the coupling of beta phase to BBG amplitude during rest was significantly higher in PD patients compared to patients with ET. This phase-amplitude coupling (PAC) was highest in primary motor cortex (PMC) in both groups. In PD patients, following placement of the DBS lead, PAC acutely decreased in PMC while movement-related BBG spectral power increased over both primary motor and sensory cortices. Five out of ten PD patients experienced improvement in arm rigidity within 1-3 min of lead insertion. **Conclusions** We have shown that PAC in patients with PD exceeds that of a comparison group without basal ganglia dysfunction during the resting state. In PD patients, this elevated coupling decreases acutely following DBS lead placement, a change restricted to primary motor cortex. During a whole arm reach task in PD patients, the degree of movement-related BBG synchronization increases over a distributed area of the sensorimotor cortex following DBS lead placement. We conclude that the so-called 'microlesion effect' in PD, in which temporary improvement in symptoms is seen acutely in some patients after DBS lead placement and prior to electrical stimulation, may be mediated in part by decreased phase-specific entrainment of cortical BBG activity by beta oscillations, resulting in a more robust gamma signal able to resume efficient processing of motor control signals.

Title: Studies on a transgenic (zQ175) model of Huntington's disease using functional imaging in awake mice: evidence of huntingtin-associated-protein 1 dysfunction

Authors: *J. R. YEE[1], P. KULKARNI[1], W. KENKEL[1], S. TODDES[2], M. NEDELMAN[3], C. F. FERRIS[1]
[1]Ctr. for Translational Neuroimaging, Northeastern Univ., Boston, MA; [2]Animal Imaging Res., Holden, MA; [3]Ekam Imaging, Boston, MA

Abstract: BOLD imaging in awake mice was used to identify differences in brain activity between wild-type, HETzQ175 and HOMzQ175 genotypes in response to the odor of almond. The study was designed to see how alterations in the huntingtin gene in a mouse model of Huntington's disease would affect the perception and processing of almond odor, an evolutionarily conserved stimulus with high emotional and motivational valence. Moreover, the mice in this study were "odor naive" i.e. never having smelled almond or any nuts. Using a segmented, annotated MRI atlas of the mouse and computational analysis, seventeen out of one-hundred and sixteen brain regions were identified as responding differently to almond odor across genotypes. These regions included the glomerulus of the olfactory bulb, forebrain cortex, anterior cingulate, subiculum and dentate gyrus of the hippocampus, and several areas of the hypothalamus. In many cases these regions showed a gene-dose effect with HETzQ175 mice showing a reduction in brain activity from wild-type that is further reduced in HOMzQ175 mice. Conspicuously absent were any differences in brain activity in the caudate/putamen, thalamus, CA3 and CA1 of the hippocampus and much of the cortex. These targeted areas in Huntington's disease, that show dramatic changes in function and morphology with disease progression, were not identified with the presentation of almond odor. Instead, the pattern of brain activation differentiating these genotypes fit very closely with the reported neuronal localization and concentration of huntingtin-associated-protein 1. The imaging findings suggest that the mutant Htt protein expressed by the HETzQ175 and HOMzQ175 genotypes interferes with one of the reported functions of huntingtin-associated-protein 1 - regulation of feeding behavior.

[1]Neurol., UCLA, Los Angeles, CA; [2]Evotec Ltd, Hamburg, Germany; [3]CHDI Management/CHDI Fndn., Los Angeles, CA; [4]Isis Pharmaceuticals Inc., Carlsbad, CA

Abstract: We have previously shown that short term (2 weeks) administration of antisense oligonucleotides (ASO) dose-dependently decrease the levels of huntingtin in the brain of Q140 mice, a knock-in model of Huntington's disease (HD) that presents robust behavioral, pathological and molecular deficits from a young age. Specifically, Htt ASO 75ug/d decreased Htt mRNA and HTT protein ~50% immediately following termination of treatment and the effect persisted several weeks. In the present study we tested the efficacy of the same Htt ASO that targets both mutant and wild type (WT) huntingtin mRNA to ameliorate deficits in heterozygous Q140 knock-in (Het Q140) mice. Lead anti-Htt ASO (30 or 75ug/d), a control,

RNase H-inactive, ASO (30 or 75ug/d), or sterile saline vehicle were infused intracerebroventricularly (ICV) in male Het Q140 mice or WT littermates at 5.5 months. Mice were tested at 7 months in Open Field (4 weeks post-treatment), at 7.5 months in Holeboard cognitive test (6 weeks post-treatment) and at 8-8.5 months for running wheel activity (8-10 weeks post-treatment). Behavioral deficits in Het Q140 mice were not ameliorated by lead Htt ASO at either dose. Striatal transcripts for enkephalin, dopamine receptor 2, phosphodiesterase 10a, cannabinoid receptor 1 and DARPP-32 were decreased in 8.5 months Het CAG140 mice, with no effect of ASO treatment. Total Htt mRNA and WT and mutant Htt protein levels were still decreased ~35% in striatum, cortex and posterior brain regions at ten weeks post-treatment in 8.5 months old Het Q140 mice administered with lead Htt ASO 75ug/d. In contrast, as expected, Htt ASO did not significantly affect the levels of an aberrantly spliced exon 1 Htt mRNA that encodes an N-terminal mutant HTT fragment and was detected in Het Q140 mice striatum. The results indicate a lack of beneficial effects of lead Htt ASO in Het Q140 mice despite sustained reduction of 35-50% of full length Htt mRNA and HTT protein for up to 3 months.

Title: Alterations in thalamostriatal glutamate input to the direct and indirect pathway striatal medium spiny neurons in the R6/2 mouse model of Huntington’s disease

Authors: *C. K. MESHUL[1,2], C. MOORE[1], C. CEPEDA[3], M. S. LEVINE[3]
[1]Neurocytology Lab/Bldg 101, Room 520, VA Med. Ctr., PORTLAND, OR; [2]Behavioral Neurosci., OHSU, Portland, OR; [3]Intellectual and Developmental Disabilities Res. Ctr, Semel Institute, Brain Res. Inst., UCLA, Los Angeles, CA

Abstract: Huntington's disease (HD) is a progressive neurological disorder with symptoms of chorea and cognitive disturbances. HD is characterized by the loss of neurons primarily within the striatum and cerebral cortex. The R6/2 is a rapid progressing model of HD and can be used to determine synaptic changes by 90 days of age. Alterations in corticostriatal function and glutamate release have been well characterized in this model (Raymond et al., 2011). Using the Q140 HD animal model, Deng et al. (2013) reported a long-term decrease in the number of striatal nerve terminals making an asymmetrical synaptic contact originating primarily from the thalamus with no change in the number of contacts projecting from the cortex. We determined the changes in the relative density of nerve terminal glutamate immuno-gold labeling in identified terminals originating from either the motor cortex (vesicular glutamate transporter 1:VGLUT1) or thalamus (vesicular glutamate transporter 2: VGLUT2) that were contacting either the direct pathway (dopamine D1 receptors) or the indirect pathway (dopamine D2 receptors) medium spiny neurons. We find that within the dorsolateral striatum, there was a 38% decrease in the number of VGLUT2 (thalamostriatal) positive synaptic contacts onto spines in the R 6/2 vs the wildtype group (WT) per field of view (14 μm2) ($p \leq 0.0003$). There were no changes in the number of VGLUT1 (corticostriatal) contacts. The density of glutamate immuno-gold labeling within nerve terminals contacting direct pathway spines was significantly decreased in R6/2 mice (WT: 113.9±2.7 particles/μm2 vs R6/2: 92.4±4.4, $p \leq 0.001$) but increased in terminals contacting indirect pathway spines in the R6/2 mice vs WT (WT: 95.2±3.6 vs R6/2: 127.5±4.9, $p \leq 0.001$). There was a decrease in the density of glutamate immuno-gold labeling within the thalamostriatal positive terminals (WT: 80.3±2.1 vs R6/2: 65.2±3.2, $p \leq 0.001$) but no change in the density of glutamate labeling from corticostriatal positive terminals (WT: 73.4±2.3 vs R6/2: 78.5±3.6). There was a significant decrease in the R 6/2 mice in the density of nerve terminal glutamate immuno-gold labeling from cortical terminals making synaptic contact onto either direct or indirect pathway labeled spines (WT: 89.8±3.5 vs R6/2: 75.3±2.5, $p \leq 0.006$ for direct pathway endings; WT: 99.5±4.1, R6/2: 86.5±3.9, $p \leq 0.03$ for indirect pathway endings). These data suggest that in the R6/2, the thalamostriatal pathway is significantly affected compared to the corticostriatal pathway and that the decrease in thalamostriatal nerve terminal glutamate immuno-gold labeling occurs in terminals contacting MSNs of both the direct and indirect pathways.

Abstract: Huntington's disease (HD) is an autosomal dominant neurodegenerative disorder caused by a mutation localized in the gene encoding the huntingtin protein. Damaging mainly subcortical structures such as the basal ganglia, of which the most affected, are the caudate nucleus and putamen, which in lower mammals are referred to as striatum. Numerous mechanisms has been proposed in the pathophysiology as excitotoxicity, lack of neurotrophic support, disruption of energy metabolism and transcriptional alterations. It is postulated that interact together, allowing partially explain the selective degeneration of striatal GABAergic neurons observed in Huntington disease. Thus, murine models have provided a stage for the investigation of the pathophysiological mechanisms associated with the development and the selectivity of the pathology of Huntington's disease. Using the animal model of the 3-nitropropionic acid 3-NP, it is a toxin that is used as animal model for Huntington disease; we studied the possible compensatory change of GABA currents. We did whole cell recordings of GABA currents in medium (MSN) and large neurons (LN) acutely dissociated from striatum of mice C57BL/6. By using the voltage clamp technique (whole cell), we analyze MSN and LN. We used concentrations from 100 nM to 1000 µM of GABA. Taking the control condition as 100% of current, the current GABA in mouse treated with 3-NP shows a biphasic effects meanwhile at 100 nM of 3-NP increased GABA currents by 62.2 %, at concentrations from 3 µM to 1 mM GABA currents were decreased with an EC50 of 6.16 µM in MSN for the control and 45.1 µM for 3 -NP. In LN we found a reduction EC50 of 83.0 µM for the control and 76.2 µM for the 3-NP-treated group. The recovery time constant tau (τ), to two successive applications of the neurotransmitter, is 12.1 ± 0.7 s (n = 3 cells) for the control group and τ = 9.0 ± 0.6 s (n = 3 cells) for treated with 3-NP. In addition, we also analyze IV of GABA current

(100μM)in order to determine the equilibrium potential of IGABA and GABA current conductance. Our results suggest that 3-NP treatment induce changes in GABA currents that can explain the differential effect founded between MSN and LN from striatum in Huntington disease.

Title: Characterizing a novel knock-in mouse model of Huntington's Disease

Authors: *J. K. CAO[1], P. DETLOFF[2], N. STELLA[1]
[1]Pharmacol., Univ. of Washington, Seattle, WA; [2]Biochem. and Mol. Genet., Univ. of Alabama, Birmingham, Birmingham, AL

Abstract: Huntington's Disease (HD) is a devastating inherited autosomal dominant neurodegenerative disease with no known cure and few palliative treatment options available. HD is characterized by progressive deterioration of motor, cognitive and psychiatric function. At disease onset, the average survival time is 15-25 years and end-stage patients are profoundly demented and debilitated. There is need for an improved HD mouse model that thoroughly recapitulates the neuropathological and symptomatic features found in human HD to better understand the pathological process and to develop novel treatments. The HdhQ mouse model was developed by knocking-in pathogenic-sized CAG repeats into the *Hdh* gene, the mouse homolog of the Huntington's Disease gene. An allelic series of the HdhQ model has been generated with repeats from 50 to 350 CAGs in length and this mouse line represents a developing, powerful mouse genetic tool. Several of these lines recapitulate critical HD pathological processes and symptoms, however it is unclear whether this holds for repeat lengths above 300. Here we seek to characterize several pathological indices and behavioral impairments in the longest of the allelic series, the newly developed HdhQ350 model. Longitudinal studies of behavioral phenotypes and histology will uncover the age of disease onset in this mouse line.

Behavioral tests will address motor, cognitive and psychiatric-like phenotypes commonly measured in HD research. Semi-quantitative immunohistochemistry will be used to study disease progression at various time points, examining classic HD molecular pathogenesis, such as mutant Huntington protein aggregation in the nucleus and cytoplasm, loss of synaptic proteins and astrocyte activation. Our preliminary results indicate that at 20 weeks of age, there is no distinguishable difference in behavioral phenotypes between HdhQ350 mice and their wild-type littermates. Our studies are designed to uncover accelerated motor and cognitive decline, as well as mutant Huntington aggregation and reduced synaptic markers in the striatum in the HdhQ350 mouse line. These studies will disclose if the HdhQ350 mouse line is an improved model for the elucidation of pathogenic pathways in HD, providing a foundation for future HD studies and drug discovery.

Abstract: Early stages of Huntington's disease (HD) are characterized by subtle dysfunctions in cortical synaptic and network physiology that may contribute to motor and cognitive deficiencies and lead to later stage neurodegeneration. Therapeutic intervention at early stages could halt or reverse disease progression prior to gross neuronal loss. Identification of an EEG biomarker to detect early neuronal network dysfunction in HD animal models and in humans would provide a valuable tool to guide therapeutic discovery and development. In previous studies (Cottrell et al., SFN 2012, 154.02), we observed alterations in network activity in HD mouse models (zQ175, BACHD) in prefrontal cortex during habituation to a novel environment and in auditory cortex

during an auditory steady state response paradigm (ASSR, auditory click trains over a range of discrete frequencies: 20-100 Hz). We have extended these studies, performing a longitudinal study of the zQ175 model as well as additional HD models (HdhQ20, HdhQ80) using the ASSR paradigm. Alterations in the steady state response recorded in auditory cortex were observed in all HD models at all ages tested. Preliminary results indicate the potential of utility of ASSR as an EEG biomarker for HD.

Title: Mutant-huntingtin transgenic songbirds: A new model for the study of progressive vocal learning disorder

Authors: ***W.-C. LIU**, J. KOHN, S. SZWED
Rockefeller Univ., NEW YORK, NY

Abstract: Progressive speech or vocal disorder characterizes many neurodegenerative diseases; however, the lack of complex vocal-learning behavior in current mammalian models makes it difficult to study deteriorating vocal-motor learning within specialized brain regions. Vocal learning in songbirds is a complex and highly quantifiable vocal-motor behavior. The learning and production of a song involves a well-defined and specialized cortico-basal ganglia (CBG)“song circuit” that is comparable to human brain regions used for speech learning. We use transgenic songbirds as a genetic model for the study of progressive vocal-learning disorder in Huntington’s Disease (HD). HD is a genetic, neurodegenerative disorder caused by mutation of

the huntingtin (Htt) gene. Subsequent mutant-huntingtin protein induces neuronal degeneration in the CBG circuit, which results in progressive motor dysfunction. Here we created transgenic songbirds expressing lentiviral-mediated human full-length mutant-huntingtin gene (145Q). Remarkably, the mutant birds show severe and progressive vocal learning disorders that are comparable to those of human HD. These vocal deficits include poor imitation of tutor song, progressive song degradation, sustained variability in syntax and syllable structures, and variation in the timing of song crystallization. Additionally, the degree of vocal disorder in mutant birds is correlated with down-regulation of dopamine and androgen receptor expression in the CBG "song circuit". These transgenics are the first experimentally created songbird functional mutants, making songbirds a powerful new animal model system to explore and manipulate the genetic mechanisms and brain circuit function that underlie complex vocal learning or vocal disorders.

Title: Muscular volumetric and metabolite characterization of R6/2 and zQ175 knock in mice of Huntington's disease

Authors: K. LEHTIMÄKI[1], T. LAITINEN[1], T. HEIKKINEN[1], A. NURMI[1], *O. M. KONTKANEN[1], I. MUNOZ-SANJUAN[2], L. C. PARK[2]

Abstract: HD patients suffer from debilitating and progressive motor defects such as chorea, rigidity, dystonia and general muscle weakness and wasting. In the current study, we have characterized the MR imaging (MRI) -based volumetric changes in gluteus maximus and quadriceps muscles in R6/2 (4 and 12 weeks age) and zQ175KI (6, 9 and 12 months) mice to assess HD-associated muscular changes in rodent models of HD. In addition, ^{1}H MR spectroscopic (MRS) data from quadriceps muscle were acquired to evaluate whether muscle wasting is accompanied with low-molecular weight metabolite and fatty acids changes. MRI and MRS experiments were carried out using a horizontal 11.7 Tesla Bruker BioSpec small animal

scanner. Smaller but non-significant gluteus maximus and quadriceps muscle volumes between the wild-type and R6/2 transgenic mice was detected at 4 weeks old. At 12 weeks of age, the muscle volumes in WT mice increased by over 40%; whereas, those in R6/2 didn't increase. In zQ175KI, muscles at 6 months old homozygotes and 9 months old heterozygotes display the significant volume loss compared to those in wild-type littermates and continued to have the muscle volume loss (>20%) over the next three months. R6/2 quadriceps muscle showed mild genotype differences in ^{1}H MRS analysis compared to wild-type littermates at 4 weeks old, with increase in the intra-myocellular lipids, taurine and total cholines, but no significant changes at 12 weeks of age. Based on these observations, HD related muscle wasting in rodents does not seem to be associated with significant fatty acid accumulation. These MRI/MRS readouts may help to further understand the muscle pathophysiology of HD as well as to develop a potential biomarker for the disease and therapeutic application.

Title: Early fine motor skill impairment of R6/2 and zQ175 knock in mice of huntington's disease

Authors: T. HEIKKINEN[1], T. BRAGGE[1], *J. T. PUOLIVALI[1], A. NURMI[1], O. KONTKANEN[1], I. MUNOZ-SANJUAN[2], L. C. PARK[2]

Abstract: R6/2 mice and zQ175 knock-in (KI) mice of Huntington's disease (HD) exhibit progressive gross motor deficits as studied with conventional sensory motor tests. We have previously shown characteristics of fine motor skill deficits of R6/2 and Q175 mice at symptomatic age of 10-12 weeks. In this study, we characterized fine motor deficits in these mice at early, 4-5 weeks of age using an automated high precision movement analysis system. HD and wild-type mice were tested at three modes of moving: walking, ladder walking and wading. The gait was recorded with a high speed camera, imaged and analyzed simultaneously

from three spatial dimensions, via comprehensive kinematic algorithms. Body parts were marked with a contrast agent to enhance point-wise detection in the x- and y-axis. Each point of movement trajectory was calculated as a change in coordinates and used for data analysis. The parameters analyzed, including gait characteristics and fine motor movements, were compared between the genotypes to reveal disease specific defects. Results indicate that both R6/2 and zQ175KI mice display phenotypical HD-like fine motor deficits already at an early age of 4-5 weeks, such as lowered back body postures and increased angle ranges of the limb joints. Specific deficits are observed in the more challenging modes of movement, i.e. in ladder walking and wading. This method is applicable not only to study motor defect development in rodent models of HD and other motor impairment diseases, but also to capture very early, more subtle pathological symptoms with fine motor skill changes, and may offer a sensitive tool to investigate the efficacy of therapeutic drugs that improve early and subtle motor functions.

Title: Modulation of GABAergic plasticity in a mice model of striatal degeneration

Authors: E. NIETO-MENDOZA, *E. HERNANDEZ-ECHEAGARAY, Dr
Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Dopamine (DA) is involved in several functions of basal ganglia like motor functions, cognition and synaptic plasticity. In the striatum, DA modulates synaptic transmission, as well as short and long term synaptic plasticity. Activation of D1 dopamine receptors (D1), increases glutamatergic currents of corticostriatal pathway, and stimulation of D2 dopamine receptors (D2) attenuates them. In addition D1 and D2 activation play a part in corticostriatal long-term depression (LTD), while D1 plays a role in the long-term potentiation (LTP). DA also modulates

short term depression (STD) in GABAergic synapses; however it is not well known how DA participates in long term plasticity of striatal inhibitory synapses. As local circuits in the striatum are GABAergic, and MSNs activity is under the control of GABAergic interneurons (GI), in this work we analyze both dopaminergic modulation in GABAergic synapses and synaptic plasticity between the GI and MSNs. Our results demonstrated that DA was important for synaptic plasticity. Differential activation of DA receptors with specific agonist or DA in high or low concentration modifies plasticity; high concentrations of DA (20μM) induced LTP mainly while low concentration of DA (200nM) produced LTD. Modulation of DA on GABAergic synapses and in striatal plasticity was compared in an animal model of striatal degeneration induced with the mitochondrial toxin 3-nitropropionic acid (3-NP). Striatal damage changed plasticity and DA modulation of GABAergic synapses. Interestingly DA in high concentration mimics the plasticity induced in the animal model of striatal degeneration.

Title: Accelerated disease progression in the r6/2 mouse model induced by the tetracycline transactivator

Authors: K. L. WHEATON[1], K. OBRIETAN[2], *K. R. HOYT[1]
[1]Pharmacol., [2]Neurosci., Ohio State Univ., COLUMBUS, OH

Abstract: The tetracycline-controlled transcriptional activation system is a popular, and powerful method for enhancing or mitigating expression of a gene *in vivo*. We are interested in using this system to overexpress genes of interest in the r6/2 mouse model of Huntington's disease (HD) as a means to slow the progression of disease. As our research was ongoing, Han et al 2012 (J Neurosci. 31:10574) reported deleterious hybrid strain effects when the tetracycline transactivator (tTA) protein was driven in neurons using the calcium/calmodulin-dependent kinase II α (CaMKIIα) promoter, similar to our experimental approach. Since the r6/2 mice are a hybrid strain of C57BL/6 and CBA mice, this potentially complicates the interpretation of our

results. To assess the impact of neuronal tTA expression in the hybrid background r6/2 strain, we studied four cohorts of animals, HD, WT, HD/tTA and WT/tTA. We determined the progression of HD by measuring motor coordination and weight, as these are evident markers of disease in human patients. Starting at four weeks of age and continuing weekly until euthanized at ten weeks, mice in each cohort were challenged on the rotarod and weighed. Interestingly, mice in the HD/tTA cohort performed significantly worse on the rotarod. At six weeks HD mice failed the rotarod after 230.4s (n=15), whereas HD/tTA mice failed after 160.5s (n=11). Additionally, the HD/tTA genotype had a more rapid increase in weight from four to eight weeks, followed by a more rapid weight loss from eight to ten weeks, compared to the HD cohort. Expression of tTA did not alter rotarod performance or weight in WT mice. Preliminary results indicate that neuronal tTA expression in HD mice does not lead to increased neuronal cell death (by fluorojade labeling) nor increases in neuronal expanded-repeat huntingtin expression/aggregation (by fluorescence immunohistochemistry). Additionally, tTA expression levels were comparable in HD and WT mice (by qPCR). The aforementioned research group linked a protective gene in the C57BL/6 mice, and when diluted in a hybrid strain, led to tTA neurotoxicity. While the precise mechanism of how tTA exacerbates the progression of HD has yet to be elucidated, our results raise awareness of the deleterious impact of neuronal tTA in hybrid background animals. Strain differences may create undesired effects from the transgenic system alone, compromising the credibility of the observed gene-effect.

Title: Electrophysiological characterization of R6/2 and zQ175 knock in mice of huntington's disease using implanted telemetry

Authors: *H. CHADCHANKAR[1], T. HEIKKINEN[1], A. NURMI[1], O. KONTKANEN[1], I. MUNOZ-SANJUAN[2], L. C. PARK[2]
[1]Charles River Discovery Res. Services Finland, Kuopio, Finland; [2]CHDI Management/CHDI Fndn., Los Angeles, CA

Abstract: Huntington's disease (HD) is a progressive neurodegenerative disease characterized primarily by the symptoms of chorea and seizures. However, chorea has not been well studied in HD preclinical models. Moreover, the sporadic nature of subclinical and overt seizures presents a significant challenge in studying these changes in mouse models. In this study, we used implanted telemetry devices equipped with biopotentials to measure changes in electroencephalogram (EEG) and electromyogram (EMG) in HD mouse models. 7-week old zQ175 knock-in (KI) homozygous mice and 6-week old R6/2 mice were implanted with a telemetric radio transmitter. Recordings were made biweekly over a period of three months in zQ175KI homozygous mice and weekly in R6/2 mice over a period of 18 weeks. EEG was recorded with biopotentials implanted in the cortex and EMG was recorded with biopotentials implanted on trapezius and gluteus maximus muscles. Subclinical seizures, as defined by lack of overt convulsions, were observed cortical EEG in R6/2 mice from the age of 8 weeks and their prevalence increased significantly with increasing age. 10-week old R6/2 mice displayed significant electrical discharge consistent with overt seizures. Similar subclinical seizures were also found in cortical EEG in 9-month old zQ175KI homozygous mice. No such activity was observed in age-matched WT mice. Preliminary analysis of EMG revealed that the R6/2 transgenic mice show rhythmic, irregular innervation of muscles at rest possibly indicating deficits in neuromuscular junction and hyperexcitability of muscles in HD mice. These results provide a novel approach to study chronic electrophysiological alterations in HD mice to study underlying abnormalities and screen potential therapeutic drugs.

Title: Central and autonomic dysfunction induces severe abnormalities of circadian rhythm and cardiac function in R6/2 and zQ175 knock in mice of huntington’s disease

Authors: H. CHADCHANKAR[1], T. HEIKKINEN[2], A. NURMI[1], *N. E. VARTIAINEN[1], O. KONTKANEN[1], I. MUNOZ-SANJUAN[3], L. C. PARK[3]

[1]Charles River Discovery Res. Services, Kuopio, Finland; [2]Charles River Discovery Res. Services Finland, Kuopio, Finland; [3]CHDI Management/CHDI Fndn., Los Angeles, CA

Abstract: Huntington's disease (HD) is a progressive neurodegenerative disease that produces a wide variety of symptoms in addition to primary motor deficits. However, the precise nature of these symptoms and causes of mortality are poorly understood. In this study, we characterized circadian rhythm and cardiac abnormalities in two HD mouse models using implanted telemetry device. 7-month old zQ175 knock-in (KI) homozygous and 6-week old R6/2 transgenic mice were used along with their wild-type (WT) littermates. Locomotor activity and core body temperature were monitored using intraperitoneally implanted radio transmitters equipped with biopotentials. Electrocardiogram (ECG) was recorded with biopotentials implanted in lead II configuration. Recordings were made biweekly over a period of three months in zQ175KI homozygous mice and weekly in R6/2 mice over a period of 18 weeks. Both HD mouse lines displayed significant hypoactivity during the dark cycle phase compared to WT mice. However, there was no difference between their activity during the light cycle phase. Both HD mouse lines also displayed lower core body temperature than WT mice. These HD mouse lines also exhibited significantly elevated heart rate. The difference in heart rate became pronounced from the age of 7 months and 9 weeks in Q175 and R6/2 mice, respectively. The R6/2 mice also showed age-dependent alterations in PQRST waves in ECG from the age of 7-8 weeks with clear exacerbation in cardiac wave propagation by the age of 15 weeks, including cardiac arrhythmia. Detailed frequency domain analysis of ECG revealed clear deficits in parasympathetic and sympathetic innervations of cardiac function in HD mice in comparison to WT mice, reflecting autonomic dysfunction induced by HD. Consistent with earlier studies, we also observed decreased heart rate variability in HD mice further suggesting impairment in maintaining adequate cardiac output. This study highlights that HD produces significant impairment in the circadian rhythm and cardiac function in HD mouse models. The study also highlights novel therapeutic areas to target autonomic dysfunction in HD.

Title: Engineered mesenchymal stem cells to overexpress BDNF for the treatment of Huntington's disease

Authors: *H. STEWART[1], K. POLLOCK[1], W. CARY[1], H. NELSON[1], C. NACEY[1], K. PEPPER[1], K. D. FINK[1], W. GRUENLOH[1], G. ANNETT[1], T. TEMPKIN[2], V. WHEELOCK[2], J. A. NOLTA[1]
[1]Stem Cell, UC Davis, Sacramento, CA; [2]Neurol., Univ. of California, Davis, Sacramento, CA

Abstract: Huntington's disease (HD) is an autosomal dominant disorder caused by an expanded CAG trinucleotide repeat that causes a progressive degeneration of neurons in the putamen and caudate nucleus. Survival and function of striatal neurons is dependent on brain-derived neurotrophic factor (BDNF), and levels of this trophic factor are significantly reduced in HD patients. Recently, strategies aimed at BNDF restoration have become a leading candidate for the treatment of HD. Transplantation of adult stem cells, such as bone marrow-derived mesenchymal stem/stromal cells (MSC), show considerable therapeutic promise through stimulation of endogenous neuronal growth, decreased neuronal apoptosis, regulation of inflammation, and the secretion of trophic factors. MSC are readily available, easily expanded *in vitro*, have immunomodulatory properties, and can be easily engineered to over-produce trophic factors. Previously, in mouse and rat models of HD, it has been shown that allogeneic transplantations of MSC can significantly delay the onset of behavioral abnormalities and reduce the severity of neuropathological changes in both transgenic and toxic lesion models of HD. In a pivotal proof-of-concept study, transgenic mice showed significant behavioral and neuropathological sparing following the intrastriatal administration of MSC engineered to over-express BDNF. The aim of the current study is to test the pre-clinical safety and efficacy of human MSC, genetically engineered to produce BDNF, for the treatment of HD. Our developmental candidate is allogeneic human MSC engineered, using a lentiviral vector, to secrete BDNF (MSC/BDNF). Our product combines the beneficial effects of MSC administration with the benefits of sustained BDNF production. These proof-of-concept and safety studies are being conducted in support of HD-Cell, a planned future Phase I clinical trial designed to examine the safety and potential efficacy of MSC/BDNF. The current studies focus on the optimal transduction coefficients, the level of BDNF produced by our developmental candidate, the karyotypic stability of the candidate, the safety profile following transplantation in immune deficient mice, cell retention *in vivo*, and efficacy following transplantation in the YAC128 and R6/2 (120 CAG) transgenic

mouse models of HD, as IND-enabling studies for the FDA, in support of a future planned Phase I clinical trial. *Support for this project was provided by CIRM grants no. TR1-01257 (Nolta) and DR2-05415 (Wheelock/Nolta), NIH Director's transformative award 1R01GM099688 (Nolta), and philanthropic donors from the HD community, including the Roberson family and TeamKJ.*

Title: A detailed description of the Huntington's disease-like pathology exhibited by the HdhQ150/150 mouse

Authors: *I. RATTRAY[1], E. J. SMITH[1], W. R. CRUM[2], T. A. WALKER[1], R. GALE[1], G. BATES[1], M. MODO[3]
[1]Dept. of Med. and Mol. Genet., [2]Dept. of Neuroimaging, King's Col. London, London, United Kingdom; [3]McGowan Inst. for Regenerative Med., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The HdhQ150/Q150 knock-in mouse model of Huntington's disease (HD) carries an expanded polyglutamine sequence in the mouse huntingtin homologue, resulting in the eventual development of HD-like pathology at a slower rate than the more commonly used transgenic models. Using a combination of behavioral assessments, magnetic resonance imaging (MRI) and histology, this study will provide a longitudinal, integrated analysis of the progressive pathology exhibited by this mouse line with a particular focus on the early stages of disease progression. Both male and female, wild type and HdhQ150/Q150 mice were used. To probe functional abnormalities, a detailed battery of behavioral measures was applied including rotarod, grip strength, open field, olfactory discrimination, social interaction, cued and contextual fear conditioning, as well as learning in a swimming T-maze. These tests were coupled with

longitudinal *in vivo* MRI to monitor regional brain atrophy and T2 relaxivity (reflective of brain tissue composition) at 2, 4, 6, 9, 12, 18 and 22 months of age, whereupon the mice were culled. Preliminary analyses indicate age-related loss of volume in several key brain regions. Indeed, high resolution *ex vivo* MRI was conducted prior to post-mortem histological analysis of neuropathology to further support *in vivo* measures. Tensor Based Morphometry analyses of these images revealed a substantial, widespread brain volume loss at this late age. Correlative analyses will ultimately probe links between behavioral changes and brain abnormalities determined through MRI and histology. This continuing and developing description of the HdhQ150/Q150 knock-in mouse model will provide crucial information as to the progression of HD-like pathology, as well as to what extent functional deficits are associated with neuropathological changes in this line.

Title: Reducing caspase 6 activity by AAV-mediated RNAi partially ameliorates disease manifestations in the YAC128 mouse model of Huntington's disease

Authors: *L. M. STANEK[1], B. MASTIS[1], S. P. SARDI[1], B. WONG[2], S. LADHA[2], D. EHRNHOEFER[2], M. HAYDEN[2], S. H. CHENG[1], L. S. SHIHABUDDIN[1]

Abstract: Huntington’s disease (HD) is a fatal, dominant neurogenetic disorder. The molecular basis of HD has been determined to be due to an expansion of the trinucleotide CAG in exon 1 of the huntingtin gene (HTT). The resultant expansion of a polyglutamine tract in the mutant huntingtin (HTT) protein confers a toxic gain of function. Fragments resulting from proteolysis of the mutant HTT protein (mHTT) by caspases have been implicated in the pathogenesis of HD. In particular, proteolysis of mHTT by caspase-6 cleavage has been implicated in mediating neuronal dysfunction and neurodegeneration. Inhibiting caspase 6-mediated proteolysis of mHTT in the YAC128 mouse model of HD reportedly rescues all of the HD-like phenotypes

evaluated in this model. This observation of abatement of the HD phenotype in caspase-6-resistant (C6R) YAC mice (harboring 133CAG repeats in the HTT gene) suggests that caspase 6-mediated cleavage at residue 586 of HTT contributes to the development of disease. Hence, facilitating a reduction in caspase 6 activity may be protective for HD. To further validate caspase 6 as a therapeutic target for HD, we generated a recombinant AAV2/1 vector encoding a miRNA-based hairpin designed to lower expression of caspase 6 (AAV-miRNA-C6). Vectors were delivered via direct intra-striatal injections into 3 months old YAC128 mice or wild type littermate controls. Both motor and affective behaviors were evaluated and tissues were harvested for histological and biochemical analysis at 4 months post-injection. Biochemical analysis of striatal extracts from AAV-miRNA-C6-treated animals showed significantly lower levels of caspase 6 compared to AAV-null injected controls. Behavioral analysis of YAC128 mice injected with AAV-miRNA-C6 showed improvements in the rota-rod motor test for coordination and a trend towards improvement on the tail suspension test for depression. These findings support an important role for caspase 6 in HD pathogenesis and provide a rationale for developing therapeutic strategies to inhibit caspase 6 activity.

Title: Earlier deficits are associated with increased aberrantly spliced mutant huntingtin in knock-in mouse models of Huntington's disease

Authors: *N. R. FRANICH[1], M. A. HICKEY[1], A. NEUEDER[2], T. CHU[1], C. ZHU[1], N. H. BOVE[1], V. LEMESRE[1], R. P. LERNER[1], J. S. STEFFAN[3], S. O. ZEITLIN[4], G. P. BATES[2], M.-F. CHESSELET[1]

Abstract: We have previously shown marked differences in onset/progression in fully backcrossed Q140 knock-in (KI) and HdhQ150 KI mice. These lines differ in the sequence of exon 1, with the Q140 mice carrying a chimeric human/mouse exon 1 containing an expanded CAG repeat and the human proline-rich region (PRR) inserted into the mouse Htt gene whereas the HdhQ150 KI mice have an expanded CAG repeat inserted into the Htt gene with a murine PRR. Both models exhibit ~40% neuronal loss in the striatum by 2 years of age, preceded by progressive neuropathological abnormalities and motor deficits, but Q140 mice present abnormalities and deficits at a much younger age than HdhQ150 KI mice. Specifically, backcrossed Q140 mice show decreased locomotion in the open field at 1, 4 and 6 months, impairment in the pole task at 4 months and decreased running wheel performance at 6 months. Q140 mice also show early cognitive impairment with decreased spontaneous alternation in the Y-maze at 3 months. In contrast, HdhQ150 mice were not impaired in these tests at the same ages. Furthermore, a marked difference in huntingtin (HTT) immunostaining between these mice was evident by 4.5 months of age, with Q140 mice, but not HdhQ150 mice, showing diffuse nuclear staining, microaggregates, nuclear inclusions and neuropil aggregates in the striatum and cortex using pEM48, MW8, and S830 antibodies. Both lines show similar HTT staining using 4H7H7 expanded polyglutamine antibody following antigen retrieval. Western blotting of striatal nuclear protein extracts using anti-HTT PW0595 shows that Q140 mice have 2-fold more insoluble aggregates than HdhQ150 at 6 months, whereas HdhQ150 mice show 5-fold more soluble HTT fragments (Franich et al., 2011 SfN abstract). We now show that, at 6 months, both lines have similar decreases in striatal transcripts including enkephalin, DARPP32, dopamine receptor 2 and cannabinoid receptor 1, indicating that alterations in these transcripts precede pathological and behavioral deficits in HdhQ150 mice. Notably however, the level of an aberrantly spliced exon 1 Htt mRNA that encodes a toxic N-terminal mutant HTT fragment (Sathasivam et al., PNAS 2013) is significantly higher in Q140 mice than HdhQ150 mice at 2 months of age. The results indicate that earlier deficits are associated with increased level of this aberrantly spliced Htt transcript, suggesting it may be a potentially important target for therapeutic intervention.

Title: Phenotypic characterization of BACHD hemi rats of huntington's disease

Authors: J. PUOLIVÄLI[1], *S. KIM[1], T. HEIKKINEN[1], T. BRAGGE[1], K. LEHTIMÄKI[1], T. LAITINEN[1], O. KONTKANEN[1], H. NGUYEN[2], I. MUNOZ-SANJUAN[3], D. HOWLAND[3], L. C. PARK[3]

Abstract: Huntington's disease (HD) is an autosomal neurodegenerative disorder, characterized by severe behavioral, cognitive, and motor deficits. BACHD transgenic rats (line TG5) are shown to display a robust, early onset and progressive HD-like phenotype including motor deficits and anxiety-related symptoms (Yu-Taeger et al. 2012). The purpose of this study was to further characterize the model with additional behavioral and imaging measurements. Both female and male hemi BACHD and WT rats at age of 2-13 months of age were used. Rats were tested for motor balance and coordination in rotarod, for locomotor activity in open field, for anxiety in Elevated Plus Maze, and for fine motor movements and gait properties using an automated high precision movement analysis system. Moreover, brain volumetry and metabolite levels were analyzed using MRI & 1H-MRS measurements. In a separate cohort, the BACHD and WT rats were tested in a water maze at 9-10 months of age using two different water temperatures (22°C and 28°C). BACHD rats did not differ from WT rats in their survival or general condition during the follow-up. Body weight was significantly increased in all study groups during ageing. The body weight of female BACHD rats was significantly higher compared to WT rats. Rotarod fall latency and open field activity were significantly decreased in BACHD starting as early as 2-3 months of age. In Elevated Plus Maze, BACHD rats spent more time in open arms at 6 and 10 month time points studied. No differences were observed between BACHD and WT rats in fine motor movements or gait properties. Volumetric MRI measurements revealed that BACHD rats had decreased brain volumetry starting as early as 2-3 months of age. In addition, several hippocampal and striatal metabolite changes were observed by 1-H MRS measurements at 2-10 months of age. In the water maze test, BACHD rats showed impaired reference memory acquisition compared to WT rats independent of water temperature as shown by increased distance and latency to find the hidden platform. In addition, BACHD rats

showed decreased swim speed and increased floating behavior compared to WT rats. These results confirm previously published observations that BACHD rats show clear motor deficits and anxiety-related symptoms compared to WT rats. Moreover, the BACHD rats also manifest decreased brain volumetry compared to WT rats. In conclusion, BACHD rats show several motor, emotional, cognitive and pathological changes resembling those observed in HD patients making them a valuable model for preclinical studies.

Title: Neurophysiological biomarkers for evaluating a Phosphodiesterase9A inhibitor for Huntington’s disease

Authors: D. NAGY, F. D. TINGLEY III, M. STOILJKOVIC, *M. HAJOS
Comparative Med., Yale Univ. Sch. of Med., New Haven, CT

Abstract: Several neurophysiological abnormalities have been described in Huntington's disease, including auditory gating deficit, which are considered to reflect impaired brain information-processing. Using clinically equivalent acoustic-stimulation paradigms, we have recently reported impaired auditory gating in transgenic BACHD (line5) rats under anesthesia and in freely-moving condition. The main goal of our current studies was to establish if auditory gating deficit in these transgenic animals could serve as a translational biomarker in drug development of Huntington’s disease. Phosphodiesterase (PDE) inhibitors have been considered as potential treatments for Huntington’s disease since previous findings have indicated dysregulations of PDEs activities, leading to a decrease in cyclic guanosine monophosphate levels in the striatum and hippocampus in Huntington’s disease patients and Huntington’s disease transgenic animals. Therefore, effects of PF-04447943 ((6-((3S,4S)-4-methyl-1-(pyrimidin-2-ylmethyl)pyrrolidin-3-yl)-1-(tetrahydro-2H-pyran-4-yl)-1H-pyrazolo[3,4-

d]pyrimidin-4(5H)-one), a recently developed selective phosphodiesterase9A (PDE9A) inhibitor (Kleiman et al., JPET, 341:396-409, 2012) were tested on auditory gating in BACHD transgenic rats. Electrophysiological recordings from the hippocampus CA3 region and primary auditory cortex were carried out under chloral hydrate anesthesia and non-anesthetized, freely-moving condition. PF-04447943 (1 mg/kg, sc) significantly improved auditory gating in anesthetized transgenic rats, fully abolishing the gating difference between transgenic and wild type rats. In freely moving transgenic rats, PF-04447943 dose-dependently improved their gating in both the hippocampus and primary auditory cortex. Furthermore, treatment of transgenic BACHD rats with daily administration of PF-04447943 (1 mg/kg) over 7-days resulted in an improvement in their auditory gating in both regions as evaluated 24 hours after the last treatment. In fact, differences in auditory gating and gamma band power between wild-type and transgenic BACHD rats were totally abolished after sub-chronic treatment with the PDE9A inhibitor. Our findings indicate that BACHD transgenic rats show abnormal auditory gating with features resembling those of Huntington's disease patients, which could be considered as potential translational biomarker for drug development in treatment of this disease.

Abstract: Huntington's disease (HD), a dominantly inherited neurodegenerative disorder with no effective therapy, is caused by expansion of the polyglutamine repeat in the huntingtin (Htt) gene. The most pronounced neuropathology in HD occurs in striatal medium spiny projection neurons (MSNs) leading to dysfunction of the cortico-striatal-thalamo-cortical network.

Impairment in this circuitry is also present in HD transgenic mice bearing mutated Htt including R6/2 and Q175 mouse models. Previous reports have shown that the hyperexcitable electrophysiological phenotype that develops in cortico-striatal brain slices with disease progression can be reversed acutely by exposure to several subtype-selective phosphodiesterase inhibitors (PDEi) *in vitro* (Kleiman et al., 2011 SFN) and that chronic, 6 month administration of the PDEi MP10 improved MSN function in slices prepared from Q175 mice. The aim of the present set of experiments was to evaluate behavioral and cognitive effects of long term, prophylactic treatment of MP10 in Q175 mice beginning in early adolescence, prior to the onset of disease progression. Mice began daily chronic treatment of MP10 at 2 months of age and were assessed for acquisition of touchscreen visual discrimination and reversal learning tasks in separate cohorts: cohort A) early training (acquisition began in pre-diseased mice at 4 months) and cohort B) training began at 6 months of age at a timepoint when disease symptoms are observed. The results of these studies and additional behavioral measures including motor assessments (open field and inverted screen tests), and activities of daily living (nesting) will be presented.

Title: Application of home cage monitoring in the behavioural characterization of Huntington R6/2 transgenic mouse model: An early diagnostic tool?

Authors: *R. DE HEER[1], M. MELLACE[2], G. BATES[3], B. M. SPRUIJT[2]
[1]Delta Phenomics, Ede, Netherlands; [2]Utrecht Univ., Utrecht, Netherlands; [3]King's Col., London, United Kingdom

Abstract: A lot of CNS compounds developed by pharmaceutical companies failed to get to the clinic and there is a need for more valid and faster animal models with more translational value. Many conventional tests have certain limitations and automated home cage monitoring could be

a solution. Not only is the latter as free from human intervention as possible, it provides a rich and varied environment and, thus, maximizes ethological validity, animal welfare and relevant behavioral challenges during (automated) behavioral tests. Because computer software takes care of monitoring, animals can be observed 24 hours a day, 7 days a week. Especially behavioral characterization of animal models for relatively slow developing neurodegenerative diseases may benefit from automation of otherwise laborious longitudinal studies. The R6/2 mouse strain is a frequently used model for Huntington's Disease and we observed 28 R6/2 females (15 transgenic and 13 wildtype) for several weeks in a row in their home cage (PhenoTyper®, Noldus Information Technology, Wageningen, the Netherlands) and many aspects of their locomotion, circadian rhythm and feeding/drinking behavior were measured using EthoVision XT® software (Noldus Information Technology, Wageningen, the Netherlands). Mice had ad libitum access to food and water and a shelter was provided as a place to sleep and/or hide. Home cage monitoring was interrupted in order to weigh the mice, to measure grip strength and quantitatively assess footfalls and gait. Differences in grip strength and gait became apparent when animals were 8 weeks old. With home cage monitoring behavioral symptoms were already evident at the age of 4 weeks: transgenic animals showed an increase in the time spent inside the shelter, but a significant decrease in the time they spent on top of the shelter. Differences in locomotion were found as well, but only after dividing locomotion bouts into slow movements (lingering) and fast movements (progressing): compared to the wildtype, transgenic mice showed less fast movements. With aging the differences between transgenic and wild type mice became more and more pronounced. Finding differences already at the age of 4 weeks indicates that automatic home cage monitoring could be used as an early diagnostic tool and may be the answer to the pharmaceutical companies' need of better and faster animal models.

Title: Structure/function analysis of the murine huntingtin N-terminus encoded by Htt exon 1 using knock-in mouse mutants

Authors: *E. ANDRE, J.-P. LIU, S. ZEITLIN
Neurosci., Univ. of Virginia, Charlottesville, VA

Abstract: The polyglutamine (polyQ) stretch of mammalian huntingtin (htt) is flanked by a highly conserved 17 amino acid N-terminal domain (N17), and a proline-rich region (PRR). The PRR can modulate the aggregation properties of mutant htt N-terminal fragments, and is a binding site for many proteins that interact with htt. The N17 domain regulates several normal htt functions, including htt relocation into the nucleus in response to ER stress, and htt's association with organelles such as ER, endosomes, and autophagosomes. In addition, post-translational modification of amino acids within the htt N17 domain can affect normal htt subcellular localization, and can also regulate the toxicity and degradation of mutant htt. To explore further the contribution of the protein domains encoded by the *Htt* exon 1 to normal htt function, we have generated knockin mice expressing versions of htt lacking both the polyQ and PRR regions ($Htt^{\Delta QP}$), and mice expressing a version of htt lacking the N17 domain ($Htt^{\Delta N17}$). We have obtained $Htt^{\Delta QP/\Delta QP}$, and $Htt^{\Delta N17/\Delta N17}$ mice from heterozygous intercrosses at the expected Mendelian frequency, suggesting that deletion of the domains encoded by the *Htt* exon 1 do not affect htt's essential embryonic functions. We have completed characterizing these new models with respect to their motor function and performance in a spatial learning and memory test (Morris water maze, MWM). $Htt^{\Delta QP/\Delta QP}$ mutants exhibit improvements in motor coordination tasks but alterations in the MWM task that are dependent on the age of testing when compared to controls. $Htt^{\Delta N17/\Delta N17}$ mutants do not exhibit any differences in motor coordination in comparison to controls; however, these mutants do exhibit a phenotype in the MWM that is similar to that observed in $Htt^{\Delta QP/\Delta QP}$ mice. To determine if these deletions can affect HD pathogenesis *in trans*, we have also generated mice that express both a mutant version of htt with an expanded polyQ stretch, and either the N17 or QP domain deletion mutant versions of normal htt. At multiple ages, we have observed a rescue in MWM deficits in both the $Htt^{140Q/\Delta QP}$ and $Htt^{140Q/\Delta N17}$ mice in comparison to $Hdh^{140Q/+}$ mice, but deficits are observed in their motor coordination and activity levels in comparison to controls. We are currently characterizing these mice to determine if alterations in neuronal autophagy or in neuronal stress response occur.

Title: Principal component analysis of fine motor skill impairment of R6/2 and zQ175 knock in mice of huntington's disease

Authors: *T. HEIKKINEN[1], T. BRAGGE[1], J. PUOLIVÄLI[1], A. NURMI[1], O. KONTKANEN[1], I. MUNOZ-SANJUAN[2], L. C. PARK[2]
[1]Charles River Discovery Res. Services, Kuopio, Finland; [2]CHDI Management/CHDI Fndn., Los Angeles, CA

Abstract: In this study we implemented a principal component analysis (PCA) based method to create algorithms that would allow for data obtained from a high speed kinematic imaging analysis to show linear combinations of different pathological features that provides greater insight and sensitivity in the detection of fine motor skills in mice. Through implementation of these methods we have been able to establish the presence of progressive, earlier deficits in mouse models of Huntington's disease (HD). These deficits are observed in multiple combinations of different parameters describing gait properties and fine motor capabilities, at various ages in the mice and reveal linear combinations of different pathological features correlated to the disease progression with increased sensitivity in kinematic analysis. HD and wild-type mice, of both genders and at various ages were tested at various ages: walking, ladder walking and wading. The gait was recorded with a high speed camera, imaged and analyzed simultaneously from multiple viewing angles and utilizing comprehensive kinematic algorithms. Anatomical landmarks were marked with a contrast agent in order to enhance the detection of trajectories between particular landmarks in the images. A large number of parameters describing gait characteristics and fine motor movements were determined from the recognition of marker trajectories, and were compared between the genotypes to reveal disease specific defects. PCA was used to transform the parameter set into a new, smaller set of mutually uncorrelated parameters. In addition, PCA was applied directly to the marker trajectory data vectors, of which each were composed of referenced and interpolated marker data of individual gait cycles (, i.e., kinematic information of whole gait cycle). These results indicate that by employing PCA previously observed progressive HD-like fine motor deficits of R6/2 and zQ175KI mice can be further expressed as linear combinations of different parameters of fine motor movements. Moreover, the PCA shows stronger HD-phenotype and genotype difference than conventional parameter analysis, offering better power and a wider therapeutic window for possible treatment intervention in HD. Thus, the fine motor skill analysis using PCA offers a sensitive and perhaps more translatable tool in order to investigate the efficacy of therapeutic drugs that improve early and subtle motor functions in HD.

Title: Impact of phosphodiesterase 10A inhibition on spontaneous and cortically-evoked spike activity in the striatum of Q175 mice that model Huntington's disease

Authors: S. CHAKROBORTY[1], A. M. DEC[1], C. J. SCHMIDT[2], *A. R. WEST[1]
[1]Rosalind Franklin Univ. Med. Sci., NORTH CHICAGO, IL; [2]Pfizer Inc., Cambridge, MA

Abstract: Huntington's disease (HD) is a genetic neurodegenerative disorder associated with abnormal expansion in CAG trinucleotide repeats within the Huntingtin gene. This genetic mutation induces the degeneration of striatal medium-sized spiny projection neurons (MSNs) via the synthesis of mutant huntingtin protein. It is now clear that one consequence of this mutation may be abnormalities in the metabolism of cyclic nucleotides by phosphodiesterases (PDEs). Specific findings point to decreased striatal cAMP/cGMP production, which may be linked to aberrant spontaneous discharge of MSNs and deficits in corticostriatal transmission. Thus, drugs designed to inhibit striatal PDE activity may be useful therapeutic agents for slowing disease progression and alleviating motor and cognitive symptoms of HD. The current study monitored spontaneous and cortically-evoked firing in aged (5-7 months old) wild-type (WT) and Q175 heterozygous knock-in mice treated with vehicle or the potent and selective PDE10A inhibitor PF-2545920. WT and Q175 mice were anesthetized with urethane and single-unit spike activity was isolated during low frequency electrical stimulation of the ipsilateral motor cortex. MSNs recorded in Q175 mice exhibited higher spontaneous firing rates than MSNs recorded in WT controls. The incidence of spontaneously firing MSNs was also significantly increased in Q175 mice, indicating that overall population activity is elevated in the HD striatum. Furthermore, MSNs recorded in Q175 mice exhibited significant decreases in cortically-evoked firing. Given this, it is likely that corticostriatal transmission is compromised in the HD striatum in a manner

that leads to increased background noise (spontaneous firing) and a decrease in the cortically-driven signal (i.e., decrease in the signal to noise ratio). Interestingly, PF-2545920 (1 mg/kg, s.c.) administration potently suppressed the spontaneous firing of MSNs recorded in Q175 mice to levels similar to that observed in WT controls. Less robust suppressive effects of PF-2545920 administration were also observed in WT controls. Preliminary observations from within-subjects recordings performed in Q175 mice revealed no significant differences in the probability of cortically-evoked spikes ~30 minutes after PF-2545920 administration. While more studies are needed to determine the impact of PF-2545920 administration on cortically-evoked activity, these observations indicate that PDE10A inhibition may partially normalize aberrant firing and population activity observed in the HD striatum and improve pathological disturbances in the above mentioned signal to noise ratio.

Title: Determining the role of ARD1 in SBMA

Authors: *H. L. MONTIE[1], S. HOSEIN[1], D. SIMPSON[1], W. LIU[2], D. E. MERRY[3], E. M. HEINE[1]
[1]Bio-Medical Sci., Philadelphia Col. of Osteo. Med., PHILADELPHIA, PA; [2]Dept. of Genet., Louisiana State Univ., New Orleans, LA; [3]Biochem. and Mol. Biol., Thomas Jefferson Univ., Philadelphia, PA

Abstract: The goal of these studies is to determine the role of N-acetyltransferase arrest-defect 1 protein (ARD1, Naa10) in the aberrant acetylation, aggregation, and toxicity of polyglutamine (polyQ)-expanded androgen receptor (AR) in Spinal and Bulbar Muscular Atrophy (SBMA, Kennedy's disease). SBMA is an X-linked neuromuscular disorder, caused by the expansion of a polymorphic CAG tract ($n \geq 40$) in the coding region of the AR gene, which encodes a glutamine tract in the protein. SBMA is similar to other polyQ expansion diseases in that it presents in the third to sixth decade of life, the length of the polyQ tract is predictive of disease severity and

onset, and the disease associated protein aberrantly aggregates. Unlike the other polyQ expansion diseases, which are autosomal dominant, SBMA affects only men and is predominantly a lower motor neuron disease. There are currently no curative treatments for SBMA and this presents a critical challenge to define specific disease targets for therapeutic intervention. In previous studies, we have shown that polyQ-expanded AR is hyperacetylated and that AR acetylation modulates its nuclear aggregation and toxicity in cell models of SBMA. It has been recently reported that ARD1 enhances normal AR acetylation. Thus, we hypothesize that decreasing ARD1 protein levels or activity will reduce polyQ-expanded AR acetylation, aggregation, and toxicity in cell models of SBMA. To determine the effects that ARD1 has on these disease features, we are initially utilizing an inducible PC12 cell model of SBMA (AR112Q). Preliminary studies indicate that knockdown of ARD1 in these cells decreases AR112Q aggregation. We are currently evaluating whether decreased ARD1 also reduces polyQ-expanded AR acetylation and toxicity. We have also stably transfected AR112Q-expressing cells with exogenous ARD1 to determine the effect of overexpressed ARD1 on polyQ-expanded AR acetylation, aggregation and toxicity We propose that improved understanding of how polyQ-expanded AR acetylation may be regulated by ARD1 will lead to new therapeutic options for SBMA patients.

Abstract: Polyglutamine-repeat disorders are part of a larger family of neurodegenerative diseases characterized by protein misfolding and aggregation. In spinal and bulbar muscular atrophy (SBMA), polyglutamine expansion within the androgen receptor (AR) causes progressive debilitating muscular atrophy and lower motor neuron loss in males. Soluble aggregates of the AR are considered a toxic intermediate in the aggregation process. Here, we utilized SDS-agarose gel electrophoresis, sedimentation analysis, and atomic force microscopy to identify a novel aggregation species of the polyglutamine-expanded AR - one that is soluble, consists of full-length AR, and binds the toxicity-predicting antibody 3B5H10. Disease relevance was confirmed *in vivo* and correlations were made to toxicity based on a library of well-characterized structural and functional mutations of the polyglutamine-expanded AR. Identifying a common signature of soluble AR species will advance the development of targeted therapies applicable to a wide range of neurodegenerative diseases caused by protein misfolding.

Sch. of Med., Fukuoka, Japan; [5]Neurol., Nagoya Universtiy Grad. Sch. of Med., Nagoya, Japan; [6]Neurol., Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan

Abstract: Spinal and bulbar muscular atrophy (SBMA) affects only men, is androgen-dependent, and linked to an expanded polyglutamine (polyQ) tract in the androgen receptor (AR). While traditionally viewed as neurogenic, data from a novel "myogenic" mouse model suggest that SBMA is driven by AR toxicity originating in skeletal muscle (Monks et al., *PNAS* (2007) 104:18259), a notion that has recently been confirmed in other models (*Neuron* (2014) 82:295; *Cell Report* (2014) 7:1). However, whether muscle or motoneuron dysfunction underlies motor dysfunction remains unknown. While muscle strength is impaired in SBMA mice, no data exist about whether disease also affects neuromuscular synaptic strength. Thus, we recorded spontaneous (miniature) and evoked endplate potentials (mEPPs and EPPs, respectively) intracellularly from healthy and diseased muscle fibers of three different mouse models of SBMA: the "myogenic" model which overexpresses a wild-type (wt) AR exclusively in skeletal muscles, the "AR97Q" model that globally expresses a full length human AR with 97 polyQs, and a knockin (KI) model where the first exon of the endogenous *AR* is replaced by the human exon with 113 CAGs. We find diseased synapses are appreciably weaker, likely due to a lower release probability of synaptic vesicles. For example, quantal content (QC), an indicator of the amount of acetylcholine (ACh) released in response to action potentials, was significantly reduced (30-40%) in all three SBMA models. We also find decreases in both size of the readily releasable synaptic vesicle pool (RRP) and in short term synaptic facilitation. Interestingly, in early symptomatic KI mice, the RRP size was unaffected but short term synaptic facilitation was increased, suggesting reduced release probability might be an early cause of reduced ACh release. Disease also affected postsynaptic mechanisms: resting membrane potential of diseased fibers was depolarized by ~10-15 mV (relative to wt controls) and associated with a resistance to μ-conotoxin, a selective blocker for skeletal muscle sodium channels. Increased amplitude of mEPPs, and prolonged decay times for both mEPPs and EPPs, suggest SBMA also impairs expression of several critical ion channels in muscle. Together, these data show comparable defects in neuromuscular transmission across three *different* SBMA mouse models, involving both pre- and post-synaptic mechanisms. That the *same defects* are seen in the muscle-specific model as in the other two models argues that AR toxicity emanating from muscle imparts dysfunction to *both* muscles and motoneurons and that wt AR is capable of engaging the same toxic mechanisms as polyQ-expanded AR.

Title: Androgen-dependent deficits in muscle-derived BDNF correlate with motor dysfunction in two mouse models of spinal bulbar muscular atrophy

Authors: *K. HALIEVSKI[1], Y. XU[1], C. L. HENLEY[1], M. KATSUNO[2], H. ADACHI[3], G. SOBUE[2], S. M. BREEDLOVE[1], C. L. JORDAN[1]
[1]Neurosci., Michigan State Univ., East Lansing, MI; [2]Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [3]Univ. of Occup. and Envrn. Hlth., Kitakyushu, Japan

Abstract: Spinal bulbar muscular atrophy (SBMA) is a late-onset, progressive neuromuscular disease linked to a polyglutamine expansion mutation in the androgen receptor (AR) gene. SBMA is also androgen-dependent, requiring male levels of testosterone for expression of the disease. Target derived neurotrophic factors, including brain-derived neurotrophic factor (BDNF), are critical for the survival and function of neurons. We previously reported a reduction of BDNF mRNA in skeletal muscles of symptomatic mice in two different transgenic SBMA models: 1) the myogenic model that overexpresses wild-type rat AR in skeletal muscle fibers, and 2) the AR97Q model that globally overexpresses a full length human AR with 97 glutamine repeats. We now show that the deficit in BDNF mRNA expression in diseased muscle is androgen-dependent, and thus, tightly correlates with motor dysfunction, and is independent of transgene expression per se. In the myogenic model, castration of chronically diseased males greatly improves motor performance, which is paralleled by a significant increase in BDNF mRNA expression in muscle. Furthermore, when asymptomatic myogenic females are treated with testosterone, their motor function quickly plummets, reaching male levels of motor dysfunction in only five days of treatment. Likewise, the level of BDNF mRNA in skeletal muscle of acutely diseased myogenic females drops to that of chronically diseased males within that time. Ongoing experiments in our laboratory are characterizing the time-course of this BDNF reduction in acutely diseased myogenic females to determine whether the deficit in BDNF mRNA expression precedes the onset of motor dysfunction, supporting the idea that BDNF is an important regulator of motor function. In the second, AR97Q model, we find comparable androgen-dependent deficits in BDNF expression in diseased muscle. Castrating AR97Q males at P28-32 prevents the decline in both motor function and BDNF expression in muscle that occurs when AR97Q males remain gonadally intact. In sum, we find BDNF mRNA deficits in SBMA muscle are dynamically regulated by androgen levels and change in step with the quality of motor function. Moreover, these data suggest that reduced BDNF levels may underlie motor dysfunction in SBMA and raise the question of whether replenishing the system with BDNF could rescue function in mouse models of SBMA. This work was funded by NIH NS04519 (CLJ).

Title: The role of Tip60, an androgen receptor acetyltransferase, in SBMA

Authors: ***E. HEINE**[1], C. N. ROBSON[2], D. E. MERRY[3], H. L. MONTIE[1]
[1]Philadelphia Col. of Osteo. Med., PHILADELPHIA, PA; [2]Newcastle Univ., Newcastle upon Tyne, Tyne and Wear, United Kingdom; [3]Thomas Jefferson Univ., Philadelphia, PA

Abstract: Spinal and Bulbar Muscular Atrophy (SBMA; Kennedy's Disease) is an adult-onset, slowly-progressive, X-linked neuromuscular disease. SBMA results from a CAG repeat expansion in the coding region of the androgen receptor (AR) gene, leading to a polyglutamine (polyQ) repeat expansion in the amino-terminal domain of the AR protein. Patients are primarily male, both due to random X-inactivation as well as the disease requirement of high circulating levels of androgens, and present with weakness and atrophy of muscles of the limbs, mouth, and throat. These symptoms result from the loss of lower motor neurons in the spinal cord and brainstem and due to muscle atrophy. A histopathological hallmark of SBMA, as well as other polyQ-expansion diseases, is the presence of intranuclear inclusions composed mainly of amino-terminal portions of the polyQ-expanded AR protein. To date, there is no curative treatment or effective therapy for SBMA. Recently, we have shown that hormone-dependent AR acetylation at K630/632/633 is a major modifier of polyQ-expanded AR toxicity and inclusion formation. Tip60 (Tat-interactive protein, 60kDa) functions as a histone acetyltransferase (HAT) and has been shown to enhance AR transactivation by directly interacting with and acetylating K630/632/633. Here, we are studying the role of Tip60 in SBMA by investigating the loss of Tip60 protein or pharmacological inhibition of its acetyltransferase activity. Transient knock-down of Tip60 in a PC12 cell model of SBMA reduced the formation of nuclear inclusions of polyQ-expanded AR. Clonal cell lines are currently being screened for Tip60 knock-down and will be used to further study the affect of Tip60 on AR acetylation, aggregation and toxicity. In addition to genetic knock-down of Tip60, we have found that pharmacological inhibition of this

enzyme abrogates polyQ-expanded AR aggregation in PC12 cells. Future studies will assess the mechanism of Tip60's role in the pathogenic mechanisms of SBMA as well as to determine the therapeutic potential of inhibiting Tip60 *in vivo*. The ultimate goal of these studies is to identify whether Tip60 is a valid therapeutic target for the treatment of SBMA.

Title: Analysis of nuclear export of polyglutamine-expanded androgen receptor in a cell model of spinal and bulbar muscular atrophy

Authors: F. ARNOLD[1], H. MONTIE[2], *D. E. MERRY[1]
[1]Dept Biochem & Molec Biol, Thomas Jefferson Univ., PHILADELPHIA, PA; [2]Philadelphia Col. of Osteo. Med., Philadelphia, PA

Abstract: Spinal and bulbar muscular atrophy (SBMA) is an X-linked neurodegenerative disease caused by a polyglutamine (polyQ) expansion in the androgen receptor (AR) protein. The AR is a steroid hormone receptor that, upon ligand binding of testosterone or dihydrotestosterone (DHT), undergoes a conformational change that induces nuclear localization of the AR and subsequently, the transcriptional regulation of AR-target genes. In SBMA, both the presence of hormone and the nuclear localization of the AR are necessary for toxicity, with the formation of intranuclear inclusions of aggregated AR a hallmark of the disease state. Given the importance of nuclear localization in disease-mediated toxicity, we sought to examine whether there are alterations in the nuclear export of polyQ-expanded AR, compared with wild-type AR and known AR export-deficient mutants. To test the hypothesis that polyQ-expansion impairs nuclear export of the AR, we developed a heterokaryon assay using a well-characterized PC12 SBMA cell model and mouse fibroblast (NIH/3T3) cells. In these experiments, nuclear localization of the AR is induced in PC12 cells by a short hormone treatment to avoid nuclear inclusion formation in cells expressing polyQ-expanded AR. Concurrently, protein synthesis is inhibited with cyclohexamide. Heterokaryons are then formed by fusing PC12 and NIH/3T3 cells; after

cell fusion, any AR detected in an NIH/3T3 cell nucleus must first have been exported from a PC12 cell nucleus. Results of these studies suggest that polyQ-expansion in the AR protein impairs nuclear export, as 55% of heterokaryons formed with PC12 cells expressing polyQ-expanded AR had either no detectable AR in the NIH/3T3 cell nucleus, or significantly more AR in the PC12 cell nucleus than in the NIH/3T3 cell nucleus. On the other hand, 100% of heterokaryons formed with PC12 cells expressing wild-type AR had detectable AR in the NIH/3T3 cell nucleus and only 11% of these heterokaryons had significantly more AR in the PC12 cell nucleus than the NIH/3T3 cell nucleus. These data highlight a novel metabolic deficit inherent in polyQ-expanded AR and the importance of further studying the role of nuclear export in SBMA disease pathogenesis.

Title: A pharmacological approach to induce the clearance of mutant androgen receptor in spinal and bulbar muscular atrophy

Authors: *P. RUSMINI, E. GIORGETTI, V. CRIPPA, R. CRISTOFANI, M. CICARDI, A. POLETTI
Dept. of Pharmacol. and Biomolecular Sci., UNIVERSITY OF MILAN, Milan, Italy

Abstract: Spinal and bulbar muscular atrophy (SBMA) is a motoneuronal disease caused by the expansion of a CAG repeat in the coding region of the Androgen Receptor (AR) gene, resulting in a protein with an abnormally elongated polyglutamine (polyQ) tract. The binding of the physiological ligand testosterone to the mutant protein induces ARpolyQ misfolding and aggregation in lower motoneurons. These aggregates colocalized with several molecular chaperones, and components of the ubiquitin-proteasome system (UPS) and the autophagic pathways, involved in protein quality control system. This suggests the possibility that the degradative pathways may be actively involved in the clearance components of these inclusions but they fail to completely degrade the ARpolyQ protein. In particular, cytoplasmic ARpolyQ aggregation seems to depend on autophagic flux blockage. We have already demonstrated that the anti-androgen, Bicalutamide, is able to retain the activated ARpolyQ for a long time period

into the cytoplasm without triggering aggregate formation. Moreover, trehalose, an autophagic inducer, is able to induce the ARpolyQ clearance through this cytoplasmic degradative pathway. We have tested the combined effects of these two compounds. Bicalutamide and trehalose co-treatment decreased the ARpolyQ accumulation and had a more potent effect in reducing the soluble and insoluble forms of ARpolyQ than the single treatments. Analysing the autophagic markers LC3 and p62, we observed that trehalose strongly actived the autophagic pathway while casodex had no effects. Interestingly, Bicalutamide and trehalose co-treatment, is also able to induce the clearance of soluble and insoluble forms of a long expanded polyQ tract (ARQ112), which led to the formation of nuclear aggregates. These data suggest that Bicalutamide and trehalose co-treatment offers the opportunity to retain into cytoplasm the activated ARpolyQ for a long period improving the effects of trehalose-induced autophagic clearance, leading to a more efficient removal of ARpolyQ. These results might represent a possible therapeutic approach for SBMA. GRANTS: Fondazione AriSLA; AFM Telethon France; Regione Lombardia multicentric project; UNIMI

Title: Study of intermediate-length polyQ repeats in sporadic amyotrophic lateral sclerosis

Authors: *F. L. NUNEZ SANTANA, N. A. SIDDIQUE, T. SIDDIQUE
The Ken & Ruth Davee Dept. of Neurol., Northwestern University, Feinberg Sch. Med., Chicago, IL

Abstract: Amyotrophic lateral sclerosis (ALS) is a progressive, paralytic, and ultimately fatal neurodegenerative disease characterized by motor neuron degeneration. Approximately 10% of ALS cases have a familiar origin (FALS) with the remainder of cases being sporadic (SALS). To date, disease mechanisms for both FALS and SALS have yet to be elucidated; however, about 20% of FALS cases are known to occur from mutations in the Cu, Zn Superoxide dismutase 1 (SOD1) gene (Rosen et al. 1993). An ongoing challenge in the study of ALS is that its pathogenesis is largely unknown. Nonetheless, recent studies have shown a significant association between intermediate-length polyQ repeats (CAG) in the ataxin-2 gene (ATXN2) and genetic risk factor for ALS (Elden et al. 2010). In other words, it appears that depending upon the length of the repeat expansions in ATXN2, individuals can present a higher risk for development of the disease. However, the overall number/range of intermediate or fully pathological repeats associated with ALS have been found to vary among studies. We have analyzed the size of ATXN2 CAG repeats from SALS and healthy age/race matched control patients, with aims of refining the range of intermediate and/or pathological repeat number significantly associated with SALS. The ATXN2 repeat regions from genomic DNA samples were amplified by polymerase chain reaction using Taq Gold Polymerase in the presence of fluorescent forward and reverse primers. PCR fragment analysis and number of CAG repeats were determined after capillary electrophoresis using a Beckman Coulter CEQ 8000 Genetic DNA Analysis Sequencer System. As previously reported, the length of the normal allele for SALS patients was found to be between 20-22 CAG repeats, whereas, the longer alleles in SALS patients ranged from 27 to 31 repeats (2.41%). Controls patients ranged from 27 to 28 repeats (0.48%). Our preliminary findings further confirm an association between ATXN2 intermediate CAG expansions and increased risk for ALS. However, given the overlap between SALS and control patient repeat expansions, our preliminary data indicate that individuals with repeat expansion of 29-33 may carry a bigger risk for development of ALS.

Abstract: Amyotrophic lateral sclerosis (ALS) is a fatal neuromuscular disease characterized by muscle wasting, weakness and spasticity, reflecting a degeneration of upper and lower motor-neurons (MNs). The mechanisms of neuronal death in ALS are still largely obscure. It is well known that Glutamate(Glu)-mediated excitotoxicity plays a major role in the degeneration of motor neurons. According to our studies, we suggested that the high levels of synaptic Glu are due, not only to a reduced astrocytary transport (1), but also to an abnormal release (2). Recently, pre-synaptic mGlu1 and mGlu5 receptors were described in rat cerebral cortex nerve terminals, whose activation produced potentiation of Glu release (3). In the present work we investigated on the presence of similar autoreceptors in the spinal cord of SOD1/G93A mice, a widely used animal model of human ALS. Exposure of spinal cord synaptosomes to increasing concentrations of the mGluR1/5 agonist 3,5-DHPG produced distinct effects in SOD1/G93A mice and controls: concentration above 0.3 μM stimulated the basal release of [3H]D-Aspartate, used to label the endogenous pools of Glu, both in control and SOD1/G93A mice. At variance, concentrations of 3,5-DHPG equal to or lower than 0.31 μM increased [3H]D-Asp release in SOD1/G93A mice, only. Experiments with selective mGluR1 or mGluR5 antagonists indicated that the both high and low concentration effects of 3,5-DHPG involved mGluR1 and mGluR5 activation. Low 3,5-DHPG concentrations induced increase of IP3 in SOD1/G93A but not in control mice; whereas, high 3,5-DHPG induced IP3 formation in both mouse strains. Release experiments confirmed that 3,5-DHPG produced exocytotic release of [3H]D-Aspartate, involving intra-terminal Ca2+ release through IP3-sensitive channels. Protein and mRNA determination pointed towards a more elevated expression of mGluR5 in SOD1/G93A mice. Overall our results demonstrate the existence of an abnormal mGluR1/5-mediated release of Glu in SOD1/G93A mice, which may represent a cause of the excessive Glu levels. This phenomenon can be modulated by selective antagonists, confirming an interplay between the two receptors and an involvement in ALS. These data provide a rationale for new pharmacological approaches based on the selective block of Group I mGluRs. (1) Rothstein JD, Van Kammen M, Levey AI et al Ann. Title: Induction of NF-KB activation by ALS-linked Ubiquilin-2 mutant

Authors: *V. PICHER-MARTEL, A. AYOUAZ, D. PHANEUF, J.-P. JULIEN
Psychiatry and Neurosci., CRIUSMQ, Québec, QC, Canada

Abstract: Amyotrophic lateral sclerosis (ALS) is the most frequent adult-onset motor disease and is characterized by progressive death of upper and lower motor neurons. This degeneration leads to progressive paralysis of skeletal muscle and, unfortunately, to patient's death within 2-5 years of symptoms. Most of ALS cases are sporadic (90%) and only 5-10% are familial. In familial cases, some gene has been linked to the pathology like superoxide dismutase 1 (SOD1) (20%), TAR DNA-binding protein (TDP-43), FUS, P62/SQSTM1 or C9ORF72. Ubiquilin-2 (UBQLN2) plays an important role in ubiquitin proteasome system (UPS) and autophagy by connecting the UPS and ubiquinated protein. Recently, an X-linked mutation in UBQLN2 gene has been discovered in (ALS) familial cases. Approximately ten mutations have been identified and the main one is P497H. These patients developed cytoplasmic inclusions positive for major proteins implicated in this neurodegenerative disorder and also show UPS impairment. Furthermore, ALS patients without UBQLN2 mutation also express UBQLN2 positive inclusions, supporting an important role of this protein in ALS physiopathology. There is an emerging role of nuclear factor kappaB (NF-κB) in ALS and other neurologic diseases. For example, it has been shown in our lab that TDP-43 upregulation can enhance activation of NF-κB. We used cell cultures to determine if UBQLN2 mutation and accumulation induce NF-κB activation in ALS pathology. Neuro2A cells, neurons derived from mouse, were stably transfected with NF-κB activation luciferase reporter and then with UBQLN2 WT or P497H plasmids for 48 hours. Luciferase activity and western analysis show an increase in NF-κB activation in cells overexpressing UBQLN2 P497H compare to non-transfected and UBQLN2 overexpressing cells. These inclusions also seem to be related to NF-κB pathway proteins, which can explain this activation.

Ctr., Maywood, IL; [4]Res. and Develop. Service, Hines VA Hosp., Hines, IL; [5]Mol. Virology, Immunology, and Med. Genet., The Ohio State Univ., Columbus, OH

Abstract: In the mouse, the immune system plays an important role in promoting facial motoneuron (FMN) survival after facial nerve transection at the stylomastoid foramen. In wild type (WT) mice, 87% of FMNs survive axotomy, whereas in recombination-activating gene-2 knockout (RAG-2 KO) mice, only 66% of FMNs survive. RAG-2 KO mice lack the adaptive arm of the immune system, causing them to be immunodeficient. In the present study, we examined how the immune system promotes motoneuron survival by analyzing gene expression changes in axotomized WT and RAG-2 KO mice using laser capture microdissection and qPCR. First, we studied the ability of FMNs to regenerate by studying expression of growth-associated protein 43 (GAP-43), which is a key molecule expressed by FMNs and is involved in axonal regeneration and target reconnection. Interestingly, both RAG-2 KO and WT FMNs significantly upregulate GAP-43 in response to injury. Next, we studied the surrounding microenvironment by assessing astrocyte and microglia response to axotomy. When glial fibrillary acidic protein (GFAP) and CD68 expression levels were measured, the RAG-2 KO facial motor nucleus had a significantly reduced activation response relative to WT. This result suggests an impairment in the astrocytic/microglial response to peripheral axotomy in immunodeficient mice. Another molecule expressed in the microenvironment surrounding the FMN after axotomy is tumor necrosis factor-α (TNFα), a key signaling molecule of the immune system. In WT mice,

expression of TNFα increased 10-fold in the axotomized facial motor nucleus for the first two weeks after injury, and then subsequently decreased to below detectable levels. In RAG-2 KO mice, the increased TNFα levels observed within 2 weeks post-axotomy were approximately half of WT levels. These data support a role for TNFα in neuroprotection. Expression of beta-2 microglobulin (B2M), a component of major histocompatibility complex I (MHC I), was also significantly decreased in the axotomized facial motor nucleus of RAG-2 KO mice relative to WT. Collectively, these data suggest that in the RAG-2 KO mouse, a dysregulated microenvironment involving significant suppression of both astrocytic and microglial responses to peripheral axotomy plays a role in increased FMN death with injury. In contrast, the intrinsic neuronal repair process appears unaffected. Comparing these gene expression results to those of SOD1-G93A mice reveals striking similarities, as this mouse model of ALS also demonstrates a strong neuronal regenerative response but deficient astrocytic and microglial response to facial nerve axotomy.

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult-onset neurodegenerative disease with higher selectivity in degeneration of motor neurons. However, the molecular mechanism by

which the ALS-linked mutants of human superoxide dismutase 1 (SOD1) gene induce neurotoxicity remains obscure yet. Here, we show that depletion of CIIA expression by RNA interference (RNAi) promoted cytotoxicity caused by ALS-linked G93A mutant of the SOD1 gene. The RNAi-mediated knockdown of CIIA also enhanced the SOD1(G93A)-induced interaction between ASK1 and TRAF2 as well as ASK1 activity. Furthermore, endogenous silencing of CIIA by RNAi augmented the effects of SOD1(G93A) on reduction of mitochondria membrane potential ($\Delta\psi m$), release of cytochrome c into the cytoplasm, and caspase activation. Together, our results suggest that CIIA negatively modulates ASK1-mediated cytotoxic signaling processes in a SOD1(G93A)-expressing cellular model of ALS.

Title: Linking mitochondrial and autophagic activities in neurotoxic yeast cell death models

Authors: ***C. LEIBIGER**[1], R. BRAUN[2]
[1]Inst. of Cell Biol., [2]Inst. of Cell Biol., Bayreuth, Germany

Abstract: Introduction: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease with progressive dysfunction and death of motor neurons in brain and spinal cord. The loss of neurons results in muscular weakness and atrophy, speech deficits and death due to respiratory paralysis. Mutations in the genes C9orf72, SOD1, FUS/TLS, and TDP-43 have been associated with ALS. The RNA-binding protein TDP-43 (TAR DNA-binding protein) has been found to accumulate in ubiquitinated, phosphorylated and insoluble inclusions in the cytoplasm of neurons of ALS patients. Mutations of TDP-43 cause similar pathophysiological effects in different model systems, such as mammalian cell cultures, flies and yeast. Saccharomyces cerevisiae is an established model for TDP-43 proteinopathies and many other neurotoxic diseases. Previous works revealed a connection between mitochondrial activity and TDP-43 cytotoxicity. Here, we investigate the link between the cytotoxicity of TDP-43, mitochondrial and autophagic activities in yeast. Methods and Results: We used the drop dilution assay to determine the cytotoxicity of

TDP-43 by measuring growth deficiency. Therefore, yeast wild type (wt) and atg (autophagy related) knock-out strains were transformed with expression constructs encoding human TDP-43 or vector control. The growth media were supplemented with different carbon sources (e.g., Glc and Gal) to modulate mitochondrial respiratory activities. In order to increase autophagy, growth media contained rapamycin blocking the TORC1 (target of rapamycin complex 1) signalling pathway. Expression of human TDP-43 causes cytotoxicity in yeast. We observed enhanced TDP-43 cytotoxicity with increased respiratory capacity and with increased autophagy, respectively. TDP-43 cytotoxicity was relieved by deletion of ATG genes. atg1, atg11 and atg15 are examples. Thus, autophagy seems to be important for the cytotoxicity of TDP-43. We used the GFP-Atg8 processing assay to study autophagic turnover upon TDP-43 expression. By transforming wt and atg1 with TDP-43 and GFP-Atg8, we examined the level of autophagy, which is indicated by the degree of free GFP. We observed an increase of processed GFP by expression of TDP-43 during starvation and non-starvation conditions. Thus, TDP-43 increased the level of autophagy. Conclusions: Our preliminary results suggest that mitochondria and autophagy influence TDP-43-triggered cytotoxicity. We believe that insights gained by applying yeast as cell death model promote a better understanding of the relation between autophagy and mitochondrial activities in ALS.

Title: Visualization of CSMN in the absence of Alsin function in AlsinKO-UeGFP mice reveals details of cellular vulnerability

Authors: *M. GAUTAM[1], G. SEKERKOVA´[2], M. V. YASVOINA[1], J. H. JARA[1], M. MARTINA[2], P. H. OZDINLER[1]

Abstract: Corticospinal motor neurons (CSMN) are unique in their ability to collect, integrate, translate and transmit cerebral cortex's input towards spinal cord targets. However, they are not easy to study due to the complexity and the heterogeneous nature of the cerebral cortex. Their degeneration is key in numerous neurodegenerative diseases, such as amyotrophic lateral sclerosis (ALS). Mutations in the Alsin 2 (ALS2) gene are responsible for juvenile primary lateral sclerosis, infantile onset ascending hereditary spastic paraplegia, and are the most common cause for autosomal recessive juvenile ALS. In addition, upper motor neuron signs and bulbar symptoms are often prevalent in patients with juvenile ALS. Here, we investigated the health, stability and cellular vulnerability of CSMN in the absence of Alsin protein using Alsin KO and the novel reporter line, the AlsinKO-UeGFP mice, which is generated by crossbreeding Alsin KO with the UCHL1-eGFP mice. In the WT-UeGFP and the AlsinKO-UeGFP mice, the CSMN are genetically labeled with eGFP that lasts through adulthood and late ages, allowing visualization and cellular analysis of CSMN at P300, P500 and beyond. Our ongoing studies suggest very subtle, yet important cellular changes that occur in CSMN. There is axonal degeneration of the subcerebral projection neurons, including CSMN, increased autophagy with age and changes in the localization of autophagic vesicles toward apical dendrites. Even though the neurons are not completely cleared from the motor cortex, detailed cellular visualization and analysis using immunocytochemistry coupled with electron microscopy (EM) reveal lack of health. Investigation of pure upper motor neuron defects in mouse is challenging, but here we demonstrate that using UCHL1-eGFP mice as a reporter for CSMN, their health and potential pathways that contribute to their vulnerability can be studied at a cellular level with high precision.

Title: Mutant SOD1 misfolding and ER dysfunction in the pathogenesis of familial ALS

Authors: *H. KAWAMATA
Weill Med. Col. of Cornell Univ., NEW YORK, NY

Abstract: Protein misfolding and the formation of insoluble aggregates containing multiple proteins are pathological disease hallmarks of many neurodegenerative diseases, including amyotrophic lateral sclerosis (ALS). Mutations in superoxide dismutase 1 (SOD1) are associated with autosomal dominant familial ALS. SOD1 is a soluble and ubiquitous antioxidant protein, which, when mutated, forms intracellular aggregates and cytoplasmic inclusions with toxic functions. Through cell fractionation experiments, SOD1 aggregates have been identified in various subcellular compartments of mutant cells, including the endoplasmic reticulum (ER)[1]. The ER is involved in a multitude of cell functions including calcium homeostasis, lipid biosynthesis, and protein folding and secretion. The ER protein folding machinery involves a series of coordinated redox relay systems. Misfolding of proteins in the ER causes a burden for the ER protein folding machinery, which cause activation of the unfolded protein response (UPR) and ER-associated degradation to regain cellular homeostasis. If the ER cannot cope with this stress, the UPR eventually activates apoptotic cell death mechanisms. UPR activation is a pathological hallmark in neurodegenerative conditions. However, the relationship among misfolded mutant SOD1, UPR and ER stress, and disease pathogenesis remains unknown. Recently, we discovered the role of mutant SOD1 in enhancing redox protein modification of the ER resident protein STIM1, and resulting alterations in store operated calcium entry and intracellular calcium dynamics. Importantly, abnormal STIM1 redox modifications and intracellular calcium abnormalities were ameliorated by supplementation of the redox agent glutathione[2]. Here, we show that mutant SOD1 expression in cells causes enhanced protein folding rate and that the ER environment is more oxidative as compared to wild type SOD1 expressing cells. The consequences of mutant SOD1 misfolding on ER function and the downstream pathogenic pathways are being investigated. [1] Urushitani M et al. FASEB J. 2008, 22(7): 2476-87 [2] Kawamata H et al. Title: Nuclear TDP-43 induces neuronal cell death by associating with heterogeneous nuclear ribonucleoprotein-U

Authors: *H. SUZUKI, M. MATSUOKA
Pharmacol., Tokyo Med. Univ., Tokyo, Japan

Abstract: Amyotrophic lateral sclerosis (ALS) is the most common motor neuron disease, characterized by a selective loss of upper and lower motor neurons. Frontotemporal lobar degeneration (FTLD) is characterized by the degeneration of the frontal and anterior temporal lobes. It is currently thought that the pathogenesis of these neurodegenerative diseases is at least partially linked to dysfunction of transactive response DNA-binding protein-43 (TDP-43) since TDP-43 has been identified as a major component of ubiquitinated inclusions in most cases of ALS and some cases of FTLD and a variety of mutations in TARDBP, the gene encoding TDP-43, have been identified in ALS and FTLD. TDP-43 predominantly localizes in nucleus (nuclear TDP-43) and a portion of TDP-43 forms aggregation in cytoplasm (cytoplasmic TDP-43) in the affected area of ALS and FTLD patients. It remains unknown which of nuclear and cytoplasmic TDP-43 exerts neurotoxicity. In this study, we first found that nuclear TDP-43 is more toxic to neurons than cytoplasmic TDP-43. To further investigate the molecular mechanism underlying TDP-43-induced neuronal cell death, we searched for TDP-43 interactors by GST pull down assay and mass-spectrometry analysis and identified heterogeneous nuclear ribonucleoprotein-U (hnRNP-U) as a TDP-43 interactor. The siRNA-mediated reduction of hnRNP-U expression induced cell death. Reciprocally, overexpression of hnRNP-U attenuated TDP-43-induced cell death by binding to TDP-43. These data together suggest that nuclear TDP-43 exerts neuronal toxicity and hnRNP-U negatively regulates TDP-43 neuronal toxicity.

Title: The role of ephrin-b2 in amyotrophic lateral sclerosis

Authors: L. RUE[1], L. SCHOONAERT[1], L. POPPE[1], M. TIMMERS[1], A. VAN HOECKE[2], P. VAN DAMME[1,3], R. LEMMENS[1,3], *W. L. ROBBERECHT[3,1]

Abstract: Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease that affects lower motor neurons in brainstem and spinal cord, and the upper motor neurons in the motor cortex, and leads to a progressive muscle phenotype in patients. ALS is characterized by considerable genetic heterogeneity since mutations in more than 10 different genes (eg SOD1, FUS, TDP, C9ORF72) are known to cause the hereditary form of ALS. Similar heterogeneity is observed in the clinical presentation. This indicates that there are factors that modify the phenotypic expression of the disease. The tyrosine kinase receptor EphA4 was recently shown to be a modifier of ALS. Genetic and pharmacological inhibition of EphA4 rescued the phenotype in a zebrafish model of ALS and increased survival in ALS rodent models. In ALS patients an inverse correlation was found between EphA4 expression and disease onset. However, the mechanism of action has not yet been fully elucidated. EphA4 interacts with ephrin-a and ephrin-b ligands. Several of these EphA4 interaction partners have been shown to be not only expressed on motor neurons, but also on astrocytes, microglia and oligodendrocytes. These cells surrounding the motor neurons play an important role in the pathogenesis of ALS. Here, we aimed to determine the contribution of these various cell types and one specific EphA4 ligand, ephrin-b2, in ALS disease progression. First we performed immunofluorescence stainings of ephrin-b2 in the spinal cord of an ALS mouse model, overexpressing mutant SOD1 (SOD1G93A) and compared this pattern to mice overexpressing wild-type SOD1 (SOD1WT) at different stages of the disease. In SOD1WT spinal cord we observed ephrin-b2 to be highly expressed in motor neurons and oligodendrocytes, while only faint expression was detected in astrocytes. In symptomatic SOD1G93A spinal cord the expression pattern of ephrin-b2 in astrocytes and motor neurons changed. Immunoreactivity was markedly upregulated in astrocytes, but the presence of ephrin-b2 was clearly reduced in the neuronal population. As the expression pattern changed in the different cell types with disease progression, we next explored a possible modifying cell-specific role of ephrin-b2 in ALS, by generating a conditional ephrin-

b2 knockout mouse, in which ephrin-b2 is deleted upon GFAP expression. Deleting ephrin-b2 in reactive astrocytes of the SOD1G93A ALS mouse model resulted in a delay of disease onset and prolonged disease duration. These results suggest astrocytic ephrin-b2 to play a role in modifying ALS. In future experiments we intend to further explore the cellular mechanism of ephrin signalling in the pathophysiology of motor neurodegeneration.

Title: Pathways of degradation of dysfunctional mitochondria in NSC34 motor neurons expressing mutant SOD1

Authors: G. M. PALOMO[1], J. MAGRANE[1], I. SHAHI[1], *G. MANFREDI[2]
[1]Brain and Mind Res. Institute, Weill Med. Col. of Cornell Univ., New York, NY; [2]Weill Med. Col. Cornell Univ., NEW YORK, NY

Abstract: Amyotrophic Lateral Sclerosis (ALS) is a fatal disease caused by the degeneration of upper and lower motor neurons. Familial forms of ALS represent a 10% of the all cases, and mutations in the gene Cu-Zn superoxide dismutase (SOD1) account for 20% of familial forms. Numerous molecular mechanisms have been proposed to explain the neuronal degeneration in SOD1 mutants. Among these, mitochondrial dysfunction appears to play a central role. Mitochondria quality control processes are key mechanisms evolved to ensure the maintenance of an adequate pool of functional mitochondria. This can be of vital importance in ALS mutant motor neurons, where there are extensive mitochondrial functional and structural abnormalities. Abnormal mitochondria are found in NSC34 motor neuron-like cells expressing mutant SOD1. We have investigated mitochondria quality control systems in NSC34 cells, stably transfected

with mitochondria-targeted (inter membrane space, IMS) and untargeted G93A-SOD1 constructs. We have measured markers of autophagy in relationship to mitochondria. We have detected increased levels of the autophagy adaptor p62 in NSC34 cells expressing G93A-SOD1, especially in cells expressing IMS-targeted protein. p62 co-localized with mitochondria, in both soma and neurites. Additionally, lysosomes, labeled with LysoTracker Red, accumulated in NSC34 differentiated cells expressing mutant SOD1. Studies of autophagy fluxes, determined in the presence of the lysosomal inhibitor bafilomycin A1 indicated a dysfunction in IMS-targeted G93A-SOD1 cells, but surprisingly not in untargeted G93A-SOD1 cells. The relevance of studying IMS-targeted G93A-SOD1 cells resides in the fact that mitophagy is determined exclusively by a mitochondrial damage, as the source of stress is by design confined to mitochondria. Further studies aimed at determining if the cellular pathways required to accomplish mitophagy are specifically impaired in SOD1 mutants or if the excessive accumulation of damaged mitochondria is due to clogging of the system will shed new light on the involvement of mitochondria quality control in ALS.

Title: Elp3 is a disease modifier of amyotrophic lateral sclerosis

Authors: A. BENTO-ABREU[1], M. TIMMERS[1], *P. VAN DAMME[2], L. VAN DEN BOSCH[1], W. ROBBERECHT[1]
[1]KU Leuven - Univ. of Leuven, Dept. of Neurosciences, VIB - Vesalius Res. Center, Exptl. Neurol. - Lab. of Neurobio., Leuven, Belgium; [2]Dept. of Neurol., Neurol. Department, UZ Leuven, Leuven, Belgium

Abstract: Amyotrophic Lateral Sclerosis (ALS), the most common motor neuron disorder of adulthood, is characterized by the degeneration of motor neurons in the spinal cord, brainstem and motor cortex resulting in muscle weakness, atrophy and spasticity. In a genome-wide association study, our group identified a polymorphism in the ELP3 gene to protect against ALS (1).This finding showed to have biological relevance as, within the same study, an independent genetic screen in *Drosophila* identified two different loss-of-function mutations in the fly homologue of ELP3 that induced aberrant axonal outgrowth and synaptic defects. Furthermore, lower expression levels of ELP3 were found in brain of individuals with the ALS at-risk genotype and finally the knock-down of Elp3 in the zebrafish induced motor axonal abnormalities similar to those induced by mutant SOD1 and mutant TDP43. Taken together, these initial findings suggested that low ELP3 expression may render motor neurons vulnerable to neurodegeneration and that overexpression may protect (1). ELP3 is the catalytic subunit of the Elongator complex, comprised of six subunits (ELP1-ELP6). Elongator is known to regulate translation efficiency - is involved in tRNA wobble modifications - and also transcription elongation - it associates with RNA polymerase II (2, 3). Little is known about proteins regulated or affected by ELP3, except for the stress response transcription factors Atf1 and Pcr1, which are downregulated in yeast lacking ELP3 after stress (4). We investigated the overexpression and knock-down of Elp3 in the SOD1G93A mouse model of ALS and also in the SOD1A4V zebrafish model. ELP3 overexpression was achieved both by intrathecal delivery of AAV9-ELP3 viral particles in neonatal mice and by generation of an inducible transgenic HuELP3 mouse. We found that Elp3 overexpression delays disease onset and prolongs survival of SOD1G93A mice whereas it deletion (Elp3 -/- mouse) leads to embryonic lethality at E9. We also found a protective effect of ELP3 on mutant SOD1-induced motor axonopathy in the zebrafish. Finally, we also investigated the molecular mechanism involved in Elp3 neuroprotective effect. We found that the neuroprotective effect of ELP3 in the SOD1A4V zebrafish is abrogated by mutations in the SAM domain, but not in the HAT domain. Further investigation is needed to clarify the role of Elp3 in neuroprotection in general and as ALS disease modifier in particular.

Genet., The Ohio State Univ., Columbus, OH

Abstract: The rodent facial nerve axotomy model is a widely used injury paradigm to study motoneuron (MN) survival and regeneration. It is well-established that the majority of facial MN survive 4 weeks following facial nerve transection at the stylomastoid foramen in adult wild-type (WT) mice. In contrast, there is ~50% loss in facial MN at 4 weeks following facial nerve transection in immunodeficient mice, which can be effectively reversed with reconstitution of WT CD4+ T lymphocytes prior to axotomy. Thus, CD4+ T cells play a critical role in facial MN viability following facial nerve transection. Upon further investigation of this immune-mediated neuroprotection, our laboratory discovered that facial MN survival in both WT and reconstituted immunodeficient mice significantly decline to similar levels at 10 weeks post-axotomy. Therefore, the ability of the adaptive immune system to mediate facial MN survival after axotomy is transient, and appears to occur within a few weeks after injury. We hypothesize that two subpopulations exist within the mouse facial motor nucleus. One subpopulation, making up 50% of all facial MN, is dependent upon a functional peripheral immune system in order to survive from target disconnection to reconnection; and a second subpopulation that is capable of surviving for a prolonged period of time regardless of immune status or establishment of target reconnection. In order to test our hypothesis, we performed a facial nerve axotomy on WT and immunodefieinct mice and examined facial MN survival at 18 and 26 weeks post-axotomy. Our results indicate that the resilient subpopulation of facial MN persists indefinitely in WT and immunodeficient mice and remains at about 50%. We conclude that this resilient subpopulation of facial MN is viable regardless of immune status, and does not require target innervation, therefore presenting a unique opportunity for therapeutic intervention in peripheral nerve injury. We are currently exploring mechanisms underlying the distinct phenotypes.

Title: SMA motor neurons show impaired mRNP complex assembly

Authors: *P. G. DONLIN-ASP[1], C. FALLINI[1,4], J. P. ROUANET[1], M. E. MERRITT[1,2], G. J. BASSELL[1,3,2], W. ROSSOLL[1,2]
[1]Cell Biol., [2]Lab. of Translational Cell Biol., [3]Neurol., Emory Univ. Sch. of Med., Atlanta, GA; [4]Neurol., Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Spinal muscular atrophy (SMA) is a neuromuscular disease characterized by a specific degeneration of motor neurons. SMA results from a reduction in the survival of motor neuron (SMN) protein, which is ubiquitously expressed with a well characterized role in promoting the assembly of spliceosomal small nuclear ribonucleoproteins (snRNPs). While underlying defects in splicing have been observed in SMA models, these defects are not unique to motor neurons, leaving their role in the selective motor neuron degeneration unclear. Data from our lab and others led to the hypothesis that SMN plays a critical role in the assembly and/or trafficking of messenger ribonucleoproteins (mRNPs) in neuronal processes. Previously we have discovered specific defects in the axonal localization of mRNAs (*β-actin, Gap43*) and mRNA-binding proteins (HuD, IMP1) in axons and growth cones of primary motor neurons from SMA mice or depleted of SMN. We also observed that overexpression of both HuD and IMP1 can mitigate the effects of low SMN levels on axon outgrowth and GAP43 protein levels in growth cones. However, the molecular function(s) of SMN in the biology of mRNPs remained unclear due to

the lack of specific assays.To investigate the biological role of SMN and the effects of SMN deficiency in axonal mRNA regulation, we have established a trimolecular fluorescence complementation (TriFC) assay in motor neuron cultures as a sensor for mRNA and protein association, to validate the proposed role of SMN in mRNP assembly and localization. Our findings revealed a deficiency in the assembly of IMP1 protein/*β-actin* mRNA containing complexes in SMA motor neurons, which is consistent with SMN acting as a chaperone for mRNP complex assembly. These results are further supported by RNA immunopreciptation experiments from SMA mouse tissue extracts which show a substantial reduction in the levels of *β-actin* and *Gap43* mRNAs pulled down with IMP1. We can also show for the first time that SMN-deficiency causes defects in axonal local translation, likely a downstream consequence of impaired mRNP transport complex assembly.

Abstract: Introduction: Amyotrophic lateral sclerosis (ALS) is a rapidly progressive disease of the nervous system involving both upper and lower motor neurons. Automated whole-brain analysis techniques have been developed to quantify grey matter (GM) morphology using MRI T1-weighted images. Voxel-based morphometry (VBM) studies have yielded a number of discrepancies in their results. However, more and more studies have observed GM volume loss beyond motor and premotor cortices. Only two recent positron emission tomography (PET) studies, combined with 18F-fluorodeoxyglucose (FDG), investigated the effect of ALS on cerebral glucose metabolism, using a whole brain analysis method (Cistaro et al. 2012; Van

Laere et al. 2014). They reported both hypometabolism in bilateral premotor cortex and hypermetabolism in several posterior regions such as the medial temporal cortex and the cerebellum. The present study combined for the first time MRI and ^{18}FDG-PET to investigate morphological and functional brain abnormalities in a group of ALS patients. Method: Twenty-nine patients diagnosed with ALS according to the Revised El Escorial criteria (mean age 60.6 years old) and twenty-nine sex and age-matched normal volunteers (mean age 60.8 years old) underwent both ^{18}[F]FDG positron emission tomography and high-resolution 3 T MRI T1-weighted anatomical imaging. MRI data were handled using VBM5. The PET data were coregistered to their corresponding MRI, corrected for partial volume effect and normalized using the deformation parameters defined from the MRI procedure. A t-test was performed, using Statistical parametric mapping 5, with a threshold p(uncorrected)<0.001 with k>80 voxels. Results: compared with the healthy controls, ALS patients showed decreased GM volume mainly in left precentral gyrus as well as in several parts of the temporal, parietal and occipital lobes. We also found GM volume loss in subcortical regions such as the right amygdala, and the putamen and thalami on both sides. Hypometabolism concerned the left precentral and postcentral gyri and left inferior orbital part of the frontal lobe. Increased glucose metabolism consumption was also found in ALS patients in bilateral medial temporal lobe as well as in the cerebellum. Conclusion: ALS is not only associated with GM volume loss and hypometabolism in premotor and motor cortices as well as other cortical and subcortical areas, but also with hypermetabolism in the medial temporal cortex and the cerebellum. The mechanism of this phenomenon in ALS is still unknown and needs further consideration and research.

Title: Micrornas at the *C. elegans* neuromuscular junction: Potential sma modifiers?

Authors: ***P. J. O'HERN**, A. C. HART
Neurosci., Brown Univ., Providence, RI

Abstract: Spinal Muscular Atrophy (SMA) is a neurological disorder characterized by loss of lower motor neurons. This degeneration is almost exclusively caused by mutations in the SMN1 gene that lead to decreased levels of Survival of Motor Neuron (SMN) protein. smn-1 is the *C. elegans* ortholog of SMN1, disruption of which results in motor defects (Briese et al. 2009). It is unknown how loss of SMN protein perturbs motor neuron function, however evidence suggests that miRNA disruption may play a role (Mourelatos et al. 2003). miRNAs are small non-coding RNAs predicted to regulate protein expression of mRNAs. The RNA helicase Gemin3 is found in numerous complexes with SMN and also pulls down with numerous miRNAs in cultured mouse motor neurons (Dostie et al. 2003). I hypothesize that Gemin3-associated miRNAs are misregulated in smn-1 loss-of-function animals leading to NMJ defects. I have identified *C. elegans* orthologs of Gemin3-associated miRNAs that regulate neuromuscular junction (NMJ) signaling. smn-1 lf animals are defective on aldicarb and have reduced pumping, suggesting NMJ defects. Using tissue-specific rescue analysis and genetic epistasis, I will elucidate miRNAs that regulate NMJ function in the same pathway as SMN-1. I will also compile a list of potential mRNA targets for candidate miRNAs utilizing online bioinformatics tools, assigning priority to conserved targets with known synaptic function. For each potential mRNA target, I will confirm miRNA regulation and investigate whether expression of these targets is altered in smn-1 lf animals. These experiments will advance our knowledge of how SMN protein contributes to essential neuronal function and expand our understanding of how miRNA misregulation may contribute to neurodegeneration.

Title: The role of bid in toll-like receptor signalling in glial cells following mutant SOD1-induced neuroinflammation in Amyotrophic Lateral Sclerosis

Authors: *S. KINSELLA, K. S. COUGHLAN, H. G. KOENIG, J. H. M. PREHN
Dept. of Physiol. and Med. Physics, Royal Col. of Surgeons In Ireland, Dublin 2, Ireland

Abstract: Neuroinflammation is a pathological hallmark of neurodegenerative disease, with evidence of increased microgliosis and astrogliosis in Amyotrophic Lateral Sclerosis (ALS). Non-cell autonomous death of motoneurons mediated by activated microglia and astrocytes is proposed to be a key event in ALS aetiology. Toll-like Receptors (TLRs) are the master regulators of immune response and are highly expressed on glial cells, with elevated levels of TLRs -2 and -4 identified in the brain and spinal cord in ALS pathology. The Bcl2 family member, Bid has recently been shown to have a role in inflammatory regulation via interactions with the IKK component of the TLR-NF-κB pathway. This study examined both the role of Bid in the inflammasome and the effects of Superoxide Dismutase 1 (S0D1), mutations of which are associated with ALS, on TLR-induced glial activation *in vitro*. Transient transfection of microglia (BV-2) with $SOD1^{wt}$ and $SOD1^{G93A}$ revealed increased *tlr2*, *tlr4* mRNA and increased TLR2 and TLR4 membrane expression. Interestingly, the expression of the NF-κB target gene, COX-2, is decreased in BV2 cells following Bid siRNA transfection and subsequent treatment with motoneuron $SOD1^{G93A}$ -conditioned media, compared to control siRNA-transfected cells exposed to $SOD1^{G93A}$ -conditioned media. Furthermore, a decreased level of NF-κB activation in response to LPS stimulation was seen when Bid is inhibited in microglial (BV2) cells. Reduced CD45 and IL-1β expression is evident in the absence of Bid compared to *wt* microglia treated with either TLR2 (Pam_3CSK4) and TLR4 (LPS) agonists 24 hours post stimulation. Our data also shows a delayed IκBα degradation in $Bid^{-/-}$ primary microglia compared to *wt* upon LPS stimulation, indicating a differential role of Bid in the activation of NF-κB. This data demonstrates that TLR signalling is activated by overexpressed $SOD1^{wt}$ and $SOD1^{G93A}$, and that Bid may play an important role in mediating TLR-induced pro-inflammatory signalling in glial cells.

Title: Axonal transport and translation of α- and γ-actin mRNAs are altered in Smn-deficient motoneurons

Authors: *M. MORADI, L. SAAL, R. BLUM, M. SENDTNER
Inst. For Clin. Neurobio., Würzburg, Germany

Abstract: Axonal mRNA translocation and local protein synthesis are crucial for axonal guidance, growth, maturation and maintenance of synapses in developing motoneurons. Therefore, impaired axonal mRNA trafficking and translation might contribute to the pathogenesis of various neurodegenerative diseases such as Spinal Muscular Atrophy (SMA). ß-actin mRNA and protein are highly abundant in the growth cone of developing motoneurons where they regulate cytoskeletal dynamics required for the axon outgrowth and path finding. Previous findings have revealed that the axonal localization and translation of ß-actin mRNA are disturbed in primary motoneurons of a mouse model of SMA. Interestingly, this observation correlates with reduced axon length and growth cone size suggesting that axonal ß-actin mRNA deficiency might be related to the SMA phenotype. In order to address whether axonal translocation and translation of α- and γ-actin mRNAs are also affected in Smn deficient motoneurons, we cultured motoneurons in compartmentalized microfluid chambers and analyzed these RNAs by qRT-PCR. We also investigated alterations in actin protein synthesis by transducing motoneurons with lentiviral eGFPmyr-act 3'UTR reporter constructs and quantifying newly synthetized proteins in the axon terminal using Fluorescence Recovery After Photobleaching (FRAP). Our data reveal that all three actin isoforms become translocated into axons of motoneurons, in contrast to sensory neurons. In addition, we found that α-actin is highly enriched in axons of motoneurons compared to ß- and γ-actin suggesting that this isoform might have a particular function during axon development. We also observed that actin is not only translated from ß-actin mRNA in motoneurons but also at significant levels from α- and γ-actin mRNAs. Upon Smn depletion, both axonal transport and translation of all three actin isoforms are impaired suggesting that dysregulation of axonal transport of actin is functionally associated with the SMA phenotype. Ongoing experiments will determine whether the different actin isoforms accomplish different functions in the axon development in motoneurons in comparison to sensory neurons and thus could explain why these cells are predominantly affected in spinal muscular atrophy.

Title: Dynein/dynactin mutations associated with amyotrophic lateral sclerosis and their effect on axonal transport and neuromuscular junction formation

Authors: *V. BERCIER[1,2,3], T. AUER[1,4], F. DEL BENE[1,2,3]
[1]Developmental Biol., Inst. Curie-Research Ctr., Paris, France; [2]Ecole doctorale Cerveau-Cognition-Comportement (ED3C), Pierre et Marie Curie University-Paris VI, Paris, France; [3]École des Neurosciences de Paris-Ile-de-France (ENP), Paris, France; [4]Ctr. for Organismal Studies, Ruprecht-Karls-Universität Heidelberg, Heidelberg, Germany

Abstract: Amyotrophic lateral sclerosis (ALS) is an adult-onset neurodegenerative disease, which is mainly sporadic in nature. This progressive pathology has an estimated incidence of 1:1000 and generally leads to death within 2-5 years of diagnosis due to muscle wasting and severe motor neuron loss. Over the last years, mutations have been identified in both sporadic and familial ALS patients, interfering with the function of many genes, including DCTN1, which encodes for a subunit of the motor protein complex component dynactin. The dynactin complex serves as an adaptor for the dynein motor complex, responsible for retrograde axonal transport, and it is believed to regulate dynein activity and the binding capacity for cargos. Interestingly, axonal transport deficits have been reported in various neurodegenerative diseases owing to the fact that neurons are highly polarized cells that depend on active axonal transport for growth, establishment and maintenance of synapses. Defects in transport of material for development or clearance of detritus in the axon can lead to neuronal stress and cell death and could arise from different causes: preferential type of transport, varying load size, and depletion or dilution of the motor protein populations. In order to determine how retrograde axonal transport is involved in the pathogenesis of ALS, we are characterizing a mutant zebrafish line for dctn1 with regard to axonal development of primary motor neurons, formation and stability of the neuromuscular junction and the behavioral phenotype produced. Fast axonal transport defects are quantified in primary motor neurons using the GAL/UAS bipartite system and fusion protein tracking *in vivo* by confocal timelapse microscopy. We are investigating the transport dynamics of cargos such as endosomes, mitochondria, synaptic vesicles and neurotrophic receptors in the motor neurons of wild-type versus dctn1 mutant embryos *in vivo*, and over time. The yeast MSN/PP7 system allows us tagging and visualization of target mRNAs as they are transported to the synapse for local synthesis. As dynactin was reported to be essential to synapse stability, we are examining the formation and maintenance of the NMJ by immunohistochemistry (structure), by use of

synaptophysin-GCaMP for calcium imaging (function) and we will observe its integrity over time. Behavioral analysis of the mutant embryos will serve as readout of the defects at the motor neuron and NMJ level. We hope to elucidate key molecular mechanisms in ALS etiology by revealing the role of dynein in NMJ maintenance and identifying novel regulatory events in axon degeneration and muscle atrophy along disease progression.

Title: TDP-43 associated proteins as modulators of TDP-43 aggregation and toxicity in primary neurons

Authors: C.-C. CHOU[1], O. ALEXEEVA[1], Y. ZHANG[1], B. MO[1], K. R. WILLIAMS[1], D. C. ZARNESCU[4], G. J. BASSELL[1,2,3], *W. ROSSOLL[1,2]

Abstract: Among the growing number of known amyotrophic lateral sclerosis (ALS) disease proteins, TAR DNA binding protein 43 (TDP-43) has emerged as a key player. Nearly all sporadic and familial ALS cases are characterized by cytoplasmic aggregations of hyper-phosphorylated, ubiquitinated, and cleaved TDP-43 fragments and the loss of nuclear TDP-43. TDP-43 pathology is also common in frontotemporal dementia (FTD-TDP), as well as other TDP-43 proteinopathies. In rare cases, mutant TDP-43 can trigger the ALS disease process, establishing a clear causal role for TDP-43 in neurodegeneration. It is still not clear whether pathogenic aggregation of TDP-43 is causing a toxic gain of function that contributes to the neurodegeneration observed in patients. TDP-43 inclusion pathology may reflect an exaggeration

of normal accumulation of TDP-43 into cytoplasmic RNA granules under stress conditions. In this study, we investigated the effect of pathogenic TDP-43 and regulators of TDP-43 toxicity on mouse primary neurons. We identified distinct cytotoxic effects of full-length TDP-43 and its C-terminal fragment (TDP-CTF), and ALS-associated TDP-43 mutants (Q331K, M337V and A382T). As compared with the overexpression of full-length TDP-43, TDP-CTF and mutant TDP-43 had an increased toxic effect on primary neurons. In a yeast-two-hybrid screen we have identified TDP-43 interacting proteins, and further tested their effect on the accumulation of pathological TDP-43 aggregates. In our assays, overexpression or knock-down of poly(A) RNA-binding protein (PABP) modulates cell viability and the accumulation of TDP-CTF aggregates. In addition to our primary cultured mouse neurons, PABP mutations also modulate neurodegeneration in a *Drosophila* model of TDP-43 proteinopathy. We further show overexpression of full-length TDP-43 caused increased stress granule (SG) formation under conditions of oxidative stress. We found that TDP-43 was colocalized with TIAR, eIF3 and PABP in SGs, whereas, TDP-CTF reduced SG formation, and HuD and TIAR but not eIF3 were sequestered into TDP-CTF aggregates. Taken together, these results suggest that TDP-43-induced cellular dysfunction and resultant toxicity may be associated with an altered function of stress response pathways, contributing to the neuronal degeneration observed in ALS/FTD.

Title: The effects of metabolic disturbances on the levels of misfolded SOD1 in ALS patient-derived fibroblast lines

Authors: *I. KESKIN[1], E. FORSGREN[1], J. GILTHORPE[1], E. TOKUDA[2], A. BIRVE[1], P. M. ANDERSEN[1], S. MARKLUND[2]
[1]Dept. of Pharmacol. and Clin. Neurosci., [2]Dept. of Med. Biosci., Umea Univ., Umea, Sweden

Abstract: Introduction The neurotoxicity of mutant SOD1's is believed to be exerted by misfolded SOD1 species. The patho-mechanism is poorly understood but has been suggested to involve perturbation of mitochondria, induction of ER-stress, reduction of proteasome and

autophagy efficiency and aggregation. Another unresolved feature of ALS is why carriers of SOD1 mutations are apparently healthy until middle age, and then undergo rapid neurological decline. Perhaps age-related decline in proteostasis and energy metabolism contributes, amplified by vicious circles that increase the levels of misfolded SOD1 in the tissue. Objectives We have generated fibroblast lines from skin biopsies derived from 8 ALS patients carrying mutations in SOD1 (A4V, H46R, E78_R79insSI, N86S, D90A, L117V, D126fsX24, G127instggg); from 1 ALS and 1 FTD patient with C9orf72 GGGGCC-hexanucleotide repeat expansion, from 2 healthy control subjects. These cells, which express the mutant SOD1s under the native promoter, offer opportunities for exploration which are not accessible in the other model systems. We used the cells to gain information on the effects of various metabolic disturbances on the levels of misfolded SOD1. Methods We cultured the fibroblast cell lines under a variety of stress conditions and with/without inhibitors. Misfolded SOD1 from fibroblast extracts was measured with a specific ELISA (misELISA) as described (Zetterström et al. J Neurochem 2011;117:91). Results All fibroblast lines derived from the ALS patients contained more misfolded SOD1 than those from control individuals. The proteasome inhibitor bortezomib caused marked increases in misfolded SOD1 levels. Induction of ER stress with tunicamycin, inhibition of mitochondria with rotenone, and suppression of autophagy with 3-methyladenine decreased misfolded SOD1 levels. Hyperoxia might conceivably stabilize SOD1 by artificially promoting the C57-C146 disulfide bond. There were, however, no differences between cells cultured in physiological oxygen tension (4% O2) and hyperoxia (20% O2). Under none of the conditions could any detergent-resistant aggregates be demonstrated in the cell extracts. Conclusion Proteasome inhibition caused large increases in misfolded SOD1 levels. Other cellular perturbations occurring in ALS and aging did not per se induce increases in misfolded SOD1 levels.

Abstract: Proximal spinal muscular atrophy (SMA) is an early onset, autosomal recessive motor neuron disease caused by loss of or mutation in SMN1 (survival motor neuron 1). Despite understanding the genetic basis underlying this disease, it is still not known why motor neurons (MNs) are selectively affected by the loss of the ubiquitously expressed SMN protein. Using a mouse embryonic stem cell (mESC) model for severe SMA, the RNA transcript profiles between control and severe SMA (SMN2+/+;mSmn-/-) mESC-derived MNs were compared in this study using massively parallel RNA sequencing (RNA-Seq). The MN differentiation efficiencies between control and severe SMA mESCs were similar. RNA-Seq analysis identified 3094 upregulated and 6964 downregulated transcripts in SMA mESC-derived MNs when compared against control cells. Pathway and network analysis of the differentially expressed RNA transcripts showed that pluripotency and cell proliferation transcripts were significantly increased in SMA MNs while transcripts related to neuronal development and activity were reduced. The differential expression of selected transcripts such as Crabp1, Crabp2 and Nkx2.2 was validated in a second mESC model for SMA as well as in the spinal cords of low copy SMN2 severe SMA mice. Furthermore, the levels of these selected transcripts were restored in high copy SMN2 rescue mouse spinal cords when compared against low copy SMN2 severe SMA mice. These findings suggest that SMN deficiency affects processes critical for normal development and maintenance of MNs.

Title: A stem cell model of motor circuits reveals distinct requirements of SMN for motor neuron survival and function

Authors: ***C. M. SIMON**, A. JANAS, F. LOTTI, L. PELLIZZONI, G. MENTIS
Col. of Physicians and Surgeons, Motor Neuron Ctr., New York, NY

Abstract: Neuronal circuit perturbations are emerging as important determinants in the pathogenesis of neurodegenerative diseases. Spinal muscular atrophy (SMA) is a neurodegenerative disease caused by deficiency in the ubiquitously expressed SMN protein. SMA is characterized by loss of motor neurons (MNs), muscle atrophy and abnormal reflexes. In SMA mice, sensory-motor circuit dysfunction precedes motor neuron loss raising the possibility that SMN deficiency in premotor neurons may play a critical role in the pathophysiology of SMA. The effects of SMN deficiency in premotor neurons on MN survival and function are currently unknown. To address this, we developed a stem cell-based model of the motor circuit in which SMN protein levels can be selectively depleted either in both MNs and interneurons (INTs), or in only one of the two neuronal types. To do so, we employed MNs (Hb9::GFP) and INTs (Syn1::mCherry) differentiated from mouse embryonic stem (ES) cell lines with regulated RNAi knockdown of endogenous SMN. The survival of MNs was measured using whole-well automated fluorescence imaging. When MNs and INTs were co-plated, a time-course analysis revealed significantly reduced survival of SMN-deficient MNs but not INTs relative to controls. Purified MNs by FACS resulted in a similar extent of MN death induced by SMN deficiency, suggesting that MN loss is mediated via cell autonomous mechanisms. To study the effects of SMN-deficiency on motor neuron function, we employed intracellular patch clamp recordings. In co-cultures of SMN-deficient MNs and INTs we found an increase in MN membrane excitability compared to controls with normal SMN levels. MN output - measured by the

spontaneous firing frequency - was also significantly reduced by SMN deficiency. In contrast, FACS purified SMN-deficient MNs were not hyperexcitable. To address whether MN hyperexcitability and reduced output are governed by similar mechanisms, we studied the effects of SMN-deficiency in INTs when co-plated with normal MNs and vice versa. We found that the increased MN membrane excitability is due to SMN-deficiency in INTs only, suggesting non-cell autonomous mechanisms. However, the reduced spontaneous MN firing was a result of SMN-deficiency in both MNs and INTs, suggesting that this phenotype is governed by both cell autonomous and non-cell autonomous mechanisms. Collectively, our study reveals that dysfunction and loss of MNs are distinct events that occur downstream of SMN deficiency as a result of differential effects in specific neuronal types.

Title: Characterization of iPSC derivatives from spinal and bulbar muscular atrophy patients

Authors: *I. KATS, C. GRUNSEICH, K. ZUKOSKY, L. GHOSH, G. HARMISON, L. C. BOTT, C. RINALDI, K.-L. CHEN, G. CHEN, M. BOEHM, K. H. FISCHBECK
NIH, Bethesda, MD

Abstract: Spinal and bulbar muscular atrophy (SBMA), also known as Kennedy's disease, is an X-linked neuromuscular disease caused by a polyglutamine repeat expansion in the androgen receptor. The disease is known to cause degeneration of motor neurons through a ligand-dependent toxic gain of function, but the exact mechanism is not well understood. Motor neurons differentiated from SBMA patient derived induced pluripotent stem cells (iPSCs) provide a model for characterizing the disease mechanism and designing potential therapy. iPSCs were generated from six patients and compared to three control lines. Motor neurons were differentiated from the iPSCs and assessed for disease relevant phenotypes. The expanded polyglutamine repeats were unstable during re-programming, with several lines showing

expansion or contraction. Patient iPSCs expressed less androgen receptor than control lines but show androgen dependent stabilization and nuclear translocation with ligand exposure. Stem cell derived motor neurons showed immunoreactivity for HB9, Isl1, ChAT, and SMI-32, and were differentiated with similar efficiency between the patient and control lines, with no detectable difference appreciated following androgen treatment. Patient-derived motor neurons were found to have decreased HDAC6 levels and those with longer repeat lengths were shown to also have increased acetylated α-tubulin. This finding was confirmed in patient spinal cord sections and in stably transfected mouse cells. Another HDAC6-dependent process, intracellular lysosomal enrichment, was disrupted in motor neurons from iPSC lines with longer repeat lengths. The observed reduction in androgen expression, increase in acetylated α-tubulin and decrease in HDAC6 provide opportunities for further investigation of the SBMA disease mechanism and potential treatment.

Title: Nuclear transport defect underlies C9ORF72 ALS/FTD neuronal injury in human neurons and is rescued by antisense and small molecules that target GGGGCC RNA

Authors: *C. J. DONNELLY[1,2], K. ZHANG[3], A. R. HAEUSLER[5], J. WANG[5], T. E. LLOYD[1,4], R. SATTLER[1,2], J. D. ROTHSTEIN[1,2,4]

Abstract: A hexanucleotide repeat expansion in the C9ORF72 gene has recently been identified as the most common known genetic cause of familial and sporadic amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). Recent evidence employing iPS-neurons from C9ORF72 ALS patients suggests that the GGGGCC RNA products transcribed from the repeat expansion form complex G-quartet RNA structures and are neurotoxic. Similar to other repeat expansion disorders (e.g., myotonic dystrophy type I and II), the C9ORF72 GGGGCCexp RNA can sequester nuclear factors, including RNA binding proteins, and we hypothesize that these aberrant interactions are the primary cause of C9ORF72 neurotoxicity. Previous work from our laboratory has indicated that the GGGGCC RNA interacts with Ran-GAP1, a regulator of Ran-mediated cyto-nuclear trafficking. We have also found that Ran-GAP1 is a robust suppressor of neurotoxicity in a *Drosophila* model system that overexpresses GGGGCC RNA. Consistent with a Ran-GAP1 loss-of-function model, we have found that the G4C2 *Drosophila* model show reduced nuclear localization of NLS-containing reporters and iPS-neurons from C9ORF72 ALS patients exhibit perturbed Ran protein gradients. Importantly, these nuclear transport deficits can be rescued by treating the *Drosophila* and C9ORF72-patient derived iPS-neurons with antisense oligonucleotides that target GGGGCC repeat-containing RNAs or small molecules that bind G-quartet RNA structures to prevent any interaction with endogenous proteins. Taken together, these studies strongly support an RNA gain-of-function mechanism underlying C9ORF72 neurodegeneration. Moreover, we show, for the first time, that the toxic GGGGCCexp RNA reduces the nuclear import of classical NLS-containing proteins via an aberrant interaction with Ran-GAP1.

Title: Motor neuron hyperexcitability is induced by non-cell autonomous mechanisms in a mouse model of spinal muscular atrophy

Authors: *E. FLETCHER, C. SIMON, J. PAGIAZITIS, X. WANG, G. MENTIS
The Ctr. for Motor Neuron Biol. and Dis., Columbia Univ., New York, NY

Abstract: Spinal muscular atrophy (SMA) is a neurodegenerative disease caused by reduced levels of the ubiquitously expressed SMN protein. The hallmarks of SMA are loss of motor neurons (MNs), muscle atrophy and abnormal postural reflexes. MNs innervating proximal muscles are more vulnerable than MNs innervating distal hindlimb muscles, resulting in a proximo-distal progression of the disease. The mechanisms leading to selective motor deficits are poorly understood. Using SMA mice, we have previously shown that sensory-motor circuit dysfunction precedes MN loss. Vulnerable MNs are abnormally hyperexcitable and exhibit reduced reflexes compared to resistant MNs at early stages of the disease. An indicator of MN dysfunction is an increase in intrinsic excitability. To address whether an increase in MN membrane excitability is caused non-cell autonomously by premotor synaptic dysfunction, or cell autonomously due to SMN deficiency per se in MNs, we studied the intrinsic membrane properties in wild type and SMA MNs using whole cell patch recordings from intact spinal cords *in vitro*. At pre-symptomatic stages, half of SMA MNs innervating proximal muscles were significantly hyperexcitable compared to their wild type counterparts. Their monosynaptically-evoked EPSPs after proprioceptive fibers stimulation revealed a significant reduction. In contrast, the remaining half of SMA MNs exhibited normal membrane properties and similar evoked EPSPs compared to wild type MNs. To test whether SMN deficiency in premotor neurons results in changes of MN membrane excitability, we studied the properties of MNs in SMA animals, in which SMN was selectively restored in only proprioceptive neurons. We used SMA mice harboring a Conditional Inversion allele which reverts SMN protein to normal levels upon Cre recombination. Parvalbumin-Cre mice were used to restore SMN protein levels in proprioceptive fibers. Our results reveal that the hyperexcitability observed in vulnerable SMA MNs is significantly corrected and restored the propioceptive-induced EPSPs. Restoration of SMN in MNs only, however, (using ChAT-Cre mice), did not result in any significant correction

in either MN excitability or synaptic function. These findings strongly suggest that SMN deficiency in proprioceptive neurons alters the intrinsic excitability of SMA MNs through non-cell autonomous mechanisms, consistent with SMA being a disease of motor circuits.

Title: Elucidating the degeneration of spinal motor neurons in human models of spinal muscular atrophy

Authors: ***C. XU**[1], K. DENTON[1], X.-J. LI[1,2]
[1]Neruoscience, Univ. of Connecticut Hlth. Ctr., Farmington, CT; [2]The university of Connecticut Hlth. Ctr., Stem Cell Inst., Farmington, CT

Abstract: Spinal muscular atrophy (SMA), the leading genetic cause of infant and toddler mortality, is caused by the decreased level of functional survival motor neuron (SMN) protein. How the deficiency of SMN, a universally expressed protein, leads to specific degeneration of spinal motor neurons has remained largely unknown. Here, we have generated induced pluripotent stem cells (iPSCs) from SMA patients using the episomal transduction method. Human iPSC lines from their relatives and normal individuals were also generated and utilized as controls. Spinal motor neurons were efficiently differentiated from these iPSCs by the application of both purmorphamine and retinoic acid. We then examined the mitochondrial fast axonal transport in motor neurons derived from SMA type I patient iPSCs and control iPSCs. Spinal motor neurons derived from SMA iPSCs displayed mitochondrial transport defects, including reduced motile mitochondria and a significant decrease in the frequency of retrograde events. SMA iPSC-derived spinal motor neurons were also specifically degenerated in long-term cultures, similar as what we observed in cultures derived from SMN-knockdown human

embryonic stem cells. Interestingly, N-acetylcysteine (NAC), a potent antioxidant, rescued the mitochondrial transport defects in SMA spinal motor neurons. The disease-related apoptosis and later motor neuron degeneration also ameliorated by NAC. These data suggest that impaired mitochondrial transport is involved in the motor neuron degeneration in SMA. Furthermore, we are using the transcription activator-like effector nucleases (TALENs)-mediated homologous recombination to restore the expression of SMN at different time windows to investigate how mitochondrial transport defects and motor neuron degeneration can be rescued. Together, we demonstrate the successful establishment of human pluripotent stem cell-based models of SMA and our models will be valuable for dissecting the pathogenic mechanism and screening compounds to rescue the motor neuron degeneration in SMA.

Title: Role of a unique RNA structure in regulation of alternative splicing of spinal muscular atrophy gene

Authors: N. N. SINGH[1], *R. N. SINGH[2]
[1]Biomed. Sci., [2]Iowa State Univ., Ames, IA

Abstract: Humans carry two copies of *Survival Motor Neuron* gene: *SMN1* and *SMN2*. Loss of *SMN1* coupled with skipping of *SMN2* exon 7 causes spinal muscular atrophy (SMA), a leading genetic disease associated with infant mortality. We have previously reported an intronic splicing

silencer (ISS-N1) as a negative regulator of *SMN2* exon 7 splicing (Singh et al., 2006). ISS-N1 is the most studied and highly promising target for an antisense oligonucleotide (ASO)-mediated splicing correction in SMA (Howell et al., 2014). ISS-N1 partially overlaps with a GC-rich sequence (GCRS) and also communicates with ISS-N2, another inhibitory element, which falls on a unique RNA structure that we term Internal Stem Through Long-distance interaction 1 (ISTL1) (Singh et al., 2013). Using site-specific mutations and SHAPE (Selective 2′-Hydroxyl Acylation analysed by Primer Extension), we show the formation and functional significance of ISTL1. Our results expand the repertoire of ASO-based targets for SMA therapy and underscore the therapeutic potential of regulatory information trapped in secondary and high-order RNA structures located within an intron. Our findings also demonstrate that an ASO-based approach could be employed to favourably remodel the structural map of intronic sequences that occupy a vast portion of human genome. **References:** Howell MD, Singh NN and Singh RN (2014) Advances in therapeutic development for spinal muscular atrophy. Title: Overexpression of the amyloid precursor protein triggers an increase in P21-activated kinase (PAK) activity and disrupts neurite extension in murine trisomy 16 neuronal cell lines, an animal model of Down syndrome

Authors: N. BARRAZA[1], A. CARDENAS[2], J.-V. BARNIER[3], K. S. POKSAY[4], V. JOHN[4,5], *P. A. CAVIEDES[1]
[1]Prog of Molec & Clin. Pharmacol., ICBM Fac Medicine, Univ. of Chile, Santiago, Chile; [2]CINV, Univ. of Valparaíso, Valparaiso, Chile; [3]CNRS UMR 8195, Ctr. de Neurosciences Paris-Sud CNPS, Orsay, France; [4]Buck Inst. for Res. on Aging, Novato, CA; [5]Dept. of Neurol., UCLA, Los Angeles, CA

Abstract: Down syndrome, or trisomy of autosome 21, is the chromosomal aneuploidy that most frequently survives pregnancy, and it is the most common cause of mental retardation of genetic origin Among the genes overexpressed from chromosome 21, several can potentially affect neural development and function. One particular gene is that encoding the amyloid precursor protein (APP). APP can bind to p21-activated kinases (PAKs) and affect their activities. Hence, APP overexpression can deregulate PAK activity and in turn disrupt several developmental and neural physiological processes. Although it has been described that APP binds PAKs through the APP C-terminal domain, it is not known if the complete membrane-bound APP or if its C-31

fragment are sufficient to activate PAK. C-31 is released by the action of caspases, which cleave APP at Asp664 in the C-terminus of APP. The increased activity of PAKs may alter actin dynamics and cofilin via phosphorylation of LIMK. This in turn affects the stability of actin filaments and reduces the number of dendritic spines, as well as axon growth, all of which constitute morphological features underlying cognitive impairment. Therefore, it is important to determine the interaction of APP with PAKs in a cellular model of Down syndrome, where APP is overexpressed, to determine how APP binds and activates PAK, and simultaneously how it can alter the stability of actin filaments and decrease neurite extension. In the present study, we utilized a neuronal cell line -named CTb - derived from the cerebral cortex of a trisomy 16 mouse (Ts16), an animal model of human Down syndrome, and a control cell line - named CNh- derived from the cortex of a normal littermate. We evaluated the interaction between PAKs and APP. APP overexpression was confirmed with immnoblotting and FACS techniques. Our results indicate that PAKs do not coimmunoprecipite with the 1-664 peptide derived from the caspase cleavage of APP, which lacks the C31 peptide, suggesting that this peptide is important for APP-PAK interaction. Our results also suggest that, under differentiating conditions, CTb cells exhibit fewer and shorter processes as compared to CNh cells. This work could lead to potential therapeutic targets to address the Down syndrome pathology.

Title: Chromatin related functions of BRWD1, a neuronally enriched nucleosomal 'reader' protein: Implications for Down syndrome associated pathologies

Authors: *I. S. MAZE, W. WENDERSKI
Lab. of Chromatin Biol. and Epigenetics, The Rockefeller Univ., New York, NY

Abstract: Down syndrome (DS) is the most common chromosomal abnormality disorder in humans caused by a triplication of all or part of chromosome 21. DS is associated with physical growth delays, characteristic craniofacial abnormalities and intellectual disability. Although much is known regarding physiological aberrations associated with DS, far less is clear concerning the molecular mechanisms mediating this disease. Although DS is clearly marked by deficits in neural plasticity and increased neurodegeneration, few treatments exist that adequately reverse neuronal impairments resulting from this syndrome. Given that several neurological disorders associated with cognitive impairment result in disruptions in gene regulation, further mechanistic studies of neuronal specific histone function may provide clues into the underlying causes of neuropathology. Using SILAC in rodent neurons, coupled to LC-MS/MS, we identified H3K4me1, a classic genomic enhancer-enriched PTM, as the most abundantly enriched mark on dynamic nucleosomes. To understand the contribution of H3K4me1 to neurological function and plasticity, we set out to identify neuronally enriched reader/effector proteins binding to this mark *in vivo*. Synthesized N-terminal histone tail peptides were used to immunoprecipitate protein complexes associated with this mark from soluble nuclear extracts from brain; the chromatin effector protein Brwd1 was identified. BRWD1 is a WD40 repeat and bromodomain-containing protein that is encoded within the Down syndrome critical region 2 on chromosome 21 in humans. Given that WD40 domains have previously been shown to interact with other histone methylation marks, we sought to identify whether it might act as a multivalent binding protein that can recognize and simultaneously associate with multiple PTMs. Recombinant human BRWD1 WD40 and bromodomains were generated and purified, and custom-made histone PTM peptide arrays, as well as individual peptide IPs, confirmed these interactions *in vitro* with high affinity. Surprisingly, two other histone methylation signatures were identified as interacting partners for BRWD1, H3K27me3 and H4K20me3, both of which are transcriptionally repressive. Using a combination of biochemical and functional approaches, we are investigating the consequences of BRWD1 triplication in DS in relation to altered patterns of chromatin regulation in affected individuals, with the hope that such information may lead to the development of improved therapeutics aimed at alleviating DS associated pathologies.

Title: DSCR1 is critical for local protein synthesis in neurons

Authors: *W. WANG[1], Z. SMILANSKY[2], K. CHANG[3], K. MIN[1]
[1]biology, The Ulsan Natl. Inst. of Sci. and Techno, Ulsan, Korea, Republic of; [2]2Anima Cell Metrology, Inc, Bernardville, NJ; [3]Zilkha Neurogenetic Inst. and Dept. of Cell and Neurobio., USC, Los Angeles, CA

Abstract: DSCR1 (Down syndrome critical region1, also called RCAN1 or regulator of calcineurin) is located on human chromosome 21 and highly expressed in the brain, especially enriched in hippocampal neurons. DSCR1 belongs to a conserved family of calcineurin (CaN) inhibitors called calcipressins, which includes RCN1P in yeast, CBP1 in fungus, nebula in *Drosophila*, as well as DSCR1 in mouse and human. The DSCR1 knock-out mice show learning deficits and impaired late-phase long term potentiation (L-LTP) which requires new gene expression, implying that DSCR1 may play a role in local protein synthesis. We discovered that DSCR1 plays a critical role in local protein synthesis by regulating FMRP (Fragile X Mental Retardation Protein) function in dendritic spines. Upon BDNF stimulation, DSCR1 becomes phosphorylated, which in turn changes DSCR1 from an inhibitor to an activator of Calcineurin. Active Calcineurin then dephosphorylates phosphorylated FMRP (pFMRP), leading to release of pFMRP from target mRNAs, thus allowing local mRNA translation. It is also known that local protein synthesis is critical for axon growth cone turning in developing axons. Here, we report that DSCR1 is present in axon growth cones and required for turning and development of axon growth cones. We show that DSCR1 is located in axon growth cones using SIM (Structured Illumination Microscopy) and STORM (Stochastic Optical Reconstruction Microscopy). Furthermore, using photoswitchable dendra 2 proteins and a new FRET technique, we show that DSCR1 is involved in local protein synthesis in axon growth cones. Together, our results imply that DSCR1 plays a critical role in local protein synthesis in dendritic spines as well as axon growth cones.

Title: The PAK effector pathway as a possible pathophysiological target in immortalized cell models of Down Syndrome. Possible role of DSCAM mediated dysregulation

Authors: *R. D. PÉREZ[1], J.-V. BARNIER[2], R. CAVIEDES[1], P. CAVIEDES[1]
[1]ICBM, Fac. Medicine,University of Chile, Santiago, Chile; [2]CNRS, Paris, France

Abstract: Down syndrome (DS), or trisomy 21 in man, results from the presence of an extra copy of autosome 21, resulting in various multisystemic anomalies, where mental retardation is the most striking. The CTb cell line, derived from the cerebral cortex of a trisomy 16 fetal mouse (Ts16), an animal model of DS, is an model for the study of DS-related cell pathophysiological phenomena. When comparing CTb cells with the CNh cell line, a counterpart derived from the cerebral cortex of a normal animal, multiple DS-related gene impairments in neuronal function have been studied. One of such genes, which reportedly is involved in neuronal development and function, is dscam, which codes for the cell adhesion protein DSCAM (Down Syndrome Cell Adhesion Molecule). This protein recognizes Netrin at the membrane level, leading to a signaling cascade that is pivotal for correct neuritic development. In the latter case, the cellular signaling pathways involved are the serine/threonine p21-activated kinases (PAK), which then act downstream on effectors such as LIMK-cofilin, leading to reorganization of actin filaments. The present study shows that DSCAM is overexpressed in CTb cell by 40%, compared to CNh cells, as analyzed by western-blot and flow cytometry. This could increase PAK pathway function, in turn deregulating neuronal plasticity. This is supported by present results using Sholl analysis, which revealed a reduction in process number and length in CTb cells compared to CNh. A crucial question then arises, which involves verifying if PAK kinases are effectively deregulated in the trisomic condition. The present work further presents the correlation between dscam gene overexpression and its action on the PAK pathway, as determined by PAK activity phosphorylation states and morphological parameters of neuronal plasticity. The CTb cell line could be a model to assess relevant therapeutic in DS.

Title: Effects of maternal choline supplementation (MCS) on CA1 pyramidal neuron gene expression in adult Ts65Dn and normal disomic (2N) offspring

Authors: *M. J. ALLDRED[1,4], S. H. LEE[2], E. PETKOVA[3,5], S. D. GINSBERG[1,4,6]
[1]Ctr. for Dementia Res., [2]Med. Physics, [3]Child Psychiatry, Nathan Kline Inst., Orangeburg, NY; [4]Psychiatry, [5]Child and Adolescent Psychiatry, [6]Physiol. & Neurosci., New York Univ. Langone Med. Ctr., New York, NY

Abstract: Down syndrome (DS) is the most frequent genetic cause of intellectual disability (ID) with an increasing prevalence in the USA, with current estimates of 1 in 691 live births. Individuals with DS have system-wide impairments, including the musculoskeletal system and notably the central nervous system, with ID and decreased cognitive function seen by impairments in hippocampal learning and memory, degeneration of cholinergic basal forebrain neurons (BFCNs), and language and communication skills. In addition to abnormal CNS function during development and adult life, individuals with DS develop Alzheimer's disease (AD) neuropathological hallmarks early in mid-life, including senile plaques (SPs), neurofibrillary tangles (NFTs), and early endosomal abnormalities. To examine the gene expression changes and test a putative treatment paradigm, we are using the Ts65Dn mouse model of DS/AD, specifically assessing CA1 pyramidal neurons. The Ts65Dn mouse model recapitulates several critical components of DS/AD, including cognitive dysfunction and BFCN degeneration, providing mechanistic assessments for translation to humans. We examined the Ts65Dn mice at the start of the BFCN degeneration and tested a maternal choline supplementation (MCS) paradigm, postulating that MCS will have a beneficial effect on the ID and septohippocampal degeneration seen in the Ts65Dn mice. We will test MCS treatment for amelioration of BFCN degeneration and track pathways that may enable understanding of the

underpinnings of cognitive decline and AD pathology. Preliminary microarray results on a custom-designed platform indicate that MCS produces significant gene expression level changes compared to age-matched unsupplemented maternal choline (UMC) offspring in CA1 pyramidal neurons independent of genotype. Specifically, alterations in several classes of transcripts including both glutamatergic and GABAergic neurotransmission, along with adenylate cyclases and AD-related genes were observed in both Ts65Dn and 2N mice. Preliminary genotype differences that are MCS sensitive include App, Bace1, Grik4, Grik5, GabrA3, and Gat2. Comparing MCS offspring to UMC offspring in Ts65Dn and 2N littermates will help to elucidate specific genes and signaling pathways that may be responsive to this early intervention. Moreover, these mechanistic studies will hopefully further our understanding of choline requirements for cognitive development. This approach also has translational viability as a low cost, non-invasive method of cognitive improvement for DS, as well as having a generalized neuroprotective effect that could delay onset and development of AD.

Title: Age-dependent disruptions to signaling networks in the hippocampus of the Ts65dn mouse model of Down Syndrome

Authors: ***D. R. HOLMAN**[1], Z. GALDZICKI[1,2], X. XU[1], P. DAO[2], T. PRZYTYCKA[2]
[1]Anatomy, Physiology, and Genet., Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD; [2]NIH, Bethesda, MD

Abstract: Down Syndrome is a progressively degenerative set of cognitive deficits, caused by triplication of chromosome 21, that affects 1 in 500 live births. The DS mouse model, Ts65Dn, has a triplicated segment of murine Chr. 16 that is homologous to human Chr. 21. A major phenotype of these mice is hippocampal-mediated learning and behavioral deficits and abnormal

hippocampal synaptic plasticity. Previous work from our lab in the hippocampus of the Ts65Dn mouse model of DS identified the upregulation of miR-155 and the abnormal expression of other miRNAs, the resulting downregulation of miR-155 and miR-214 targets. The bioinformatic analysis of the miRNA profile in Ts65Dn hippocampus revealed that signaling networks critical for neuronal proliferation, inflammation, and learning and memory are disrupted in the Ts65Dn hippocampus. Here, we apply RNA-Seq on hippocampal mRNAs isolated from two-week and two-month old Ts65Dn mice to identify the potential impact of these factors on the transcriptome at developmentally critical time point and during adulthood. We then use network and ontological analysis to identify candidate networks that are likely dysregulated, as well as to infer the well-investigated phenotypic outcomes in hippocampus of Ts65Dn mice and DS individuals. Our analysis confirms the dysregulation of networks previously identified (DYRK1A-NFATc, ERK, VEGF, PI3K/AKT). It also identifies previously unknown dysregulated pathways, such JNK, JAK/STAT, and IL6 responses.

Title: Synaptic plasticity deficits in mouse models of Down syndrome and Alzheimer disease

Authors: *C. M. WILLIAM[1], L. SAQRAN[2], M. A. STERN[2], M. P. FROSCH[1], B. T. HYMAN[2]
[1]Neuropathology Service, Massachusetts Gen Hosp, BOSTON, MA; [2]MassGeneral Inst. for Neurodegenerative Disease, Neurol. Dept., Massachusetts Gen. Hosp., Boston, MA

Abstract: Investigations using intact neural circuits in mouse models of Down syndrome (DS) may provide an approach to identifying the physiological basis for neurodevelopmental delay in the disease. Synaptic plasticity plays a critical role in the refinement and function of neural circuits and may be impaired in DS. To test this hypothesis, we have assayed visual system plasticity in a partial duplication mouse model of DS, the Ts65Dn line. Ocular dominance

plasticity (ODP) is the process by which loss of vision in one eye, monocular deprivation (MD), during a postnatal critical period, results in an increase in the area of primary visual cortex responsive to the non-deprived eye, in strengthening of responses to stimulation of the non-deprived eye and in weakening of responses to stimulation of the deprived eye. Using expression of the immediate early gene Arc to define the width of the domain of visual cortex responsive to non-deprived eye stimulation following a 4-6 day period of MD, we find that trisomic mice do not demonstrate the expansion in the coronal width of the responsive domain that occurs in similarly-treated, non-trisomic littermates (trisomic width, 944 ± 77.89 microns, n=5; non-trisomic width, 1087 ± 87.44 microns, n=13; p=0.0028, T-test). Optical imaging of intrinsic signals in awake mice was used to measure the magnitude of responses to stimulation of each eye before and after MD. Non-trisomic mice demonstrate strengthening of responses to non-deprived eye stimulation (pre-MD dF/F, 0.4%, n=5; post-MD, 0.57%, n=6; p=0.01), however, trisomic mice do not (pre-MD, 0.55%, n=9; post-MD, 0.46%, n=5; p=0.13). These data suggest that DS model mice exhibit defects in early postnatal developmental plasticity. Amyloid-beta accumulation secondary to amyloid precursor protein (APP) overexpression has been implicated in early-onset Alzheimer disease in DS, however, whether elevations in amyloid-beta can impair synaptic function earlier in life is less clear. We previously found that overexpression of mutant APP can block critical period ODP (William et al., 2012, J Neurosci 32(23):8004-8011). We find that transgenic mice that neuronally-express and secrete amyloid-beta in the absence of APP (BRI-Abeta40 and BRI-Abeta42 strains), also demonstrate critical period ODP deficits, measured by Arc assay and by optical imaging, suggesting that elevated expression of amyloid-beta alone can contribute to critical period ODP deficits. These studies suggest that synaptic plasticity defects may impair neural system function in DS and lay the foundation for future studies in model mice exploring the roles of duplicated genes, including APP, in causing synaptic dysfunction.

Title: Decreased intracellular traffic after induction of autophagy in the CTb cell line, derived from the cerebral cortex of a trisomy 16 mouse, an *in vitro* model of Down Syndrome

Authors: *C. F. ARRIAGADA, D. HERNÁNDEZ, R. PÉREZ, P. SALAZAR, P. CAVIEDES
ICBM, Fac. Med, Univ. Chile, Santiago, Chile

Abstract: Trisomy of the human chromosome 21 represents the most frequent cause of mental retardation in humans. The murine chromosome 16 presents a great homology with that human chromosome, and cell lines derived from mouse trisomy 16 (Ts16) represent an *in vitro* model of the human condition. In the present study, we evaluated the autophagyc flux in cell lines derived from the cerebral cortex of normal (CNh) and Ts16 (CTb) animals. Previous experiments have shown a decreased protein degradation ratio in the trysomic condition, and that there are no differences in structural and protease markers between CNh and CTb cell lines. To evaluate intracellular trafficking of autophagyc vacuoles, we transfected the cell lines with LC3-GFP, followed by autophagy induction. Degradative compartments were evidenced by red/DQ-BSA. In the CTb cell line, an exacerbated colocalization between LC3 and DQ-BSA was observed. pH-dependant GFP fluorescence emission could explain the minimal colocalization observed in CNh cell line. To evaluate this event, cells were transfected with a LC3-GFP/mCherry construct. After autophagy induction, colocalization was observed for an increased time lapse in CTb cell line. To evaluate if protease activity could decrease GFP emission, protease inhibitors were added. In such conditions, we observed no differences between the cell lines indicating that GFP fluorescence is pH-dependent and it is unrelated to protease activity. In flux experiments, we evaluated the presence of LC3-II by western blot. Our resutls show that alkalinizing agents such as ammonium chloride and bafilomycin A induced a delay in the accumulation of LC3II after autophagy induction in the CTb cell line. These results suggest the presence of a decreased vesicular traffic in the Ts16, which could explain some neuropathological phenomena related to intracellular accumulation events observed in individuals with Down Syndrome.

Title: Mitochondria are dysfcuntional in Down's syndrome

Authors: *C. J. MCALLISTER[1], S. H. ZAMAN[1], A. SLEIGH[2], M. J. WALPERT[1], P. F. CHINNERY[3], A. J. HOLLAND[1]
[1]Psychiatry, [2]Wolfson Brain Imaging Ctr., Univ. of Cambridge, Cambridge, United Kingdom; [3]Mitochondrial Res. Group, Newcastle Univ., Newcastle, United Kingdom

Abstract: Down's syndrome (DS) is caused by the triplication of chromosome 21, which includes the gene encoding the amyloid precursor protein (APP). High risk of Alzheimer's disease (AD) and widespread AD neuropathology is characteristic of DS. However, although almost all people with DS show AD plaques and tangles, not all develop dementia, despite lifelong excess of amyloid beta (Aβ), suggesting involvement of other disease-modifying factors. Recent studies point to an etiological role for mtDNA mutations and mitochondrial dysfunction, which has been shown to predate symptoms of aging and affect brain development. Mitochondrial dysfunction is implicated in AD and mtDNA aberrations are an important cause of aging, which is precocious in DS and is the biggest risk factor for both DSAD and sporadic AD. Mitochondrial dysfunction warrants further investigation to elucidate the natural history of aging in DS. The current study was designed in two parts, *in vivo* and *in vitro*, ensuring a comprehensive assessment of DS mitochondria. Twenty eight DS participants and 24 controls took part in an *in vivo* phosphorous magnetic resonance spectroscopy (^{31}P-MRS) study assessing mitochondrial function in quadricep muscle through assessment of the recovery time of the phosphocreatine (PCr) pool after in-scanner exercise. DS participants showed a significantly longer recovery time of PCr (25.74 ±5.75 SD) compared to controls (20.8 ±4.6 SD; p=0.0034), indicating inefficient mitochondrial function. A significant relationship with age was found in both groups, (controls, p<0.05; DS, p<0.01). This cannot be accounted for by fitness as groups were matched for VO_2 peak. In addition, muscle biopsies taken from 18 DS adults were assessed using a gold standard histology technique to determine whether muscle fibres contain a mitochondrial deficiency, namely, cytochrome *c* oxidase-succinate dehydrogenase (COX-SDH) staining. COX is crucial to mitochondrial function and is affected by age-related accumulation of mtDNA mutations. COX negative fibres were counted and compared to age and sex matched controls. Findings from *in vivo* and *in vitro* data are considered together to determine the validity of each technique. We suggest that characteristics of DS including precocious aging, early dementia and sedentary lifestyle, could in part be accounted for by faulty energetics. Although people with DS have the most to gain from these studies, due to the certainty of development of AD pathology, DS is the best 'model' of understanding the early pathological changes of AD in the general population.

Abstract: Extensive brain amyloidosis, typically associated with dementia, has been noted at autopsy of older individuals who exhibited few or no cognitive complaints prior to death. Amyloid accumulates years before symptoms become apparent, and current tests depend on detection of either amyloid accumulation in brain or tau proteins in cerebrospinal fluid. Biomarkers that may help predict disease before onset or progression of symptoms are critically needed. We have previously shown in a peripheral organ that decreased expression of DYRK1A, a serine-threonine kinase active in brain and important for tau phosphorylation, induces NFkappa B activation and increased inflammation. Here, a two-hybrid screen for human DYRK1A extracellular interactants suggested the presence of DYRK1A in plasma. DYRK1A was subsequently detected by immunoblot in plasma from transgenic mouse models having different gene dosage of Dyrk1a and, consequently, different relative protein expression. We next measured plasma DYRK1A levels in individuals with Alzheimer's disease (AD) that present

either mild cognitive impairment (MCI-AD) or dementia relative to plasma from control subjects. DYRK1A but not DYRK1B levels were significantly lower in plasma ($p < 0.0001$) and in lymphoblastoid cell lines (LCLs) ($p < 0.05$) from AD patients as compared to age-matched controls. Further, plasma levels of several markers related to AD and to DYRK1A expression in mouse models (BDNF, ApoD, and homocysteine) were altered in this AD cohort. AD-like dementia is also common in older individuals with Down syndrome (DS) though with a much earlier onset. We analysed DYRK1A levels in LCLs from patients with DS: we found a decreased level of DYRK1A in patients with DS and dementia. These findings suggest that reduced DYRK1A expression might be a novel plasma biomarker for AD.

Title: Attenuation of SHH signaling due to trisomy 21

Authors: ***F. FERNANDEZ**[1], S. EDIE[2], N. ZAGHLOUL[3], D. KLINEDINST[1], J. LEBRON[1], N. KATSANIS[4], R. REEVES[2]
[1]Physiol., Johns Hopkins Univ., Baltimore, MD; [2]Dept. of Physiol. and Inst. of Genet. Med., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [3]Univ. of Maryland Sch. of Med., Baltimore, MD; [4]Ctr. for Human Dis. Modeling, Duke Univ., Durham, NC

Abstract: Animal models of Down syndrome (DS; human trisomy 21) exhibit attenuated responses to Sonic hedgehog (Shh) pathway activation, a deficit that might influence the presentation of several clinical phenotypes related to craniofacial and nervous system

development in people with the condition. In an effort to locate “causative” genes on chromosome 21 (Hsa21) that reduce hedgehog sensitivity when over-expressed, we built a library of 169 Hsa21 cDNAs, 149 of which have highly conserved murine orthologs. These cDNAs have been cloned into Gateway Entry vectors, which enable rapid subcloning into a flexible collection of Gateway Destination plasmids. For these experiments, we subcloned the clone set into the pCS2+ vector that allows transcripts to be made from a SP6 promoter and can also drive expression through a mammalian-specific promoter. We first screened for the effects of overexpression of each gene on *in vivo* readouts of hedgehog activity in zebrafish embryos where the developmental outcomes resulting from hedgehog down-regulation have been well described. For the zebrafish experiments, the clone-set was transcribed into mRNAs, injected into 1-2 cell stage embryos, and scored at five days post fertilization (dpf) for relevant phenotypes. In all, we found 10 'hits' that consistently produced visually-identifiable features associated with changes in signaling through the primary cilium and/or Sonic activity, including cyclopia, craniofacial compression, formation of distinct U-shaped somites, and heart edema. Subsequent experiments using combinatorial injections of positive candidates suggest that some of these genes act in additive fashion to increase the penetrance of these phenotypes. In a second program of study, we analyzed the effects of Hsa21 gene dosage on Shh pathway responses in Shh-LIGHT2 cells, an industry-standard *in vitro* system that has been traditionally used to uncover and optimize Shh agonists or antagonists. Plasmids encoding each Hsa21 gene were transfected with high efficiency in 96-well plates and Gli-luciferase activity upon SAG stimulation was measured alongside control transfection with a GFP Destination vector. About a dozen genes decreased LIGHT2 responses by circa 20% of baseline and some of these hits overlapped those characterized in the zebrafish screen. We are replicating these results and extending them to other assays of SHH response. Our preliminary data suggest that this approach will be useful to identify Shh modifier genes on Hsa21. These may represent druggable targets for intellectual disability and for treatment of Shh subgroup medulloblastoma in the typically developing population.

Title: Is a reduced cellular response to shh a "common denominator" for multiple phenotypes of Down syndrome?

Authors: T. DUTKA[1], N. SINGH[2], J. T. RICHTSMEIER[2], *R. H. REEVES[3]
[1]Johns Hopkins Univ., Baltimore, MD; [2]Pennsylvania State Universityr, State College, PA;
[3]Johns Hopkins Sch. of Med., BALTIMORE, MD

Abstract: Down Syndrome (DS) is caused by inheritance of three copies of human chromosome 21 (Hsa21). All individuals with DS display some level of craniofacial dysmorphology, brain structural and functional changes, and cognitive impairment. Previous work has demonstrated that Ts65Dn, a mouse genetic model of DS, recapitulates aspects of each of these defects. Developmental processes underlying midface skeletal hypoplasia and hypoplastic cerebellum have been linked to an altered Sonic Hedgehog (SHH) response in the Ts65Dn model, suggesting that an attenuated SHH could underlie many phenotypes observed in the Ts65Dn model and in DS. I.e., if all trisomic cells show a similarly reduced response to SHH, then up-regulation of the pathway in affected trisomic cells might ameliorate these (and other) phenotypes in multiple tissues. To investigate this hypothesis, Ts65Dn mice were crossed with *Ptch1*$^{tm1Mps/+}$ mice in which the canonical SHH pathway is up-regulated in every SHH-responsive cell during development due to the loss of function of one allele of the pathway suppressor, *Ptch1*. Ts65Dn; *Ptch1*$^{tm1Mps/+}$ mice were compared to Euploid; *Ptch1*$^{tm1Mps/+}$, to Euploid; *Ptch1*$^{+/+}$ and to Ts65Dn; *Ptch1*$^{+/+}$ for craniofacial, behavioral and brain phenotypes. We found that constitutive up-regulation of the SHH pathway in Ts65Dn did not normalize the craniofacial dysmorphology that arises due to trisomy. Further, haploinsufficiency for *Ptch1* affected some behaviors differently than trisomy and did not complement most trisomic behavioral deficits. However, a nest-building task in which Ts65Dn mice performed poorly was normalized to some degree in Ts65Dn; *Ptch1*$^{tm1Mps/+}$ mice. Finally, structural anomalies of the cerebellum were ameliorated in Ts65Dn; *Ptch1*$^{tm1Mps/+}$ mice, supporting previous observations of the central role of an altered SHH response in this trisomic phenotype.

Abstract: Ts1Cje, a mouse model for Down syndrome (DS) exhibits a number of the morphological, biochemical, and transcriptional changes seen in the human with DS. However, there are currently only few data on proteomic alterations in the brain of some mouse models for DS. To identify molecular candidates involved in the abnormalities of Ts1Cje mice, we here employed comparative proteomic analyses based on two-dimensional gel electrophoresis (2-DE). First, proteins from neonatal and postnatal (3-month-old) whole brains of wild-type (WT) and Ts1Cje mice were detected by staining with a fluorescence dye after 2-DE separation. No differences were detected in the proteins expressed in whole brain between WT and Ts1Cje mice (n=3 in each genotype). Although we also examined proteins from three brain regions, such as hippocampus, striatum and cerebellum, of WT and Ts1Cje mice at 3 months of age, no differences were detected between the genotypes (n=3 in each genotype). Whilst, five spots with differentially expression in the Ts1Cje brain were detected by 2-DE separation of brain proteins from WT and Ts1Cje embryos at embryonic day 14.5 (E14.5) (n=5 in each genotype). Identification of the five proteins in Ts1Cje embryos by peptide mass fingerprinting indicates that two proteins were classified to cell proliferation-related molecules, whereas other two proteins were associated to energy metabolism. Experiments focusing on cell proliferation demonstrated that the number of M-phase cells were detected immunohistochemically with anti-phosphohistone H3 antibodies, significantly increased in the ganglionic eminence (GE) of E14.5 Ts1Cje brain (n=3 in each genotype). Furthermore, *in vivo* BrdU labeling experiment revealed that cell proliferation in the GE was significantly increased in Ts1Cje mice compared with WT mice (n=3 in each genotype). Our findings suggest that the dysregulated expression of proteins

identified by a comparative proteomic analysis could participate in increased cell proliferation, which may associate with abnormalities in the DS brain during embryonic life.

Title: Functional analysis of novel collybistin missense mutations associated with intellectual disability

Authors: ***P. LONG**[1], P. WESCHE[1], V. M. JAMES[1,2], M. TOPF[2], K. HARVEY[1], R. J. HARVEY[1]
[1]UCL, London, United Kingdom; [2]Birkbeck Col., London, United Kingdom

Abstract: Selected $GABA_A$ receptor subtypes are clustered at inhibitory synapses via interactions with the scaffolding protein gephyrin, which in turn is targeted to inhibitory synapses by collybistin, a GDP-GTP exchange factor with neuroligin-dependent activity. Collybistin harbours three key functional domains: a N-terminal regulatory *src* homology 3 (SH3 domain), a RhoGEF domain (that binds gephyrin and activates the small GTPase Cdc42) and a phosphoinositide-binding pleckstrin homology (PH) domain that is vital for correct membrane apposition. Collybistin-mediated clustering of gephyrin does not appear to be dependent on Cdc42, since collybistin mutants lacking any detectable GEF activity are able to induce submembrane gephyrin clustering. Rather, collybistin binding to phosphatidylinositol 3-phosphate (PI3P), a phospholipid found in cell membranes, is pivotal since a PH domain mutant (R303N/R304N) interfering with phosphoinositide binding abolishes gephyrin recruitment to synaptic sites. We have previously shown that genetic defects in the human collybistin gene (*ARHGEF9*) give rise to a range of symptoms consistent with loss of several $GABA_AR$ subtypes, including anxiety, seizures and intellectual disability. Here, we report the structure-function analysis of new collybistin missense mutations in patients with intellectual disability, affecting amino acids in the RhoGEF and PH domains. All mutations resulted in defective collybistin-

mediated submembrane clustering of EGFP-gephyrin in recombinant systems. Mutant collybistin proteins co-localised with gephyrin in cytoplasmic aggregates. Although only one of the mutations identified (R356Q) is predicted to affect a PH domain residue required for binding to PI3P, pull-down assays from HEK293 cells transfected with pRK5-myc-collybistin revealed that all missense mutations investigated impaired binding to PI3P. Taken together, these results suggest that mutations in the either the RhoGEF or PH domains can impair binding of collybistin to PI3P, and that this is the most common pathomechanism for collybistin dysfunction in intellectual disability.

Title: Divisive inhibition prevents abrupt transition from order to chaos in a neural field model

Authors: *C. PAPASAVVAS[1], Y. WANG[2], A. J. TREVELYAN[1], M. KAISER[1,2]
[1]Inst. of Neurosci., [2]Sch. of Computing Sci., Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: Experimental results suggest that there are two distinct mechanisms of inhibition in cortical networks: subtractive and divisive inhibition. Subtractive inhibition shifts the neuronal input-output function to the right without changing the slope, whereas divisive inhibition causes a reduction in slope or the maximal firing rate. Notably, recent experiments done using optogenetics show that these mechanisms are delivered by different populations of interneurons with a well understood connectivity between them and the pyramidal population. While most research has focussed on understanding the gain control, the role of these inhibitory mechanisms in regulating the dynamics of the network is less well understood. This work presents a novel mathematical model of this basic cortical circuitry, which incorporates the two inhibitory mechanisms. We investigated the role of these inhibitory mechanisms in terms of network dynamics, and particularly focussing on the transition from ordered to chaotic behaviour. We

show that the model incorporating divisive inhibition exhibits quite different behaviour compared to an equivalent model without divisive inhibition. The presence of divisive inhibition in the network prevents the abrupt transition from regular to chaotic dynamics across the parameter space. In contrast, in models which only have subtractive inhibitory elements, there are many cases where small changes in synaptic strength result in sudden flips from stable to chaotic network behaviour. Synaptic plasticity has been postulated as a mechanism by which the brain learns and stores information. Our results have interesting implications, therefore, for how such plastic changes impact on the stability of dynamic network activity patterns. It is also relevant to other network transition such as from physiological to pathological (epileptic) brain dynamics.

Abstract: How does the brain become epileptic? Although this is a major question for modern Neurology, we do not have yet a proper answer. Despite of intense research in the field, epilepsy continues having today a high prevalence, still the only available treatments are merely palliative, and a large number of patients are pharmaco-resistant and require surgical removal of the epileptogenic area. To go further to the answer of this question, we propose here to address what are the changes in the pattern of functional connectivity (FC) occurring during the transformation from a healthy brain into an epileptic brain. To answer this question, we have analyzed longitudinal variations of FC patterns in the hippocampus in a mouse model of medial temporal lobe epilepsy (MTLE), induced by intra-hippocampal injection of kainic acid (KA), which resembles main features of human MTLE. Mice were implanted with bilateral intrahippocampal and intracortical electrodes immediately after the injection of KA, and discontinuous 4h video EEG recordings were obtained up to 42 days post injection. Data was converted to ASCII and postprocessed to calculate two different measures of FC: Network Synchronization Index (NSI), which is based on correlations, and the Interaction Information (II), a generalization of the mutual information to triplets to address the amount information (redundancy or synergy) bound up in the set of three variables. The two measures, NSI and II, were computed across the time-evolution of the disease and across different frequency bands. We found important differences in preictal and postictal states in comparison to the baseline pattern of inter-ictal activity, regarding the strength of synchronism and the amount of redundancy and synergetic interactions. In particular, we noticed that whilst the time-evolution of the FC pattern for low-frequency bands evolved with the severity of the disease, this did not happen for the time-evolution of synergy and redundancy, suggesting that the information character of the epileptogenic network was affected in a non-linear manner with the disease severity.

Title: The relationship between paroxysmal depolarizations and high frequency oscillations in focal epilepsy

Authors: *T. EISSA[1], A. K. TRYBA[3], F. BEN-MABROUK[3], S. LEW[4], C. MARCUCCILLI[2], C. SCHEVON[5], W. VAN DRONGELEN[2]

Abstract: In the human neocortex, aberrant rhythmic bursts of neural activity between 80 and 150 Hz - high frequency oscillations (HFOs) - are suggested to be a hallmark of focal seizures and may aid in localization of the focus. Clinically, this activity is typically detected via EEG electrodes, which involves recording from a relatively large (cm sized) neuronal network. However it is not clear whether such a large area is required for HFO generation or what mechanisms underlie its development. We hypothesize that HFO activity during seizures is (1) generated by microscopic networks, in association with paroxysmal depolarizing shifts (PDSs) of neurons, yet (2) remains detectible in macroscopic recordings because of: (a) volume conduction (a linear process obeying the rule of superposition) and (b) synchronization of many local networks during a seizure. We determined the presence of HFOs in single cell activity (intracellular recordings) and microscopic networks (extracellular recordings) from slice recordings of human neocortex during experimental seizures, characterized by series of PDSs. Using the multi-taper spectral estimate to reduce leakage across frequency bands (Thomson, 1982), we determined that power in the 80-150 Hz band was overtly present in single cell and sub-mm network recordings. This observation supports part (1) of our hypothesis that small networks are capable of generating HFOs. Part (2) of our hypothesis was examined using two approaches: processing of the human slice data and the use of multi-electrode array (MEA) recordings from epilepsy patients. Averaging intracellular and extracellular slice measurements was used to mimic volume conduction. Two types of averages were computed: one type triggered by PDS bursts (synchronous case) and the other used randomly selected epochs (asynchronous case). We detected significantly more HFO activity in the synchronous case as compared to the asynchronous case ($p<0.01$), supporting our hypothesis that volume conduction of synchronized neural activity can generate compound signals that include HFOs. Using recordings obtained from MEAs implanted in patients with epilepsy, we also detected HFOs during clinical seizures. Spectral estimation of both individual microelectrodes as well as averaged activity across the array (approximating clinical macroelectrode recordings) indicate

there is an increase in high gamma rhythmic activity within the focal seizure core when seizures are fully developed (Weiss et al, 2013). Our data suggests a small-network source for clinically detected HFOs and may be used for improved localization of the seizure focus.

Title: Widefield imaging of sensory and epileptiform activity in mouse visual cortex

Authors: *L. ROSSI[1], D. M. KULLMANN[2], M. CARANDINI[1], R. WYKES[2]
[1]Visual Neuroscience, Inst. of Ophthalmology, Univ. Col. of London, London, United Kingdom; [2]Clin. & Exptl. Epilepsy, Inst. of Neurology, Univ. Col. of London, London, United Kingdom

Abstract: During epileptic seizures, cortical activity spreads in a pathological and escalating manner. Does this spreading activity bear any resemblance to the flow of activity seen during normal processing? Moreover, does it depend on lateral connectivity, and therefore on the functional architecture of the underlying cortex? To image cortical sensory responses and epileptiform discharges we expressed GCaMP3 in excitatory neurons with a Emx1-GCaMP3 line. Mice were implanted with a cranial window to image the visual cortex. A hole in the coverslip allowed injection of a chemoconvulsant and insertion of a pipette to record the local field potential (LFP). All measurements were made in awake mice. We first used widefield imaging to measure visually-evoked activity and map the retinotopic organization of visual cortex. Stimuli were flickering gratings (2 Hz) at various eccentricities (0-135 deg). GCaMP3 fluorescence reported neural responses oscillating at twice the stimulus frequency. The amplitude of these oscillations (0.13±0.01 %dF/F) yielded high-quality maps of retinotopy in primary visual cortex (V1) and higher visual areas; their phase indicated a wave of activation travelling

away from the stimulated region in V1 and a delayed activation of higher visual areas. We then induced an epileptic focus by injection of pilocarpine (5 M, 300nl) into layer 5 of V1. LFP recordings showed an escalation of epileptiform activity. Within minutes sharp LFP waves (i.e interictal spikes, IIS) increased in size (1.1±0.1mV) and frequency (0.42±0.03 Hz) and gradually evolved into complex-spike trains and ictal-like events. This activity persisted for ~30 minutes and then gradually declined. GCaMP3 reliably reported epileptiform activity, yielding large signals that dwarfed those seen during normal visual processing (38±3 %dF/F). To study the dynamics of this activity we used a standing-wave model, the product of a fixed time course and a fixed footprint in space. This model provided a good fit for the IIS-triggered averaged calcium variations (explaining 53% of the variance), revealing a standing wave of activation around the epileptic focus. However, ictal-like events displayed more complex dynamics, possibly resembling travelling waves. These results indicate that widefield imaging of GCaMP3 fluorescence is a powerful technique to study normal and epileptiform cortical activity at a mesoscopic scale. This technique is revealing intriguing similarities and differences between visual response propagation and epileptiform dynamics. Our current experiments aim to determine the relationship between these dynamics and the functional organization of the visual cortex.

Title: Effective connectivity of the macaque amygdala after kindling assessed by electrical microstimulation during functional MRI

Authors: *E. CLEEREN[1,2], P. JANSSEN[1], E. PREMEREUR[1], W. VANDUFFEL[1,3,4], W. VAN PAESSCHEN[2]

Abstract: Amygdala kindling is a widely used animal model to study network changes during mesial temporal lobe epileptogenesis. The aim of the current study was to study the effective connectivity in fully kindled macaques using electrical microstimulation during fMRI. Two rhesus monkeys were implanted with low impedance electrodes in the right amygdala. Electrical kindling consisted of daily stimulation with a 1 second, 60Hz sine wave at the intensity of the afterdischarge threshold (500μA monkey S, 1100μA monkey K). Monkeys were considered fully kindled when they showed stable stage 4 seizures (bilateral tonic-clonic movements), which was after 515 days of electrical kindling in monkey S and 477 days in monkey K. When fully kindled, the monkeys were injected with a contrast agent and scanned at a 3T Siemens MR scanner with an 8-channel phased-array coil under ketamine/medetomidine sedation. The fMRI protocol consisted of interleaved stimulation and no-stimulation blocks. During stimulation blocks, the amygdala was stimulated with a squared bipolar pulse (pulse width 0.48ms, frequency 200Hz, duration 250ms, intensity 800-1000μA) every 2500ms. No seizures were evoked during fMRI microstimulation. Electrical microstimulation of the kindling site in the amygdala during fMRI revealed extensive fMRI activations in cortical and subcortical structures in both monkeys. In monkey S, we observed strong significant activations in the ipsilateral putamen, thalamus, somatosensory cortex, early visual areas and in the contralateral cerebellum. In monkey K, the main activations were observed in the contralateral amygdala, claustrum, thalamus, superior temporal sulcus and the cerebellum. A conjunction analysis of the two monkeys (at a threshold of $p<0.01$ uncorrected for each monkey) revealed common fMRI activations in the contralateral amygdala, pallidum, thalamus and cerebellum. Therefore, the amygdala in stage 4 kindled monkeys is connected to extensive, bilateral networks of cortical and subcortical structures. These networks were distinct but partially overlapping in the two animals.

Title: Grouping inter-ictal and pre-ictal epileptic states through a complex networks approach

Authors: K. GUARIN[1], M. LE VAN QUYEN[2], *M. VALDERRAMA[3]
[1]Univ. Distrital Francisco José de Cáldas, Bogotá, Colombia; [2]Inst. du Cerveau et de la Moelle Épinière, Paris, France; [3]Dept. of Biomed. Engin., Univ. of Los Andes, Bogotá, Colombia

Abstract: Complex networks analysis has allowed the study of brain connectivity in anatomical and functional contexts. In the pathological brain, the study of complex networks has revealed abnormal interactions between different areas that can be associated with a strong hub-like region tending to produce abrupt synchronizations in the brain as is the case in epilepsy. Despite this, it is still not well known if the analysis of complex networks in epilepsy can be useful in the identification of periods with increased risk of epileptic seizures. For this, we constructed and analyzed networks based on intracranial EEG recordings from epileptic patients (n=17) presenting focal and pharmacological resistant seizures. In particular, we selected a total of 87 seizures having at least 8 hours of preceding inter-ictal periods (seizure-free periods) for a total of 715 analyzed hours and 1457 electrodes. For each seizure, we estimated different features within consecutive, non-overlapping windows of 3 seconds along the whole preceding onset period. All features were related to activities in frequency bands varying from 0.3 to 420 Hz. For each of these bands, we constructed adjacency matrices between all pairs of available electrodes based on the absolute value of the normalized cross-correlation taken from the corresponding pair of frequency activities inside consecutive 1-minute windows. We subsequently defined a connectivity threshold of 0.75 above which we established an existing connection (link) between a particular pair of electrodes (nodes in the network). Based on this, we dynamically constructed networks for which we estimated six complex measurements including clustering index, density, and characteristic path length among others. We then implemented a clustering algorithm (k-means) to observe if epileptic activities could be grouped into inter-ictal and pre-ictal (ictal-facilitating) periods, according to a defined grouping criterion. We report that for 12 patients (71 %), a minimum of one pre-ictal cluster could be identified in at least one of the analyzed seizures with an average of 2.75 out of 5.25 seizures per patient and a total of 33 seizures out from 63 (52 %). Furthermore, pre-ictal clusters were found to start between 20 and 102 minutes (average 38 min) before seizure onsets. In general, qualitative observations showed that most of the pre-ictal clusters were related to a decreased connectivity between nodes, though for a few number of seizures the opposite was also observed. In conclusion, our results show that the analysis of complex networks could offer new and useful information for the identification of seizure facilitating periods.

Title: Hidden patterns might reveal new synchronies in biological distributed information networks: Examples from human intracerebral recordings and artificial data

Authors: *A. PRINCIPE[1], A. TAUSTE-CAMPO[2], G. DECO[2], R. ROCAMORA-ZUÑIGA[1]
[1]Hosp. Del Mar, Barcelona, Spain; [2]Univ. Pompeu Fabra, Barcelona, Spain

Abstract: The concept of binding by synchrony has been proposed as a mechanism to explain how information about a given stimulus is processed in a distributed network of neurons. If defining the boundaries of a physiological network is important, this identification in epilepsy is crucial for treatment. In 10-15% of all epileptic patients, the identification of this network requires intracranial electrodes. For a long time, emphasis has been put on the identification of low voltage fast discharges, which could be a specific signature of the epileptogenic tissue. Even though network periodicities have been related either to physiological or pathological states, recent data do not fully confirm such direct correlations. The likelihood quantification of regions involved in the seizure was introduced with the 'epileptogenicity index' (EI). The EI depends on the frequency spectrum and is defined as the ratio between high and low oscillations in a given time step. This practical approach assumes that two areas are involved in a seizure when their signals are similar in the frequency domain. Tackling this problem otherwise, we considered that two interacting processes must exchange data, for instance by copying parts for further processing. If true, synchronization could be detected by tracing electric field signatures. To solve this question we developed a codification that exposes only the signal shape. We then adapted a method used for data compression, the Context-Tree Weighting (CTW) algorithm, to search our stream for repeated patterns. Then we generated EEG-like signals fading into one another. The CTW was able to determine the coefficients used to mix signals better than the EI. Finally we studied data taken from deep electrodes of an epileptic patient, showing that both CTW and Granger's causality, in a similar but not identical fashion, highlighted correlations that the EI did not reveal (Fig. 1). These results suggest that complementing the frequency analysis with the recognition of shared electric field patterns might reveal relations that could help investigate neurological networks.

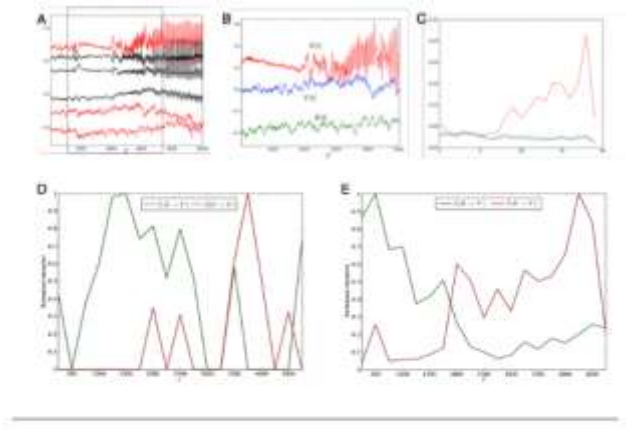

Fig. 1. Example of emergent and vanishing signal correlations that were not revealed by the EI index. (A) We first selected three channels (plotted in red), the first is clearly epileptogenic while the third is not; the second presents mixed features. (B) Plot of the selected channels, S(t) the seizure one (red), B(t) the basal one (green), Y(t) the probed one (blue). (C) EI index for each channel under study. (D) Normalized influence of B(t) into Y(t) (green) and S(t) into Y(t) (red) using the CTW estimator with a quantization of the EEG signals in 2 levels. (E) Normalized influence of B(t) into Y(t) (green) and S(t) into Y(t) (red) using Granger's causality estimator. From time step 2000 one observes correlations between {B(t), S(t)} and Y(t) that were not revealed by the EI index.

Title: Identifying the epileptogenic zone using directed information

Authors: ***R. MALLADI**[1], G. P. KALAMANGALAM[2], N. TANDON[3], B. AAZHANG[1]
[1]Dept. of Electrical and Computer Engin., Rice Univ., Houston, TX; [2]Dept. of Neurol., [3]Dept. of Neurosurg., Univ. of Texas Hlth. Sci. Ctr., Houston, TX

Abstract: The 'epileptogenic zone' (EZ) refers to the core brain region responsible for the generation of seizures in patients with focal epilepsy. Visual analysis (VA) of the electroencephalogram either recorded from the scalp or from intracranial electrodes (electrocorticogram, ECoG) remains the gold standard for diagnosing the EZ, despite its

subjective and time-consuming nature. In this work we report pilot results on a novel quantitative technique, directed information, to identify the EZ from the ECoG recordings in a patient with focal epilepsy undergoing intracranial electrode evaluation. Directed information, an information theoretic quantity, quantifies Granger causality, which is itself a measure of effective connectivity - the network of causal interactions between distinct units in the brain. In this work, the units correspond to the different ECoG electrode contacts. The main contribution of this work is broadening the notion of directed information to continuous-valued random processes like ECoG, and then use it to estimate the effective connectivity to identify the EZ. The results are compared with conventional VA.

Title: The spatiotemporal characteristics of epileptiform activity in the dentate gyrus

Authors: *B. J. WRIGHT[1], M. JACKSON[2]
[1]Physiol., [2]Neurosci., Univ. of Wisconsin-Madison, Madison, WI

Abstract: The dentate gyrus (DG) is thought to act as a filter or gate for signal entry into the trisynaptic circuit of the hippocampus. When this gating function is compromised, abnormally high electrical activity can spread through the hippocampus and generalize to other brain regions to initiate seizures. The dentate gyrus contains a powerful circuit of recurrent excitation formed by excitatory reciprocal synapses between granule cells and hilar mossy cells that can contribute to the processing of cortical inputs. The GC-MC-GC circuit has an architecture that may be capable of sustaining reverberations and generating abnormal electrical activity. To explore the role of dentate gyrus circuitry in seizure activity we used voltage imaging with voltage sensitive absorbance dye (RH 482) to investigate the spatiotemporal characteristics of epileptiform

activity in rat hippocampal slices. Slices were subjected to repetitive stimulation of the granule cell layer (20 Hz) in a $GABA_A$ receptor inhibitor and 5 mM KCl, to transform them to a susceptible state. Optical signals showed larger areas and delayed repolarization, compared to control responses recorded prior to induction. Results from thresholding experiments in which electrical stimulation was applied to the GC-MC-GC pathway revealed the minimum current at which epileptiform activity could be evoked. Electrical stimulation evoked epileptiform activity that was widely distributed throughout the slice; and there were no differences in the hyperactivity in the upper and lower blades. Epileptiform activity spread radially from the site of stimulation, and propagated to both blades of the DG before transmission to the CA3 region. Supported by R21 NS078301 and a graduate fellowship from Lily's Fund.

Title: *In vivo* low intensity optogenetic train stimulation in the mouse hippocampus produces epileptiform afterdischarges

Authors: *F. BERGLIND, M. KOKAIA
Neurol., Epilepsy Center, Lund Univ., Lund, Sweden

Abstract: Electrical stimulation in brain structures like the hippocampus has long been used to produce seizures in rodent epilepsy models. However, because of the non-specific nature of electrical stimulation and the recording artifacts inherent to its use, underlying network mechanisms involved in the generation of self-sustained activity (afterdischarges, ADs) can not be effectively dissected. With optogenetic techniques, discrete stimulation of specific neuronal populations is now possible and, combined with local field potential (LFP) recordings, we have utilized this to generate and record ADs in the mouse hippocampus *in vivo*, in a location and time dependent manner. It is also possible to follow the immediate dynamics of the induced LFP during the stimulation itself. We can show that ADs are more effectively generated when stimulating the cell bodies of the CA3 pyramidal layer rather than processes in the radial or

oriens layers, or in the CA1 or hilus. Additionally, at the low light intensity used in our studies (recruiting only a small proportion of hippocampal neurons) ADs only appeared after repeated stimulations. To achieve maximal amplitude and duration, recruitment of the contralateral hippocampus was required. The results of the present work contribute to better understanding the network involved in seizure induction.

Title: Stochastic determinants of transitions to and from seizure states in a computational network model

Authors: *W. B. SWIERCZ[1,2], K. P. LILLIS[1,2], K. J. STALEY[1,2]
[1]Massachusetts Gen. Hosp., CHARLESTOWN, MA; [2]Harvard Med. Sch., Boston, MA

Abstract: We used a computational model of hippocampal area CA3 to study ictogenesis in post-traumatic epilepsy. The model contains 22374 of integrate-and-fire neurons. They are arranged into two layers of 105 x 105 pyramidal cells and one layer of 18x 18 interneurons with GABAergic outputs. Connections between neurons were stochastically generated accounting for distance between cells and for the neuron type. Traumatic cell loss was equally and randomly distributed between both pyramidal cells and interneurons by removing subset of cells and corresponding inputs and outputs from the network. The result was a strong decrease in the level of spontaneous activity. Recovery after injury was modeled by recurrent axon sprouting and synaptogenesis. New connections between surviving cells were randomly generated using various strategies. Axon sprouting continued until surviving cells reconstituted the original number of synapses onto and from each neuron. The outcome of this recovery process varied depending on the sprouting strategy. For some networks, spontaneous activity returned to the

control level while many networks developed bursts of synchronous activity that increased in frequency and in fraction of participating neurons. Some networks developed seizures comprised of sustained (tonic) ictal-like activity that slowly transitioned into intermittent (clonic) activity. Recurrent sprouting was necessary but not sufficient for ictal-like activity. In networks with identical connectivity the transition from bursting to ictal activity depended on the initial variance, but not the mean, level of activity-dependent depression at individual glutamatergic synapses. Seizure termination occurred as a spontaneous transition from tonic to clonic activity and eventually back to periodic synchronous bursting. These transitions were not the result of global activity-dependent synaptic depression, but depended instead on changes in the network-wide variance of synaptic depression. Here we dissect the synapses where the variation in synaptic depression was most critical. These synapses on a small subset of cells and corresponding connections are responsible for dramatic changes in the mode of activity of the whole network. We are currently testing the hypothesis that ictogenesis can be disrupted in-vivo by modifying or disabling the synaptic connectivity of the most active cells in the network only. The negative impact on network performance may not be critical, although it may be technically very hard to locate and target this relatively small subset of cells.

Title: Transition mechanisms from nonsynaptic epileptiform activity to spreading depression

Authors: *A.-C. G. ALMEIDA[1], A. M. RODRIGUES[1], M. F. MIRANDA[1], L. C. SANTOS[1], C. A. SCORZA[2], F. A. SCORZA[2], E. A. CAVALHEIRO[2]
[1]DEPARTAMENTO DE ENGENHARIA DE BIOSSISTEMAS, UFSJ, SAO JOAO DEL-REI, Brazil; [2]DISCIPLINA DE NEUROLOGIA EXPERIMENTAL, UNIFESP, SAO PAULO, Brazil

Abstract: Introduction: Invariably, when nonsynaptic epileptiform activity (NEA) induced in the dentate gyrus of hippocampus slices (HS) are recorded, the transition to spreading depression (SD) can be seen. During this transition, the interplay of the different ionic species involved and

the dynamic mechanisms of action responsible for the ionic homeostasis are too complex to be experimentally accessed. Thus, we investigated the mechanisms responsible for this transition through the correlation between experimental findings and computational simulations. Experimental recordings: NEAs were experimentally induced in rat HS in interface chamber. When the slices were perfused with high-potassium (10mM) and zero-added calcium, the NEAs appeared spontaneously after 1h. The extracellular potential was recorded in the granule layer. Computational model: This model describes the electrodiffusion processes of the ionic current through the neuronal and glial membranes and along the extracellular space (ES). The mechanisms incorporated to simulate the ionic homeostasis were: Na+/K+ pumps, Cl- cotransporters, Na+/H+ exchangers and chloride/carbonate exchangers. Cell volume changes were also calculated. The ephaptic effect, the gap-junctions and the ionic fluctuations were the non-synaptic connections between neurons. The transmembrane potentials were calculated in dependence on the ionic concentrations. Network was formed by functional unities composed by granule cell body, glial segments and the ES, configured in a 50x9x9 matrix. The model was implemented in Fortran. Results: The experimental findings showed NEAs blockage by tetrodotoxin (TTX), indicating the involvement of the Na-voltage dependent channels (NVDC) in the NEAs onset. After transition to SD, the events were also blocked by TTX. Simulations showed that the NEAs onset of each event is due to the interplay between the sodium influx through the channels and electrogenic effect of the Na+/K+ pumps. The NEAs sustaining is dependent on the electrogenic current of the pump allowing conjecture that the transition between NEA and SD would be dependent on the pump action. In fact, it was possible to simulate the transition to SD by decreasing pump activity. Experimentally, reducing the Na+/K+ pumps activity during the NEAs by hypoxia, the transition was observed. Conclusions: The simulation of NEAs transition to SD using a model properly designed to study the NEAs showed that the mechanisms of the model were enough to describe the SD onset. Results suggested the interplay between the influx of Na+ through the NVDC and the Na+/K+ pump electrogenic currents that sustain the NEAs and the transition to SD as well.

Title: Point process modeling of human seizures

Authors: *G. M. FIDDYMENT[1], U. T. EDEN[2], S. S. CASH[3], M. A. KRAMER[2]
[2]Dept of Math & Statistics, [1]Boston Univ., Boston, MA; [3]Dept of Neurol. & Dept of Neurosurg., Harvard Med. Sch. and Massachusetts Gen. Hosp., Boston, MA

Abstract: Epilepsy is a serious neurological disease often resulting from complex, multiscale processes. Clinical evaluation of human epilepsy routinely involves the analysis of *ictal discharges (IDs)*: transient large-amplitude changes in the electric field. IDs appear at multiple spatial scales leading up to and during seizure. These events are fundamental to diagnosis; however there is significant controversy over whether they aid or inhibit seizures. To resolve this issue and, in turn, improve epilepsy treatment will require rigorous notions of ID likelihood and causality. Descriptive measures such as spike-field coherence and spike count correlation ***may be useful for understanding simple associations, yet they are easily confounded by variables such as spike rate.*** Point process (PP) models represent a simple yet flexible way to decompose ID probability and thereby better understand seizure dynamics and anti-epileptic treatment. With this approach, the modeler recasts factors that modulate spike probability (e.g. refractory period, rhythms) as statistical effects, estimates all effect sizes from the data, and compares their mutual importance to draw physical conclusions. Here we analyze IDs recorded during 10 seizures in 4 clinical patients. We extract IDs from the microelectrode recordings via an automated algorithm and fit PP models with intrinsic ("local") and population ("long-range") effects. While similar to bivariate measures such as the correlogram and spectrum, the effect estimates capture multivariate structure and satisfy the Cramer-Rao bound. We use these PP model estimates to show: (1) IDs are highly non-random; (2) Both intrinsic and population effects are necessary to characterize ID structure; and (3) The two types of effect (local vs. long-range) act on different time scales, often in a complementary manner. For each seizure, the effect curves suggest a possible treatment plan by identifying spatially-specific patterns that could promote seizure termination.

Title: Network burst dynamics under heterogeneous cholinergic modulation of neural firing properties and synaptic connectivity

Authors: S. KNUDSTRUP[1], *V. BOOTH[2], M. ZOCHOWSKI[3]
[1]Mathematics, [2]Mathematics & Anesthesiol., [3]Physics & Biophysics, Univ. of Michigan, ANN ARBOR, MI

Abstract: The characteristics of synchronous network bursts, that underlie seizure-like activity, depend on intrinsic neural properties and synaptic connectivity in the network. In brain networks, both of these properties are affected by the type and levels of neuromodulators present. The expression of many of the most powerful neuromodulators, including acetylcholine (ACh), dynamically varies with behavioral state, leading to dynamic, heterogeneous changes in intrinsic neural properties and synaptic connectivity properties. In this simulation study, we investigated how heterogeneity in cholinergic modulation of neural firing properties and heterogeneity in synaptic connectivity affects the initiation and maintenance of network bursting in excitatory networks. We utilized a Hodgkin-Huxley model of cortical pyramidal cells where ACh modulation was simulated by blockade of an M-type K+ mediated current. Previous work has shown that this ACh modulation significantly alters neural firing properties such that the phase response curve (PRC) switches between Type II and Type I, thus altering the propensity for network burst synchronization. Here, we show in large-scale networks with heterogeneous ACh modulation that cells that are strongly (Type I) and weakly (Type II) modulated by ACh contribute differentially to the initiation and maintenance of network bursts. Synchronous dynamics of Type II neurons is needed for burst initiation and provides synchronizing drive to Type I cells, whereas Type I cells provide the overall activity level necessary to sustain burst firing. Characteristics of network bursts, such as burst duration and intraburst synchrony, are dependent on the cell types providing the synaptic connections in the network. The existence of network bursting depends on synaptic activity from Type II to Type I cells. Intraburst synchrony varies with the fraction of synapses between Type I cells while burst duration varies with the fraction of synapses between Type II cells. These results suggest how nonuniform neuromodulation can affect network dynamics and offer targets for intervention of synchronous activity associated with seizures.

Abstract: Temporal lobe epilepsy is associated with dysfunctional brain networks. Here we investigated metabolic connectivity in the pilocarpine-induced epilepsy rat model and applied a new multiscale framework to the analysis of metabolic networks of small-animal brains. [^{18}F]fluorodeoxyglucose PET was acquired in pilocarpine-induced chronic epilepsy rats and controls to yield interregional metabolic correlation by inter-subject manner. When interregional correlation of epilepsy rats and controls was compared directly, the epilepsy rats showed the reduced connectivity involving left amygdala and left entorhinal cortex. When regional graph properties were calculated to characterize abnormal nodes in the epileptic brain network, the epilepsy rats showed reduced nodal and local efficiency in left amygdala. Then, a new multiscale framework, persistent brain network homology, was used to examine metabolic connectivity with a threshold-free approach and the difference between two networks was analyzed using single linkage distances (SLDs) of all pairwise nodes. We found a tendency of longer SLDs between left insula/left amygdala and bilateral cortical/subcortical structures in the epilepsy rats.

Persistent brain network homology analysis as well as interregional correlation study implied the abnormal left limbic-paralimbic-neocortical network in the pilocarpine-induced epilepsy rat models. In conclusion, we found globally disrupted network in the epileptic brain in rats, particularly in the limbic and paralimbic structures by direct comparison, graph properties and multiscale network analysis. These results demonstrate that the multiscale and threshold-free network analysis can be used to find the network abnormality in small animal brains as a preclinical research.

Abstract: Children with malformations of cortical development (MCD) frequently present with learning and memory deficits that are extremely detrimental to the quality of life. Currently available therapeutic strategies focus on the seizures common in this patient population, however these treatments are usually ineffective at ameliorating cognitive deficits. We recently showed that environmental enrichment improves cognition in animals exposed to methylazoxymethanol acetate (MAM) at embryonic day (E) 17, an animal model that recapitulates many of the aspects of human MCD. Using this model, we sought to understand 1) the cellular and network-level alterations that occur in animals with MCD and 2) whether or not environmental enrichment improves these putative alterations in a manner consistent with improved cognition. We show for the first time that malformations of hippocampal CA1 cause changes in neuronal oscillations and

single unit activity in the hippocampus of rats with MCD. Environmental enrichment partially restores oscillatory and single unit activity in MAM animals, changes that likely underlie improvements in cognition. Taken together, these data indicate that there are network-level alterations in the hippocampus of animals with MCD and that these changes can be partially reversed by enrichment strategies. Future studies will continue to explore the cellular and network-level underpinnings of cognitive deficits in animals with MCD in order to develop effective treatment strategies for these patients.

Title: Modeling of neocortical neural dynamics during human focal seizures

Authors: *E. C. HO[1,2], W. TRUCCOLO[1,2]
[1]Dept Neurosci, Brown Univ., Providence, RI; [2]VA, Ctr. for Neurorestoration and Neurotechnology, Providence, RI

Abstract: Recent advances in microelectrode array (MEA) recordings have made possible the simultaneous recordings of spiking activity in ensembles of neocortical single neurons during human focal seizures. As a result, a much more detailed picture of seizure initiation, spread and termination, has begun to emerge [1]. Here, we combine single-neuron spiking and local field potential (LFP) data obtained from 96-MEA recordings during human seizures with mathematical modeling. Our goals are to understand the specific cellular and synaptic mechanisms responsible for two types of observed seizures (spike-wave complexes--SWCs, 2-3Hz, and gamma-band, 40-60 Hz, seizures), and to determine how these mechanisms are related to the initiation and cessation of seizures. We model the neocortex under a (4mm x 4mm) 96-

MEA with excitatory and inhibitory conductance-based neurons embedded in 50-µm wide cortical minicolumns, including layers and typical connectivity. We have studied models consisting of up to 256 minicolumns (~ 1.1M neurons). Extracellular ionic dynamics include glial regulatory mechanisms and extracellular ionic diffusion processes between neighbouring neurons, while background synaptic inputs are represented by Ornstein-Uhlenbeck processes. Gamma-band like seizures resulted by combining strong mutual inhibitory synaptic couplings (gi->i), strong inhibitory to excitatory synaptic couplings (gi->e), and high background activity levels to both the pyramidal and interneuronal populations. In this case, irregular single-neuron spiking patterns coexisted with sustained narrow gamma band LFP oscillations, resembling the recorded human gamma-band seizures. Dynamics similar to SWC seizures were obtained by decreasing both mutual inhibitory coupling (gi->i) and inhibitory to excitatory coupling (gi->e). In this network model, transitions into seizure dynamics are closely associated with fluctuations in extracellular potassium concentrations. A transient increase in extracellular potassium concentration depolarizes neurons and tends to initiate seizures. Furthermore, the model also suggests that a breakdown of inhibitory synaptic conductance may be responsible for the network to transition into SWC seizures. Overall, the model captures several aspects of the rich dynamics in human focal seizures, and it is thus a promising tool for examining potential biophysical mechanisms underlying human epilepsy. 1. Title: Dynamic functional reconfiguration in human epileptic networks

Authors: *A. KHAMBHATI[1], B. LITT[2], D. S. BASSETT[2]
[2]Bioengineering, [1]Univ. of Pennsylvania, Philadelphia, PA

Abstract: For 33% of epilepsy patients seizures cannot be controlled by medication. These patients are often implanted with intracranial electrodes to localize and surgically resect seizure "foci." However, seizure freedom post-surgery is ~40% in patients without discrete lesions on brain MRI, spawning new implantable neuromodulation devices to control brain regions that generate seizures without removing them. The challenge remains to accurately define epileptic networks and their complex spatial interactions to inform which neural circuits to target with neuromodulation. We used intracranial recordings from epilepsy patients undergoing presurgical evaluation to analyze neocortical functional connectivity before and during seizures. We report a novel technique to track network reconfiguration in time and to parse these reconfiguration dynamics into distinct seizure phases. Our approach characterizes changes in gross connectivity throughout seizures and the spatiotemporal relationships between areas generating seizures and surrounding tissue. Our results indicate that epileptic networks reorganize before seizures and much less during these events. We found that seizures undergo three distinct phase transitions, each characterized by unique patterns of network connections that differ in their strength and topological extents. These findings suggest that different regions of the network are involved in initiating and terminating seizures. Collectively, our observations have important theoretical implications for understanding the spatial involvement of distributed cortical structures in seizure propagation and termination, and practical significance in determining which circuits to modulate with implantable devices.

Title: Multiscale wave propagation during human seizures

Authors: *L.-E. MARTINET[1], O. J. AHMED[2], E. N. ESKANDAR[3], S. S. CASH[2], M. A. KRAMER[1]
[1]Dept. of Mathematics & Statistics, Boston Univ., Boston, MA; [2]Dept. of Neurol., [3]Dept. of Neurosurg., Massachusetts Gen. Hosp., Boston, MA

Abstract: Epilepsy is a complex multiscale disease, extending spatially from microscopic synapses to macroscopic behavioral manifestations. Seizures - the hallmark of epilepsy - exhibit multiscale spatiotemporal dynamics that remain incompletely understood. Here we study the properties of focal seizure onset, propagation and termination using a unique data set of multiscale recordings from microscopic (NeuroPort, 10x10 grid, 0.4 mm spacing) and macroscopic (8x8 grid, 10 mm spacing) subdural electrode arrays implanted in patients with pharmacoresistant epilepsy. We find voltage waves propagating along the brain surface in the local field potential (LFP), as well as in the invasive electroencephalogram (ECoG) recordings. We explore different spatiotemporal properties of these waves such as amplitude, speed, width and rate of occurrence, during the evolution of seizure from onset to termination, and how these features relate to etiology and surgical outcome. We also describe the interscale relationship between waves in the LFP and EEG recordings. We hypothesize that wave features evolve during seizure, with more consistency at seizure onset and termination, compared to the mid-seizure interval. A deeper understanding of ictal wave propagation may have clinical implications such as tailoring surgical interventions or guiding stimulation induced seizure interruption.

Title: The effects of altering intra- and interhemispheric excitability on the bilateral propagation of epileptiform events and hemodynamic responses in rats

Authors: *H. MA, A. G. S. DANIEL, M. ZHAO, T. H. SCHWARTZ
Dept Neurolog. Surgery, Weill Cornell Med. Col., NEW YORK, NY

Abstract: Our previous studies have demonstrated that a strong relationship between the local neuronal activities and hemodynamic changes exists during ictal events in acute focal neocortical epilepsy and the hemodynamic change can be used to map the epilepsy focus. However; the neuronal-hemodynamic relationship on the contralateral hemisphere has not been described. We address this issue using simultaneous wide-field calcium and intrinsic optical imaging. Local injection of 4-aminopyridine (4-AP, 500nl, 15mM) was employed to induce acute ictal events in adult SD rats. Local injection of bicuculline methiodide (BMI, 500nl, 5mM) in either the ipsilateral or contralateral hemisphere was employed to manipulate the excitability of the neuronal network. 4-AP seizures could be recorded in a local area (propagated 2-3 mm from the injection site). The resulting hemodynamic changes could be recorded from the same area. Increased neuronal activity could also be recorded in the mirroring area of the contralateral hemisphere, with an amplitude lower than the injection side. However, the increased neuronal activity failed to induce obvious hemodynamic changes. We then injected BMI ~4mm away from the 4-AP site in the same hemisphere to promote the ictal events. A larger spatial propagation of the ictal event was observed (to the BMI injection site). On the contralateral hemisphere, more robust neuronal activity was also observed which induce a less pronounced hemodynamic change than the seizure side. In some cases, hemodynamic changes were barely detectable. BMI was then injected in the contralateral hemisphere to increase the neuronal activity. The ictal event could be recorded from both hemispheres with similar duration and spatial propagation. The hemodynamic changes could be reliably recorded from the BMI side but the amplitude was lower than the 4-AP side. Our data suggest that the inhibition on the mirroring side limits the bilateral propagation of local seizures. Neurovascular coupling may not be the only factor that manipulates the hemodynamic changes when a hyper-excited ictal focus exists on the contralateral hemisphere. The hemodynamic difference between the two hemispheres could serve as a biomarker to distinguish the primary seizure focus from the mirror focus.

Title: Axonal injury and behavioral deficits after ischemic stroke in the sensorimotor cortex of channelrhodopsin-2 transgenic mice

Authors: M. SONG[1], X. GU[1], L. WEI[1], *S. YU[2]
[1]Anesthesiol., Emory Univ. Sch. of Med., Atlanta, GA; [2]Anesthesiol., Emory Univ., Atlanta, GA

Abstract: Expression of the light-activated channelrhodopsin-2 (ChR2) protein is an excellent tool to conduct optogenetic stimulation and functional mapping of the cortical circuits in the brain. In an ischemic stroke investigation, we used the line 18 transgenic mice expressing ChR2 that was fused with Yellow Fluorescent Protein (ChR2-YFP) under the control of the mouse thymus cell antigen 1 (Thy1) promoter. ChR2-YFP expresses at high levels in motor and sensory neurons, as well as subsets of central neurons but not in non-neural cells. Axons are brightly fluorescent all the way to the terminals when imagined under a fluorescent microscope. In this study, we characterized the behavioral deficits and axonal injury three or more days after a focal ischemia induced by ligations of distal branches of the right middle cerebral artery. A home cage monitoring system was applied to analyze behavioral and functional changes of stroke animals with little human intervention. It was shown that stroke caused dramatic reductions in travel distance, body stretching, sniffing and chewing activities. The time hanging vertically and hanging cuddled significantly decreased, indicating deficits in the sensorimotor function associated with forepaw activities. The adhesive removal behavioral test further indicated the specific sensorimotor deficit of the left paw that is affected by the injured sensorimotor cortex. Imaging of the brain sections showed that the density of YFP-labeled axons was decreased in the ischemic region compared with normal animals. Immuno-fluorescent staining of amyloid precursor protein (APP) shows accumulated APP in the injured axonal terminals. Axonal swelling and demyelination was confirmed by electron microscopy. Optogenetic stimulation is being applied to promote functional recovery in this stroke model.

Title: Adulthood protein-energy malnutrition augments stroke-induced abnormalities in forelimb function in rats

Authors: *M. ALAVERDASHVILI, P. G. PATERSON
Neurosci. Res. Group and Col. of Pharm. and Nutr., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: Pre-existing protein-energy malnutrition (PEM) affects 12-19% of elderly stroke patients. Worse outcomes (e.g. mortality) in stroke patients due to PEM suggest that PEM is an important co-morbidity factor. Nevertheless, the impact of PEM is not clear for non-fatal post-stroke outcome such as hand use in daily activities. Thus, the aim of this study was to explore the effect of pre-existing adulthood PEM on stroke-induced abnormalities in forelimb use in rats. Male, Sprague-Dawley rats (12 week-old) fed either with a purified diet containing 0.5% protein (PEM: n=12) or the control diet (CONT: n=10) for 4 weeks were exposed to focal ischemia (I) to the motor cortex or sham surgery (SHAM). Photochemically-induced thrombosis targeted the caudal region of the forelimb area of motor cortex. PEM-I, CONT-I, PEM-SHAM and CONT-SHAM rats were tested for skilled “hand” function in a horizontal ladder walking task and for gross “hand” function in a cylinder task acutely after stroke. Rats exposed to focal ischemia made significantly more errors with the affected (contralateral to brain injury) forelimb during crossing the ladder ($p<0.05$). Most importantly, PEM augmented ischemia-induced abnormalities in forelimb placement accuracy ($p<0.05$). PEM-I rats fell between rungs after the affected limb slipped off the rung, whereas CONT-I rats adopted a compensatory strategy and replaced the limb from one rung to another rung when the affected forelimb was placed inaccurately. PEM also amplified the stroke-induced deficit in the cylinder task. PEM-I rats showed more bias than CONT-I rats for contacting the ground with the unaffected forelimb (ipsilateral to brain injury) after episodes of rearing ($p<0.05$). The findings of this study suggest a definitive link between pre-existing PEM and motor function in the acute period following ischemic stroke. (Funded by CIHR and HSFC)

Title: An activated protein C analog promotes survival, migration and differentiation of human neural progenitor cells in ischemic mouse cerebral cortex

Authors: *Y. WANG[1], Z. ZHAO[1], G. SI[1], S. REGE[1], J. GRIFFIN[2], B. ZLOKOVIC[1]

Abstract: Despite intensive research efforts, few effective treatments are available for stroke. Cell therapy offers the possibility of improving neurological deficits after stroke. However, animal studies have shown that low survival rate of transplanted stem cells in the brain precludes long-term beneficial therapeutic effects. 3K3A-APC, a recombinant analog of activated protein C (APC), exerts neuroprotective effects after an acute or chronic injury in the brain. Our recent *in vitro* studies showed that 3K3A-APC stimulated human neural progenitor cells (NPCs) proliferation, migration and differentiation and production of neuronal cells. It is unknown whether human 3K3A-APC can influence survival, proliferation and differentiation of transplanted NPCs in ischemic brain in mice. Ischemic stroke was induced by distal middle cerebral artery occlusion (dMCAo). In this stroke model striatum remains intact and damage is limited to cortex. NPCs were transplanted into ischemic cortex 7 days after dMCAo. Human 3K3A-APC (0.2 mg/kg, i.v.) was administered at 7, 9, 11, and 13 days after stroke. We found that 3K3A-APC significantly enhanced the proliferation of NPCs and potentiated their differentiation into neuronal lineage after transplantation. We also show that the combined treatment with 3K3A-APC and NPCs significantly improved motor function as early as 2 weeks after transplantation. These findings suggest that 3K3A-APC may boost beneficial effects of NPCs transplantation therapy for ischemic stroke.

Title: Evaluating the clinical significance of serum Progranulin levels in patients with acute cerebral infarction

Authors: *J. LI[1], S. LIU[1], Y. ZHAO[1], Z. Z. WEI[1], Y. ZHANG[1], Y. LV[1], S. YU[2], L. WEI[2]
[1]Dept. of Neurology, Beijing Friendship Hospital, Capital Med. Univ., Beijing Friendship Hosp., Beijing, China; [2]Anesthesiology/Neurology, Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Objective: Inflammatory factors are considered to be major contributors to systematic inflammatory diseases, metabolic syndromes and cerebral infarction (CI).Progranulin (PGRN) is an autocrine growth factor which plays a critical role in a variety of patho-physiological processes, including inflammation, cutaneous wound healing and tumorigenesis. PGRN blocks the downstream signaling of TNF through directly binding to its receptors. We attempted to study the serum PGRN level in patients with CI and its role in the disease development. **Subjects and Methods**: Patients diagnosed with CI went through brain CT or MRI for further verification. A total of 35 patients and 25 age-and-gender matched control subjects were enrolled and subgrouped by onset time, infarction size, and the degree of artery stenosis were measured for each patient. Demographic data, medical history, clinical features, risk factors and imaging of all subjects were collected and analyzed. ELISA was used to test serum PGRN levels. Correlation analyses was performed to investigate the association between PGRN levels and the patients' disease features. **Results**: The serum PGRN levels increased significantly in CI patients (41.44±10.62ng/ml) compared with control subjects (35.25±7.83ng/ml) ($P<0.05$). However, there were no significant differences between the subgroups of disease onset, infarct size, risk factors and degrees of artery stenosis. Moreover, PGRN levels were not correlated with neurological impairment levels. **Conclusion**: The serum PGRN levels were increased in patients with acute cerebral infarction. However no differences were observed in subgroup analysis of disease onset, infarct size, risk factors and degrees of artery stenosis. We suggested that PGRN might be involved in the inflammatory processes and further studies would be required to investigate the mechanism involved in cerebral infarction.

Title: Activity-dependent formation of new premotor connections in the post-stroke brain

Authors: *E. H. NIE[1,2], G. COPPOLA[3], S. T. CARMICHAEL[2]
[2]Neurol., [3]Psychiatry & Biobehavioral Sci; Neurol., [1]UCLA, Los Angeles, CA

Abstract: Each year, five million stroke survivors worldwide are left with permanent disabilities for which there are no medical treatments. However, human clinical trials have shown that constraint-induced movement therapy (CIMT), a behavioral paradigm for focused overuse of the injured limb, results in significant and lasting motor improvements after stroke. The goal of the current project is to understand how limb overuse shapes cortical reorganization after ischemic stroke, and how specific gene systems drive this critical repair process. Our work has previously identified a molecular growth program that is triggered after stroke to promote axonal sprouting in the surviving brain. To study how limb overuse shapes sprouting, we utilize a mouse model of stroke and forelimb overuse that approximates human CIMT. In this model, fluorescent neuroanatomical tracers were used to quantitatively map cortical neurons that connect to premotor cortex upon limb overuse. We find that recovery involves the activity-dependent formation of axonal connections between premotor cortex and retrosplenial cortex (RSC), a higher-order parietal area involved in spatial integration and memory. The finding was significant and replicated across two independent experimental cohorts ($p<0.05$, Hotelling's T test). Furthermore, C5 and T10 retrograde corticospinal tract tracing confirm that the activity-induced connections are indeed distinct from known layer V corticospinal motor regions. In a

second tier of studies, the tracer-labeled cells in RSC and matched control neurons were FACS-isolated, and high quality RNA (RIN=7) was extracted for RNA-Seq. Preliminary pathway analyses indicate that limb overuse induces canonical signaling in calcium signaling, cell cycle, and Ephrin A pathways. A top network hit was also found in cell growth and proliferation, tissue development, and cell morphology. The RSC-premotor circuit is characterized by circuit-specific expression of activity-induced and growth-related genes. Moreover, a relatively small group of 162 genes was identified as differentially regulated by limb overuse. The top candidate genes have been statistically prioritized (FDR<0.1, p<0.005) for in-vitro neuronal outgrowth assays using P3 primary cortical neurons. Select candidates that increase neuronal outgrowth will advance to in-vivo lentiviral and siRNA mediated functional studies within the RSC-premotor circuit mapped in the first phase of this study. These ongoing studies will shed light on how injury and activity-dependent molecular pathways may converge in CIMT, and potentially provide targets to enhance endogenous mechanisms of brain repair after stroke.

Title: Effects of Memantine on NO production, hydroxyl radical metabolism during cerebral ischemia and reperfusion in mice

Authors: *T. SASAKI, T. FURUYA, Y. ITO, M. YAMASATO, R. NISHIOKA, A. TANAKA, N. ARAKI
Dept. Neurol., Saitama Med. Univ., Saitama, Japan

Abstract: Methods: C57BL/6 mice [n=15] were used. Memantine 25 μmol/ kg was given in 5 mice 30 minutes before ischemia, and others were contol group. Both NO production and hydroxyl radical metabolism were continuously monitored by *in vivo* microdialysis. Microdialysis probes were inserted into the bilateral striatum. The *in vivo* salicylate trapping method was applied for monitoring hydroxyl radical formation via 2,3 dihydroxybenzoic acid (DHBA), and 2,5-DHBA. A Laser doppler probe was placed on the skull surface. Forebrain cerebral ischemia was produced by occlusion of both common carotid arteries for 10 minutes. Levels of NO metabolites, nitrite (NO2-) and nitrate (NO3-), in the dialysate were determined

using the Griess reaction. The temporal expression of NOS in transient forebrain cerebral ischemia was investigated by western blot analysis and immunohistochemistry. Results: (1) Blood pressure: There were no significant differences between the groups. (2) Cerebral blood flow (CBF): There were no significant differences between the groups. (3) NO2- ; Memantine group (120.9±5.00%; mean±SD) showed significantly higher than that of the control group (88.5±18.0) after repurfusion 60 minutes ($p<0.05$). (4) NO3-; Memantine group (97.2±10.1%; mean±SD) showed significantly higher than that of the control group (65.3±21.0) at ischemia ($p<0.05$). (5) 2,3-DHBA; Memantine group (90.7±2.90%; mean±SD) showed significantly lower than that of the control group (99.5±2.66) at ischemia, after reperfusion 20, 80-120 minutes ($p<0.05$). Conclusion: These *in vivo* data suggest that Memantine effects on NO metabolites and hydroxyl radical production in mice, and may have neuroprotective effect against cerebral ischemic injury.

Title: Tyrosine phosphorylation of Kv2.1 channel contributes to neuronal cell death during brain ischemia

Authors: *M. SONG, K.-S. PARK
Physiol., Kyung Hee Univ., Seoul, Korea, Republic of

Abstract: Oxidative stress induces neuronal apoptosis and is involved in brain ischemia. Oxidant induced apoptosis enabling intracellular K+ efflux is mediated by improvement of Kv2.1 channel activity. It has been shown that increased channel activity is triggered by tyrosine phosphorylation of Kv2.1 and through the Src kinase. However, the functional role of Kv2.1

tyrosine phosphorylation in brain ischemia is not fully known. Here we provide the evidences that the oxidative stress-induced brain ischemia is regulated by tyrosine phosphorylation of Kv2.1. We found that the tyrosine phosphorylation levels of Kv2.1 were increased by oxidant induced neuronal ischemia. In a brain ischemia model, the tyrosine phosphorylation of Kv2.1 is also increased after brain ischemia. A sustained increase of tyrosine phosphorylation was observed for at least 2h and peaked at 45min of reperfusion. Our results show that the tyrosine phosphorylation of Kv2.1 channel play a critical role in regulating neuronal ischemia, and may be a potential therapeutic target for brain ischemia.

Title: Stem cell neural repair after white matter stroke

Authors: *I. L. LLORENTE[1], J. CINKORNPUMIN[2], W. E. LOWRY[2], S. T. CARMICHAEL[3]
[2]Dept. of Mol. Cell and Developmental Biol., [3]Neurol., [1]Univ. of California , Los Angeles, Los Angeles, CA

Abstract: Subcortical white matter stroke (WMS) constitutes up to 25% of all stroke subtypes and is the second leading cause of dementia. In this study we developed a new WMS model which mimics many aspects of the human disease. This model has been adapted to the immunodeficient NSG mouse to avoid any risk of immune rejection. There is no therapy for white matter stroke. However, cell transplantation is emerging as a viable therapy to restore neurological function after white matter stroke. Human induced pluripotent stem cells (iPSCs) have been used as an appealing cell source for cell transplantation to repair neuronal networks disrupted by ischemic stroke. However, neural precursor cells might not be the preferred cell therapy for white matter damage. We tested 2 cell types that may produce white matter repair. iPS-neural precursor cells (NPCs) can differentiate into neurons, astrocytes and to a lesser extent oligodendrocytes. iPS-glial restricted progenitor cells (GRPs) will differentiate mostly into astrocytes but may more be bipotential for astrocyte and oligodendrocytes . To characterize how these cell types response to white matter stroke overtime (1, 7, 15 days and 2 months) and how they differentiate in this white matter stroke environment we determined the inflammatory

response (iba1), astrocyte activation (GFAP), axonal/myelin loss and repair (NF200/MBP) as well as the their differentiation potential (oligodendrocytes, astrocytes and neurons) and the endogenous migration of immature neurons (DCX). Also, we have developed mouse MRI imaging protocols that visualize the white matter stroke, with the same imaging sequences that visualize white matter stroke in humans, making possible *in vivo* tracking of white matter repair with cell transplant, and holding the promise of developing a biomarker for stem cell-mediated neural repair in this disease.

Title: Vulnerable vasculature and increased inflammation contribute to exacerbation of transient focal ischemia in a genetic mouse model of type 1 diabetes

Authors: *A. C. LO[1,2], A. K. W. LAI[1]
[1]Dept. of Ophthalmology, The Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Res. Ctr. of Heart, Brain, Hormone & Healthy Aging, The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: PURPOSE: Epidemiological studies showed that type 1 diabetic patients are more prone to cerebrovascular mortality from stroke and the median survival is only half when compared with those in the general population. It has been suggested that type 1 diabetes is a risk factor for stroke; however, the underlying mechanisms are still unclear. In the current study, we aim to elucidate the potential mechanisms contributing to the exacerbation. METHOD: $Ins2^{Akita/+}$ mice, a type 1 diabetic murine model, and their wildtype ($Ins2^{+/+}$) littermates at 12 weeks of age were challenged with experimental stroke induced by middle cerebral artery occlusion (2h ischemia and 2h or 22h reperfusion). Survival was recorded at selected intervals and neurological deficits were accessed at the end of reperfusion. Brain slices were stained with 2, 3, 5-triphenyltetrazolium chloride for estimating the infarct area, infarct volume, hemispheric swelling, and hemorrhagic area. Western blot analyses were performed to compare blood vessel

integrity (ZO-1, VEGF, MMP-2 and MMP-9) and inflammatory response (pErk and p-p38) in the infarct core and penumbra region. RESULTS: After 2h of reperfusion, the neurological deficits, infarct area and infarct volume were significantly increased in the $Ins2^{Akita/+}$ mice. A higher mortality rate and a shorter survival period were also observed. Hemorrhage was significantly increased and further advanced with longer reperfusion. At 2h after reperfusion, VEGF and pErk were remarkably up-regulated and ZO-1 was down-regulated in the $Ins2^{Akita/+}$ mice. A trend of increase in MMP-2, MMP-9 and p-p38 were also observed. At 22h after reperfusion, the increased expressions of p-Erk and p-p38 persisted at a significant level. CONCLUSION: We showed that induction of transient focal ischemia in $Ins2^{Akita/+}$ mice could mimic the clinical observations of high mortality and shortened survival in type 1 diabetic patients upon stroke. The increased hemorrhage together with VEGF up-regulation and ZO-1 decrease indicated that blood vessel integrity was more vulnerable in the $Ins2^{Akita/+}$ mice. The effect of hemorrhagic transformation was observed as early as 2 h after reperfusion and was further provoked with longer reperfusion. Inflammatory response may also play an important role in the exacerbation of ischemic injury in $Ins2^{Akita/+}$ mice.

Title: Alterations of GABAA receptor trafficking in the Oxygen-Glucose Deprivation *in vitro* model of cerebral ischemia

Authors: M. MELE[1], M. ASPROMONTE[1,2], *C. B. DUARTE[1]
[1]Ctr. Neurosci Cell Biol, Univ. Coimbra, Coimbra 3004-517, Portugal; [2]Biol. and Envrn. Studies, Univ. of Sannio, Benevento, Italy

Abstract: Cerebral ischemia is a pathological condition caused by insufficient blood supply to the brain, which causes an imbalance between excitatory/inhibitory neurotransmission and excitotoxic neuronal death. The activity of neuronal networks in the CNS is mainly determined by the balance between glutamatergic and GABAergic neurotransmission, which are up- and down-regulated, respectively, during ischemic insults. In contrast with the role of glutamate in ischemic damage, which is largely documented, the alterations in inhibitory neurotransmission remain poorly understood. *In vivo* and *in vitro* studies have shown a downregulation of GABAergic neurotransmission in the ischemic brain, both at the pre- and post-synaptic levels. GABAA receptors (GABAAR) are the major players in fast synaptic inhibition in the CNS, and a downregulation of the surface expression of GABAARs has been shown in *in vivo* and *in vitro* models of ischemia. Previous results from our lab showed that Oxygen-Glucose Deprivation (OGD) induces the internalization of GABAAR via clathrin dependent endocytosis. Furthermore, our data showed that the OGD-induced receptor dephosphorylation and consequent internalization contributes to neuronal cell death, as demonstrated using a phospho-mutant of the β3 GABAAR subunit. These evidence indicate that the number of GABAAR at the cell surface and receptor internalization play a key modulatory role in the induction of ischemic cell death, but the receptor fate after internalization in ischemic conditions have not been elucidated. In the present work we investigated the molecular mechanisms determining GABAAR sorting upon internalization in cultured hippocampal neurons subjected to the OGD *in vitro* model of ischemia. Under physiological conditions, following internalization, GABAARs are rapidly recycled back to the plasma membrane or targeted for lysosomal degradation. The decision regarding the sorting of endocytosed GABAARs depends on the interaction of GABAAR β1-3 subunits with huntingtin-associated protein 1 (HAP1). We found that OGD (70 min) reduces the recycling rate of GABAAR back to the plasma membrane when assessed after 20 min of internalization by the antibody-feeding assay. The same period of OGD also decrease the interaction of GABAAR with the HAP1 proteins evaluated by co-immunoprecipitation assay. Longer periods of OGD also induced a calpain-mediated cleavage of HAP1. Overall, we propose a new model in which the increase in GABAAR internalization and the impairment of the recycling mechanisms are key steps for GABAergic down-modulation during cerebral ischemia, contributing to excitotoxicity and consequent neuronal cell death.

Title: Endothelial progenitor cells protect ischemic cell damage after cerebral infarction

Authors: *T. NAKAYAMA[1,2], E. NAGATA[2], H. MASUDA[3], S. KOHARA[2], N. YUZAWA[2], Y. TAKAHARI[4], T. ASAHARA[3], S. TAKIZAWA[2]

Abstract: Background: Endothelial Progenitor Cell (EPC) was reported to enhance repairing and regenerating neurovascular units. So far many papers have reported repairing and regenerating experiments using EPCs derived from bone marrow, spleen, or peripheral blood. However, the results were not always satisfied. Recently, we succeeded to get higher grade quality EPCs using a novel colony assay system which we have developed (Masuda H, et al, 2011). In the present study, we used this novel EPC colony assay system, and evaluated EPC effects on ischemic stroke model in mice. Materials and methods: We made 27 ischemic stroke model mice (10 weeks male nude mice) with permanent middle cerebral artery occlusion (MCAO). We injected PBS as control and EPC derived from peripheral blood, or cultured EPC into external carotid artery 24 hours after MCAO. At 2 weeks after MCAO, we took the brains and investigated time-lapse physiological parameters including cerebral blood flow and immunohistochemistry against some anti-vasculogenetic factor antibodies. Results: Either EPC derived from peripheral blood or cultured EPC didn't decrease ischemic lesions. On the other hand, cultured EPC increased the cerebral blood flow ratio on ischemic hemisphere. In the mice which were injected with cultured EPCs, the number of CD31+ and eNOS positive cells were increased compared to controls. Conclusions: Those results indicate cultured human EPCs possibly leading angiogenesis on nude mice through the humoral immunity. Those cultured EPCs could enhance repairing and regenerating neurovascular units after ischemic stroke.

Title: Critical role of E2-25K/HIP2 in ischemic injury

Authors: E. JEONG[1], S. SONG[2], *Y.-K. JUNG[1]
[1]Sch. of Biol. Sci., Seoul Natl. Univ., Gwanak-Gu, Seoul, Korea, Republic of; [2]Harvard Med. Sch., Boston, MA

Abstract: Cerebral ischemia is a major cause of mortality and disability but there is no clear damage mechanism as well as no treatment or prevention. In this study, we report that E2-25K/HIP2, an E2-conjugating enzyme involved in ubiquitin proteasome system, modulates oxygen-glucose deprivation (OGD)/reoxygenation-induced cell death in neuronal cells. We found that the expression of E2-25K/HIP2 is induced in neuronal cells during OGD/reoxygenation. Knockdown of E2-25K/HIP2 expression protects against OGD/reoxygenation-induced neuronal cell death, while ectopic expression of E2-25K/HIP2 stimulates the cell death. This stimulation effect of E2-25K/HIP2 is dependent on the enzyme activity. We also observed the persistent expression of HIF-1alpha during the reoxygenation after OGD in E2-25K/HIP2-deficient neuronal cells. Compared to control mice, cerebral infarction lesion in E2-25K/HIP2 KO mice was ameliorated in a mouse ischemic model of transient middle cerebral artery occlusion (tMCAO)/reperfusion. Further, treatment of wild-type mice with N0001 compound which inhibits the enzyme activity of E2-25K/HIP2 *in vitro* compromises the cerebral infarction volume under tMCAO/reperfusion. In conclusion, E2-25K/HIP2 is critical in OGD/reoxygenation-mediated cell death.

Title: Effect of a cell therapy on neuropathological and neurorestorative processes following ischemic damage in rhesus monkey motor cortex

Authors: *M. E. ORCZYKOWSKI[1], M. L. MCBURNIE[2], F. MORTAZAVI[1], D. L. ROSENE[1], T. L. MOORE[1]
[1]Dept. of Anat. and Neurobio., Boston Univ. Sch. of Med., Boston, MA; [2]Tufts Univ. Sch. of Med., Boston, MA

Abstract: Many experimental agents have shown potential as treatments for stroke in rodent models. However, the only therapy to have gained FDA approval to treat stroke in humans is tissue plasminogen activator (tPA) that dissolves clots and restores blood flow with efficacy only if administered within three hours of symptom onset. Following stroke, with or without tPA treatment, patients are often left with permanent residual impairment. CNTO 0007 is an investigational cell product containing human umbilical tissue-derived cells that was tested in our established non-human primate model of cortical ischemia for efficacy in enhancing recovery and reducing the permanent impairment of stroke. To test this, rhesus monkeys were trained on a quantifiable battery of fine motor tasks. After reaching asymptotic performance, the primary motor cortex was mapped using electrophysiological stimulation to identify the hand representation. Then the cortical blood vessels of only the hand representation were disrupted creating a reproducible ischemic lesion that impaired only the contralateral hand. The next day, CNTO 0007 (10M cells/kg) or vehicle control was administered intravenously. Subsequently monkeys were re-tested on the fine motor battery. Results demonstrated that treated monkeys had a significant degree of recovery of fine motor function and strength of the hand in the two weeks following surgery. During long-term (14 weeks) behavioral testing, there was significant improvement in the time to retrieve a food reward and the quality of grasp pattern in treated monkeys. To assess possible mechanisms by which CNTO 0007 facilitates post-stroke recovery, both neuropathological and neurorestorative processes are being investigated in post-mortem tissue. Using immunohistochemistry, we are quantifying activated microglia (LN-3), astrocytosis (GFAP), oxidative stress (4-HNE), and sprouting (GAP43) in premotor and primary motor cortices ipsilateral to the ischemic damage. Qualitative analysis of LN-3 revealed a decrease in activated microglia in tissue from monkeys treated with CNTO 0007. The quantitative results of the immunohistochemical assays of LN-3, GFAP, 4-HNE, and GAP43 will help us to better understand the role of CNTO 0007 in the neuropathological and neurorestorative processes following stroke.

Title: Longitudinal *in vivo* imaging of thalamocortical projections after stroke

Authors: *K. A. TENNANT, S. L. TAYLOR, C. E. BROWN
Div. of Med. Sci., Univ. of Victoria, Victoria, BC, Canada

Abstract: The large majority of stroke survivors must cope with chronic disability often affecting the upper limbs. In order to regain sensory functions after stroke, surviving neural circuits must re-organize and make new connections. Axonal projections from the thalamus are the primary source of afferent sensory inputs to the cortex, and likely play a role in recovery of function. Currently it is unknown how these projections change over time *in vivo*, after stroke. We hypothesized that thalamocortical innervation of the peri-infarct cortex is disrupted by stroke, but undergoes extensive structural remodelling that supports recovery of function. Adult C57BL/6 mice received pressure injections of adeno-associated virus (AAV-GFP) into the ventroposteriolateral nucleus of the thalamus, which sends projections to primary somatosensory cortex (S1). Immediately following virus injection, an imaging window was implanted over forelimb and hindlimb S1 (FLS1 and HLS1). Axon terminals and cerebral vasculature were imaged *in vivo* using two-photon microscopy before and at various times after photothrombotic stroke in FLS1 to assess acute and long-term changes in structure. Preliminary data indicate that, surprisingly, a subset of thalamocortical axons survived within the infarct core, but underwent branch retraction and terminaux bouton loss. In peri-infarct cortex, terminaux boutons underwent a high rate of turnover in the first week after stroke, followed by a period of bouton stabilization. Overall, peri-infarct thalamocortical axons seem relatively resilient to the effects of small focal ischemia, maintaining branches and boutons, which may provide a scaffold for functional recovery after stroke. Current studies are underway to determine the dynamics of en passent boutons after stroke.

Title: Changes in Axin2 expression following white matter ischemic stroke in mice

Authors: *M. E. REITMAN, S. ROSENZWEIG, T. CARMICHAEL
UCLA, Los Angeles, CA

Abstract: Stroke is a debilitating neurological disorder which affects approximately fifteen million people yearly world-wide and is the leading cause of adult long-term disability. Cortical ischemic stroke and the mechanisms by which neuronal death and repair occur has been a key area of neuroscientific research. However, subcortical ischemic stroke in white matter, which accounts for approximately 25% of all stroke subtypes, has not been as thoroughly studied, and the mechanisms underlying damage, repair and recovery in white matter stroke (WMS) are still poorly understood. Recently, our lab utilized a unique mouse model of WMS and RNAseq transcriptome analysis to identify differential expression of specific proteins in peri-infarct white matter following WMS. The current study characterized the temporal and spatial expression, as well as the cellular origin of one of the identified proteins -- Axin2, which acts as part of the β-catenin destruction complex to inhibit Wnt signaling. WMS was produced in mice via microinjections of the endothelial nitric oxide synthetase inhibitor N5-(1-iminoethyl)-L-ornithine (L-NIO) at three points along the white matter ventral to the forelimb motor cortex. Immunostaining for Axin2 and markers of white matter cell types was performed at critical time-points following WMS. Axin2 was found to be up-regulated outside the infarct core at both 7 day and 2 month time points post-stroke in a population of subcortical fibrous astrocytes. This suggests a late response to WMS which may facilitate reparative responses to WMS, possibly through disinhibiting the maturation of oligodendrocyte progenitor cells. To further examine the regulation and mechanism of action of Axin2, current experiments aim to examine the changes in Axin2 expression in white matter oligodendrocytes and to explore the impact of Axin2 expression on oligodendrocyte maturation and remyelination following WMS. These will further

our understanding of the cellular and molecular response to WMS and may help identify targets for therapeutic intervention following WMS in humans.

Title: Gene expression in peripheral immune cells following cardioembolic stroke is sexually dimorphic

Authors: *B. STAMOVA[1], G. JICKLING[1], B. ANDER[1], X. ZHAN[1], D. LIU[1], R. TURNER[1], C. HO[1], J. KHOURY[2], C. BUSHNELL[3], A. PANCIOLI[4], E. JAUCH[5], J. BRODERICK[6], F. R. SHARP[1]
[1]MIND Institute-Wet Lab., UC Davis Med. Ctr. MIND Inst., Sacramento, CA; [2]Cincinnati Children's Hosp. Med. Center, Univ. of Cincinnati, Cincinnati, OH; [3]Neurol., Wake Forest Univ. Med. Ctr., Winston-Salem, NC; [4]dDepartment of Emergency Medicine, Univ. of Cincinnati, Cincinnati, OH; [5]Div. of Emergency Medicine, Med. Univ. of South Carolina, Charleston, SC; [6]fUniversity of Cincinnati Neurosci. Institute, Dept. of Neurol., Cincinnati, OH

Abstract: Epidemiological studies suggest that sex has a role in pathogenesis of cardioembolic stroke. Since stroke is a vascular disease, identifying sexually dimorphic gene expression changes in blood leukocytes can inform on sex-specific risk factors, response and outcome biology. We aimed to examine the sexually dimorphic immune response following cardioembolic stroke by studying differential gene expression in peripheral white blood cells.

Blood samples from patients with cardioembolic stroke were obtained at ≤3 hours (prior to treatment), 5 hours and 24 hours (after treatment) after stroke onset (n=23, 11 Female, 12 Male; 69 samples) and compared with vascular risk factor controls without symptomatic vascular diseases (n=23, 11 Female, 12 Male; 23 samples). mRNA levels were measured on whole-genome Affymetrix microarrays. Differentially expressed genes were identified by Mixed Effects ANCOVA (FDR $p \leq 0.05$, $|\text{fold change}| \geq 1.2$). There were more up-regulated than down-regulated genes in both sexes, and females had more differentially expressed genes than males following cardioembolic stroke. Sexually dimorphic gene expression was noted for genes in cell death and coagulation pathways and for genes specifically expressed by neutrophils, monocytes and megakaryocytes. Distinct temporal immune profile following cardioembolic stroke was observed with immune response pathways over-represented at ≤3, 5 and 24h after stroke in female subjects but only at 24h in males. This is particularly relevant since the immune system can contribute to risk of stroke and to damage and/or to repair processes following stroke. These sex differences could also contribute to some of the reported sexual dimorphic features of stroke, such as age at stroke and response to treatment. Neutrophil-specific genes were differentially expressed at 3, 5 and 24h in females but only at 5h and 24h in males. In stroke neutrophils have recently been shown to have important roles in clotting and atherosclerosis, their increased numbers correlated with risk of having an ischemic stroke and myocardial infarction as well as with poor outcomes and increased mortality. The greater percentage of neutrophil-specific transcripts in females compared to males at early times following stroke in this study could relate to reported increased rate and morbidity of cardioembolic stroke in females. In summary, this study provides additional evidence for sexually dimorphic nature of cardioembolic stroke and can guide search for sex-specific treatments and prevention. Future studies are needed to confirm findings, to determine how they relate to risk and outcome, and to compare to other causes of ischemic stroke.

Title: Ephrins are responsible for differing astrocytic response in the post-ischemic infant and adult primate brain

Authors: *L. TEO, J. BOURNE
AUSTRALIAN REGENERATIVE MEDICINE INSTITUTE, CLAYTON, Australia

Abstract: Reactive astrogliosis initiated after CNS injuries results in the formation of a glial scar, a potent inhibitor of repair. The severity of glial scarring is more profound following adulthood CNS injuries vs. comparable early-life injury in primates, correlating to the greater potential for functional sparing and regeneration following early-life vs. adulthood CNS injuries. The mammalian receptor tyrosine kinase EphA4 is a guidance cue that plays important roles throughout the developing and injured CNS. Eph-A4 signaling is crucial for activation and regulation of reactive astrocyte (RA) activity after injury and in glial scar formation. However, less is known about the ephrin ligands required to trigger EphA4 signaling and their specific downstream effects following CNS injuries. We hypothesize Eph/ephrin expression after homologous focal neocortical ischemia differs between infant and adult primate brains, contributing to diverging RA responses and severity of glial scarring. Focal ischemia was induced in infant (P14) and adult (n=4) marmosets (Callithrix jacchus) through endothelin-1 (ET-1) induced calcarine artery occlusion. Brains were harvested at 1 and 21 days post ischemia (DPI). Western blot screens revealed differences in ephrins responses after injury. In infants, ephrinA1 was upregulated acutely and sustained at 21DPI. EphrinsA2 and -A5 were downregulated at 1DPI, returning to baseline levels by 21DPI. In contrast, adults revealed no expression of ephrin-A1 in control or post-ischemic brains. Acute and sustained upregulation of ephrinsA2 and -A5 were detected in adults. Antibody labeling revealed the expression of ephrinA1 (infants) and -A2/-A5 (adults) predominantly on astrocytes, with highest labeling intensity proximal to the infarct core, diminishing distally, directly. At both ages, upregulated ephrin ligands were co-expressed with EphA4. We confirmed the interaction of ephrinA1 and -A2/-A5 with the EphA4 receptor individually through EphA4 co-Immunoprecipitation (co-IP). In adults specifically, ephrinsA2 and -A5 were found to be co-expressed on RA with significant fluorescent puncta colocalization detected. Co-clustering of ephrinA2 and -A5 ligands was also detected through ephrin-A5 co-IP. Our data indicates that Eph/ephrin expression on RA after brain injury differs between infant and adults and provides greater evidence for a role in glia-glia communication after injury. Based on our current and previous results, we propose that ephrinA2/-A5 acts synergistically on EphA4 to promote astrocyte reactivity, proliferation and migration, resulting in more severe glial scarring in adult but not infant primates.

Title: iPS cells-derived astrocytes from subjects with Monge's disease are vulnerable to hypoxia/ischemia

Authors: *H. YAO[1], H. ZHAO[1], G. G. HADDAD[1,2,3]
[1]Dept Pediat, [2]Neurosci, UCSD, La Jolla, CA; [3]Rady Children's Hosp., San Diego, CA

Abstract: The brain is one of the major target organs of Chronic mountain sickness (CMS) or Monge's disease, as manifested by the frequently seen CNS symptoms such as headache, dizziness, sleep disturbance, and mental confusion. Astrocytes play a critical role in this disease as they control fluid and electrolyte homeostasis. In this work, we obtained skin biopsies from CMS patients, healthy highlanders (non-CMS) and re-programmed the skin cells into induced pluoripotent stem cells (iPSCs). The iPSCs were then differentiated into neuroprogenitor cells and further into astrocytes. To compare the response of astrocytes to hypoxia/ischemia challenges between CMS and non-CMS, we conducted cell viability assay following chronic hypoxia (1% O_2), oxygen-glucose deprivation (OGD) and IS (a solution that mimics the ischemic penumbral environment) challenges. Cell viability was analyzed by propidium iodide stained cell counting which was normalized by the DAPI stained cell counting and presented as the percentage of injured cell number over the entire cell counting. Our results show that a 5 day chronic hypoxia induced a 19% (453/1949) cell death in CMS astrocytes, a significant increase over that in non-CMS (13%, 167/1169, χ^2 test, $p= 3.4x10^{-6}$). In OGD (24 hour) experiment, a 42% (675/1596) cell death was seen in CMS astrocytes, which doubles the amount of cell death seen in non-CMS astrocytes (19%, 206/1087, χ^2 test, $p=1.2x10^{-36}$). Finally, in IS (24 hour), cell death is 37% (593/1600) in CMS and 36% (1289/3600, χ^2 test, $p= 0.384$) in non-CMS astrocytes, respectively, with no signigicant difference between the two groups. In summary, compared with non-CMS astrocytes, CMS astrocytes show increased vulnerability to hypoxia/ischemia challenges and this may explain why pronounced CNS symptoms are seen in CMS patients.

Title: Phenotypic and transcriptomic astrocyte heterogeneity in the uninjured and post-stroke brain

Authors: *A. J. GLEICHMAN[1], M. V. SOFRONIEW[2], S. T. CARMICHAEL[3]
[1]Neurol., [2]Dept. of Neurobio., [3]David Geffen Sch. of Medicine, Dept. of Neurol., UCLA, Los Angeles, CA

Abstract: There is emerging evidence for distinct astrocyte phenotypes in the developing and adult CNS. In the adult brain, acute injury, such as in stroke, causes an initial process of local scar formation that confines the damage, and a later and limited process of tissue repair that involves the formation of new connections and new blood vessels. Astrocytes are central to both scar formation and tissue repair after stroke, but little is known about how the astrocyte mediates these dual functions of injury and repair. Here, we explore astrocyte phenotypes in the normal brain and after injury using viral vector-defined morphological analyses, immunohistochemical analyses of key molecular systems, and RNAseq of defined astrocyte populations *in vivo*, using both white matter and cortical stroke models. Astrocyte-specific lentiviral vectors driving fluorophore expression were delivered to distinct zones of astrocyte activation after stroke. The complete arbor of individual astrocytes was visualized, allowing quantification of the length and thickness of processes, arbor complexity, and domain size. These quantifications demonstrate the existence of multiple morphologically distinct astrocytic populations based on distance from infarct. These populations also differ in the expression of functionally relevant astrocytic proteins, including the inflammatory master regulator Lcn2, the water transporter Aquaporin-4, the proliferation marker Ki67, and the glutamate transporters GLT-1 and GLAST. Transcriptomic analyses of different astrocytic populations are being conducted using the RiboTag mouse model, in which actively translating mRNA can be isolated exclusively from Cre-expressing cells. By crossing the RiboTag line with a GFAP-Cre line, we have generated mice in which astrocytes express tagged ribosomes. Astrocytic mRNA was isolated from uninjured cortex vs white matter and analyzed via RNAseq; these data reveal differences in both gene and splice isoform expression patterns between uninjured fibrous vs protoplasmic astrocytes. Similar analyses are being conducted post-stroke, in morphologically and

phenotypically distinct subsets of astrocytes isolated via laser capture microscopy. Together, these data demonstrate functional differences between astrocytic subpopulations and suggest molecules and pathways to target in the development of astrocyte-directed approaches to promote neural repair post-stroke.

Title: In the wake of diffuse traumatic brain injury, enduring dendritic hypertrophy within the basolateral amygdala

Authors: A. N. HOFFMAN[1,3,4], J. B. ORTIZ[1], T. C. THOMAS[5,6,7], J. LIFSHITZ[1,5,6,2], *C. D. CONRAD[1,2]

Inst., Phoenix Children's Hosp., Phoenix, AZ; [7]Phoenix VA Healthcare Syst., Phoenix, AZ

Abstract: There is an emerging link between traumatic brain injury (TBI) and post traumatic stress disorder (PTSD), and the increasing numbers of veterans with TBI has created interest in their comorbidities. The amygdala, a phylogenetically conserved limbic structure, has long known to be involved in processing emotional and stressful stimuli, and is implicated in PTSD. Moreover, chronic stress alone results in dendritic restructuring in the amygdala, which persists

for up to one month after the stressor manipulation has terminated. Even a single stressor manipulation can produce long-lasting changes in amygdalar dendritic architecture. The amygdala has been largely overlooked in TBI research and reorganization in this structure may serve as a nidus for TBI-induced PTSD affective symptoms and a future target for treatment. In the current study, we hypothesize that enduring structural alterations within the basolateral amygdala (BLA) after TBI may be a mechanism underlying the TBI-PTSD comorbidity. The purpose of this study was to quantify temporal changes in dendritic complexity within the BLA following a single diffuse TBI using a midline fluid percussion injury model. Adult male Sprague-Dawley rats were subjected to a single moderate severity midline fluid percussion injury (1.9 atm; 6-10 min righting reflex), or sham surgery. At post injury days (PID) 7 and 28, sham and brain-injured rats were euthanized and brains were collected and processed for Golgi stain analysis (200μm sections; FD Rapid GolgiStainTM kit) to quantify dendritic complexity of individual BLA neurons. Fully stained, untruncated, and isolated pyramidal and stellate neurons were identified and reconstructed using a camera lucida microscope. The total number of branch points and overall dendritic length were quantified. Data from both pyramidal and stellate neurons were combined. Compared to sham, brain-injured rats at both PID 7 and 28 showed increased number of total branch points and overall branch length within the BLA. These data suggest a chronic enhancement of dendritic complexity within the BLA after a single TBI. Increased dendritic complexity would necessarily alter information processing into and through the extended amygdala, which may contribute a long-term risk factor or cause the development of PTSD after brain trauma. The amygdala remains a central focus for the continued analysis in the wake of TBI.

Title: Time-sensitive molecular mechanisms underlying post-TBI remodeling of the inhibitory synaptic network

Authors: *P. N. LIZHNYAK[1], P. DE DOMENICO[2,1], A. K. OTTENS[1]
[1]Dept. of Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA; [2]Univ. of Messina, Messina, Italy

Abstract: Understanding the molecular processes that underlie the pathobiology of traumatic brain injury (TBI) is instrumental to developing more effective diagnostics and treatments. Of particular interest in our laboratory are the regenerative mechanisms initiated during a critical post-acute period following TBI. Omic analysis provides us with an unbiased means to discern the temporal progression of molecular events that fashion repair and reorganization. Using a controlled cortical impact model, we induced focal brain injury in male rats and collected tissues for proteomic and immunofluorescence microscopy between 2 and 14 days post-TBI. We employed a non-targeted, data-independent mass spectrometry method to quantify TBI-induced proteome dynamics within spared somatosensory cortex adjacent to the focal injury. In this study, we tested the hypothesis that an analogous molecular mechanism that initiates inhibitory network development would be activated during the post-acute repair period following TBI. We examined the peptide data related to inhibitory-specific isoforms of synaptic proteins to include synaptotagmin-2 (SYT2), neuroligin-2 (NL-2), gephyrin, and KCC2 to evaluate post-translational changes. Results demonstrate novel, temporally resolved changes at 2 and 4 days, respectively post injury, in ubiquitin and phosphorylative motifs of NL-2, a key initiator of inhibitory network remodeling. Coinciding at 4 days post-TBI, we resolved the reduction of KCC2 chloride transporter levels at the membrane, reverting inhibitory neurons to a development-like GABA-induced excitatory state. KCC2 level recovery then coincides with a transient de-polymerization of gephyrin at 7 days following injury, suggesting prominent plasticity of the inhibitory network. Immunofluorescence results affirm the temporal reduction in punctate NL-2 staining of inhibitory synapses as well as remodeling as suggested by Syt2 staining. Study findings reveal a temporal process by which the cortical inhibitory network is reorganized following TBI that reflects similar machinery employed during development. Further, these data define a transient critical period during post-acute recovery that represent a plausible boundary for therapeutic protection or enhancement of network repair as well as post-translational events by which to study the efficacy of novel pre-clinical interventions.

Title: Loss and recovery of olfactory function induced by excitotoxicity in rats as a model for secondary neuronal degeneration in Traumatic Brain Injury: Role of adult neurogenesis

Authors: *C. A. MARIN[1], I. TEJERO[2], I. ALOBID[3], J. BERENGUER[3], M. BERNABEU[4], S. CENTELLES[3], S. LAXE[4], E. LEHRER[3], F. MARIÑO-SÁNCHEZ[3], J. MULLOL[2]

Abstract: Traumatic brain injury (TBI) constitutes one of the main causes of olfactory dysfunction. One event related to TBI is the secondary neuronal degeneration (SND), a downstream cascade of events promoting further damage. Excitotoxicity is a key factor in SND since during the TBI acute phase, a massive release of glutamate occurs. The role of excitotoxicity on TBI olfactory dysfunction is still unknown. The goal was to examine the olfactory dysfunction induced by bilateral administration of the glutamate agonist N-methyl-D-aspartate (NMDA) in the olfactory bulbs (OB) in the rat as an experimental model of SND. Sprague-Dawley rats were maintained in a food-deprivation schedule. Olfactory discrimination tests were performed before, 1 and 2 weeks after NMDA-lesion. The dish in which rats dug first and the spent time were recorded. NMDA or vehicle was bilaterally injected into OB (1, 2, or 3 injections of 1.5 µl). Nissl staining, NeuN, tyrosine hydroxylase (TH), and glial fibrillary acidic protein (GFAP) immunohistochemistry were performed in OB. Doublecortin, PSA-NCAM and PCNA immunohistochemistry were performed in the subventricular zone. One week after NMDA lesions, animals showed a significant 70% ($p<0.01$) decrease in correct trials when 3, but not 1 and 2, injections were administered ($p<0.01$). The time spent to achieve the correct odour increased ($p<0.05$). A recovery of olfactory function was observed two weeks after lesion ($p<0.01$). NMDA lesions resulted in neural injury through all bulb layers. The present results indicate that bilateral OB NMDA lesion is a useful tool to investigate excitotoxicity in the SND after TBI and to study the pathophysiology and repair mechanisms of the olfactory dysfunction. *This study was sponsored by a grant from La Marató TV3 (274/U/2011)*

Title: Regulation of newborn neuron survival and the inflammatory cell response after traumatic brain injury by suppressor of cytokine signalling 2 (SOCS2)

Authors: H. S. BASRAI, K. J. CHRISTIE, *A. M. TURNLEY
Anat. and Neurosci., The Univ. of Melbourne, Melbourne, Australia

Abstract: Suppressor of cytokine signalling-2 (SOCS2), a negative regulator of the JAK-STAT pathway, is expressed at the highest levels in the hippocampal CA3 region and dentate gyrus in the adult brain. We previously showed that SOCS2 overexpressing (SOCS2Tg) mice have increased survival of newly born adult hippocampal neurons. We have now examined hippocampal neurogenesis in SOCS2 knockout (SOCS2KO) mice. Adult SOCS2KO and wildtype mice were given one pulse of EdU per day for 7 days. One cohort was perfused on the 8th day to study effects on neurogenesis (neuroblast proliferation and differentiation) and a second cohort perfused at 35 days to examine newborn neuron survival. No difference in neurogenesis was observed between SOCS2KO and wildtype mice. However, SOCS2KO mice showed a reduction in the survival of newborn adult hippocampal neurons. This confirmed a role for endogenous SOCS2 in the regulation of newborn neuron survival in the hippocampus. Given that overexpression of SOCS2 enhanced basal adult neurogenesis, we hypothesised that SOCS2Tg mice may also display enhanced survival of newborn neurons following traumatic brain injury (TBI) compared to wildtype mice. Therefore, SOCS2Tg mice and littermate wildtype controls were subjected to a controlled cortical impact (CCI) or sham surgery. Mice were pulsed with EdU beginning immediately after injury once per day for 7 days to label cells proliferating in response to the injury. After behavioural analyses at 2, 7 and 33 days post-injury, brains were collected 35 days post injury to examine newborn neuron survival, glial and inflammatory cell responses. Newborn EdU+/NeuN+ neurons were identified in the injured cortex of animals of both genotypes following moderate but not mild CCI and SOCS2Tg mice showed functional improvement on a ladder test compared to wildtype mice. Further, there was a two fold increase in the total number of EdU+ cells in the injured cortex of SOCS2Tg animals compared to wildtype. CD11b+ microglia/macrophages were the major contributors to this increase. EdU+/Olig2+ cells were also present and their number was significantly, but not differentially, increased post-TBI in both genotypes. These results suggest a role for SOCS2 in modulating the inflammatory cell response after TBI, which may contribute to the functional recovery observed in SOCS2 overexpressing mice.

Title: Simulated blast overpressure-induced astrocyte injury in an acute brain slice model

Authors: ***M. A. KING**[1,4], S. CANCHI[2], Y. HONG[2], J. FLINT[3], M. SARNTINORANONT[2], G. SUBHASH[2]

Abstract: Exposure to explosive blasts can produce complex brain pathology and debilitating functional outcomes. The overpressure characteristics of the primary blast wave are considered to be potentially damaging to the brain. Astrocytes participate in neuronal metabolic maintenance, blood-brain barrier, regulation of the homeostatic environment, and tissue remodeling. Little is known about their specific susceptibility to blast injury apart from delayed reactive astrogliosis. Overpressure-induced tissue strain transients could mediate mechanical failure in astrocyte processes. Subsequent compromised function of single astrocytes would involve multiple neurons encompassed by the processes of individual astrocytes. Transient or sustained astrocyte injury could conceivably induce complex neuronal pathology sufficient to impair brain function, and be distributed among dispersed compartments of disturbed tissue too small to detect with diagnostic imaging. An *in vitro* rat brain tissue slice model was used to test whether direct interaction of tissue astrocytes with a simulated blast wave limited to overpressure alone will elicit acute, histologically detectable injury. A polymer split Hopkinson pressure bar (PSHPB) system was used to impart a single blast pressure peak to a slice chamber. Initial experiments control pressure at a level comparable to actual explosive blasts. Glial fibrilliary acidic protein (GFAP) immunofluorescence intensity and area fraction in confocal images were quantified and statistically analyzed by 2-way ANOVA (shock x time). Two acute astrocyte injury profiles have been identified during the initial hours after the overpressure: (a) astrogliosis

characterized by enhanced GFAP intensity without significant increase in tissue area fraction occupied by labeled astrocytes, and (b) clasmatodendrosis, an autophagic degradation of distal processes that has not been previously associated with blast-induced neurotrauma. The controlled testing platform provides insight on overpressure injury that is otherwise difficult to isolate.

Title: Matrix metalloproteinase-9 and osteopontin mediation of cellular response in the olfactory bulb during trauma-induced synaptogenesis

Authors: ***M. A. POWELL**, P. A. TRIMMER, T. M. REEVES, L. L. PHILLIPS
Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA

Abstract: Traumatic brain injury (TBI) causes damage to many different CNS circuits. This includes pathway disruption that can result in sensory deficits. Such deficits are attributed to TBI axotomy, which produces deafferentation and loss of synaptic organization. Olfactory receptor neurons are particularly vulnerable to axotomy, resulting in targeted deafferentation of synapses in the olfactory bulb (OB). Notably, this circuit can undergo reactive synaptogenesis, restoring

lost synaptic connections over time. Our laboratory has demonstrated that matrix metalloproteinases (MMPs) regulate TBI-induced synaptic repair. In OB, secreted gelatinase MMP-9 is acutely elevated after injury, consistent with its posited role in reshaping the local environment during synaptogenesis. Recently, the cytokine osteopontin (OPN) was identified as a MMP-9 substrate, its integrin binding domains exposed by MMP proteolysis. We hypothesize that injury-induced MMP-9/OPN interaction in the deafferented OB supports cell signaling and facilitates synapse recovery. Using FVB/NJ wild type (WT) and FVB MMP-9 knockout (KO) mice subjected to moderate central fluid percussion TBI, we analyzed OB OPN fragment generation at 3, 7, and 21d postinjury relative to paired sham-injured cases. These time points represent sub-acute degenerative and early regenerative phases of OB reactive synaptogenesis. MMP-9 activity of injured and control WT mice was also assessed by zymography. Results showed injury-induced elevation of MMP-9 activity at both 3d (34%) and 7d (4 fold), the latter statistically significant. By 21d, MMP-9 activity was not different from controls. Western blot OPN analysis revealed generation of a 47kD fragment, temporally correlated with changes in OB MMP-9 activity. KO of MMP-9 significantly attenuated expression of the 47kD OPN fragment at both 3 and 7d, suggesting that OB MMP-9 contributes to regulation of OPN signaling after TBI. To further explore MMP-9 and OPN expression in specific OB cell populations, we subjected mixed glial/neuronal cultures from WT and MMP-9 KO mice to OPN immunocytochemical analysis. Results showed limited OPN expression in WT cells. OPN did not co-localize with GFAP+ astrocytes or IBA1+ microglia, suggesting either neuronal or olfactory ensheathing cell labeling. Interestingly, MMP-9 KO OB cultures had a pronounced increase in OPN+ cells, as well as elevated glial density and OPN localization in microglial populations. Collectively, these data suggest that OB MMP-9 contributes to OPN processing after TBI, and that OPN is a likely mediator of postinjury cellular response during reactive synaptogenesis in the deafferented OB.

Title: Mild traumatic brain injury (TBI) *in vitro*: Network activity changes and parameters of recovery

Authors: *D. SMITH[1], G. W. GROSS[2]
[1]Ctr. For Network Neurosci., Savannah, TX; [2]Ctr. For Network Neurosci., Denton, TX

Abstract: The complex pathology of TBI requires research on all levels: from studies of holistic brain injury to cellular and even synaptic disruption. In many cases, physical evidence does not exist, as standard CTI or MRI scans are not sensitive enough. Diffuse brain injury ranges from axonal damage after minor head injury to inflammatory responses and calpain-mediated cytoskeletal changes [1]. Although networks *in vitro* do not represent brain tissue *in situ*, the highly controlled environment and multifactorial readout provides quantitative injury data for establishing reliable damage thresholds, recovery profiles, and biochemical enhancement of recovery. We have combined a ballistic pendulum rapid acceleration device with multichannel recording from frontal cortex cultures. This allows comparisons of spontaneous network activity before, and within four minutes after injury at a variety of different impact forces with subsequent long-term (days to weeks) monitoring. Single 100-g impacts have shown hyperexcitation as well as activity decreases, frequently with full recovery to reference. However, multiple impacts of 100 g's have shown consistent, significant decreases in reference activity. Two to three sequential insults spaced by thirty to ninety minutes have shown 40-60% decreases in activity with no return to reference in 24 hrs (n= 8). Adhesion was not compromised, and major functional changes occurred without loss of active unit signatures. Rapid neuronal cell death seems to require higher g-forces, and observed early deficits may be of synaptic origin or microporation. Although exact impact forces for specific responses may differ between *in vitro* and *in situ*, the recovery from cellular damage as well as the efficacy of potential interventions can be determined *in vitro* and should be scalable to animal models. **[1] Povlishock JT, Becker DP, Cheng CLY, Vaughan GW (1983) Axonal Change in Minor Head Injury. Title: 2-photon in-vivo imaging of impaired balance between excitation/inhibition and acute vascular trauma in sensory barrel cortex correlates with growth of microinfarcts following open head CCI injury in mice

Authors: *M. K. JAISWAL[1,2], F. W. LISCHKA, Ph.D[1,2], X. XU[2], Z. GALDZICKI, Ph.D[1,2]
[1]Ctr. for Neurosci. and Regenerative Med., Bethesda, MD; [2]Dept. of Anatomy, Physiol. and Genet., USUHS, Sch. of Med., Bethesda, MD

Abstract: The adult brain is soft-wired and must undergo plasticity to support adaptation to an altered environment or injury. In response to sensory deprivation caused by TBI, the functional topography of the neocortex is altered such that cortical areas or 'maps' of deprived sensory inputs shrink, while maps of the remaining spared inputs expand. However, it is not known how sensory-driven activity in individual L2/3 neurons changes over time after brain injury, and how these changes differentially occur within local excitatory/inhibitory (E/I) neuronal populations in response to alterations in plasticity after injury. There are three central unanswered questions relating to alterations in plasticity after injury. First: What is the time window for the onset of neuronal deficits? Second: How do sensory and motor circuit remodeling change over the course of the recovery period? Third: To what extent does neuronal injury cause additional vasculature disruption, and vice versa? To address the first two questions, we have proposed using in-vivo imaging of neuronal [Ca2+] by two-photon microscopy to monitor the activity of E/I neurons in GAD67-GFP knock-in mice and assess the loss/gain of spontaneously evoked neuronal activity in the core of the microinfarct after TBI and sham surgery in acute and chronic TBI. In addition we assessed the loss or disruption of functionally evoked neuronal population activity in the core of the microinfarct by imaging in the relatively large hindlimb region of the primary somatosensory cortex, where peripheral electrical stimulation could reliably activate a large number of neurons. To address the last question, we monitored vascular changes caused by damage to the integrity of the BBB with dye specific for blood vessels/arteries with simultaneous recordings of Ca2+ transients in E/I neurons. 2-photon in-vivo Ca2+ imaging revealed a decrease in overall spontaneous activity within the neuronal population of TBI mice, due to a higher number of hypoactive excitatory/inhibitory L2/3 neurons within microinfarcts of injury epicenter. At the same time preliminary experiments revealed both excitatory and inhibitory neurons from TBI mice displayed an unexpected increase in their frequency of spontaneous Ca2+ transients in comparison to sham littermates. The number of excitatory neurons responsive to hindlimb stimulation appears to decrease precipitously in the injured post injury. Overall, our preliminary results suggest reorganization of cortical population activity, traumatized vasculature and impaired balance between E/I sensory circuits with vascular defects exacerbating neuronal activities.

Title: Increased potassium current after mild traumatic brain injury

Authors: J. SUN[1], A. HANELL[1], *K. M. JACOBS[2]
[1]Anat. & Neurobio., Virginia Commonwealth Univ., Richmond, VA; [2]Virginia Commonwealth Univ., RICHMOND, VA

Abstract: Mild traumatic brain injury (mTBI) causes cognitive deficits and memory impairment in patients. Molecular pathological changes after mTBI, especially in diffuse axonal injury (DAI) are well known, but neurophysiological consequences are still emerging. Using the YFP-h mouse, that allows identification of both intact and axotomized layer V pyramidal neurons prior to whole cell patch clamp recording, we have previously reported that intrinsic neuronal properties, including action potential amplitude, were altered at one and two day survival time points. Potassium channels play a critical role in shaping action potentials and modulating intrinsic neuronal membrane excitability. The present study investigates A-type (IA) and delayed rectifier (Ikd) potassium currents in this model, that employs a mild central fluid percussion injury (cFPI) without contusion or cell death. Whole cell patch clamp recordings were made from YFP+ layer V pyramidal neurons within somatosensory cortex. Total Kv current (IK) was recorded in voltage clamp using a 300 ms prepulse at -110 mV, followed by 500 ms voltage steps (by 10 mV) from -80 mV to +70 mV. Ikd was recorded by a 300 ms prepulse at -10 mV (to inactivate IA), followed by 500 ms voltage steps (by 10 mV) from -80 mV to +70 mV. IA was isolated by subtracting Ikd from total IK. For all groups, $n \geq 11$ cells. The whole-cell current and current density of IA was increased in both intact (current 58%, density 84%) and axotomized (current 74%, density 98%) neurons one day after cFPI compared to sham and naïve controls (t-test. $p<0.05$). At the two day survival time point, in axotomized neurons IA was significantly reduced compared to 1 day axotomized, but still significantly increased compared to control (current 54%, density 97%, t-tests, $p<0.05$). In intact cells at two days, IA was not significantly different from controls (t-test, $p>0.05$). Examination of Ikd showed no alteration for either axotomized or intact neurons at one or two days post cFPI. The kinetics of voltage dependent

activation and steady-state inactivation of IA and Ikd were also unchanged after cFPI. The increased IA current may reflect compensatory changes since the groups affected, are the same ones that showed increased intrinsic excitability (Greer et al 2012 J Neurosci, 32:6682; axotomized at one and two days and intact at one day survival). The lack of decreases in either IA or Ikd currents suggest that additional alterations in either sodium or other potassium channels must underlie the previously observed increased action potential amplitude and decreased after-hyperpolarization duration. Title: Blockade of the N-type voltage gated calcium channel reduces intracellular calcium accumulation following injury visualized using the gene-encoded calcium sensor GCaMP6

Authors: *S. HUANG[1], G. G. GURKOFF[2], R. J. GARAJEHDAGHI[1], L. TIAN[3], B. G. LYETH[2], R. F. BERMAN[2]
[1]Drexel Univ. Col. of Med., Philadelphia, PA; [2]Neurolog. Surgery, [3]Biochem. and Mol. Med., Univ. of California, Davis, Davis, CA

Abstract: An estimated 3.8 million Americans experience traumatic brain injury (TBI) annually, and over 5.3 million individuals report chronic deficits related to TBI. Unfortunately there are no pharmacological treatments that substantially improve neurological outcome after TBI. Developing effective therapies requires a thorough understanding of the cellular and molecular events that lead to cell dysfunction and death following TBI. One of the early and critical mechanisms thought to trigger secondary injury is the rapid accumulation of intracellular calcium ($[Ca^{2+}]_i$) after TBI, suggesting that prevention of this event could reduce cell injury and cell death. In the past it has been difficult to examine the time course of changes in $[Ca^{2+}]_i$ that occur over hours to days following trauma longitudinally in the same neuron. In the present study we utilized a gene encoded calcium indicator to successfully image $[Ca^{2+}]_i$ levels and signaling in the same neurons over time. Specifically, mixed neuronal/astrocyte co-cultures were grown and infected with GCaMP6 using an adenoviral vector. Fluorescence imaging in GCaMP6-infected neurons showed that the majority of neurons were expressing the construct

and allowed for longitudinal imaging of intracellular calcium and synaptic activity in neurons before and after mechanical injury. Compared to baseline, injured neurons showed a large (i.e., >400%) increase in intracellular calcium that returned to baseline within 24 hr after injury. Pre-treatment with the N-type voltage gated calcium channel antagonist SNX-185 reduced the rise in intracellular calcium, validating our previous findings with SNX-185 based on calcium imaging with Fura-2-AM. These results establish the usefulness of gene encoded calcium indicators for imaging cells longitudinally in an *in vitro* model of traumatic injury and replicate our earlier findings of elevated intracellular calcium using the same *in vitro* TBI model. Furthermore, these data demonstrate that blockage of N-type voltage gated calcium channels reduces the pathological increase in intracellular calcium and represents a potential therapeutic target for neuroprotection in TBI. Therefore, utilization of gene encoded calcium indicators has the potential to improve our understanding of mechanisms related to primary and secondary neuronal injury and also to guide the development of future neuroprotective strategies.

Title: Injury-induced electric fields drive astrocyte reactivity *in vitro*

Authors: *M. L. BAER, S. C. HENDERSON, R. J. COLELLO
Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA

Abstract: Traumatic injury to the central nervous system (CNS) induces reactivity in surrounding astrocytes that can have both positive and negative influences on repair. Astrocyte reactivity is characterized by hypertrophy of the soma; realignment of cellular processes; up-regulation of the cytoskeletal elements glial fibrillary acidic protein (GFAP), vimentin, and nestin; proliferation; and migration to the lesion border. While reactive astrocytes play a necessary role in the injury response, they ultimately inhibit regeneration by blocking sprouting axons. Altering this reactive phenotype could facilitate regeneration by selectively enhancing

growth-promoting behaviors while attenuating inhibitory ones. However, it is unclear what physiologic change at the injury site induces the many cellular behaviors characteristic of astrocyte reactivity. Injury currents that induce a 10-fold increase in the physiologic electric fields (EF) have been measured in mammalian skin, cornea, and bone where they have been shown to direct cellular behaviors essential to the reparative responses in those tissues. A similar increase in physiologic EFs has been reported in the mammalian CNS upon injury, but the extent to which these injury-induced EFs can drive astrocyte reactivity has not been fully elucidated. With this in mind, our lab has become interested in chronicling the injury currents in the mammalian CNS following a stab injury, and in determining whether the intensity and duration of these EFs is sufficient to drive the reactive phenotype. Using a vibrating probe electrode to measure the injury currents, we found that a stab wound in the rat cortex induces an injury current similar to those demonstrated in other injured mammalian tissues. We then demonstrated that these physiologic EFs drive multiple behaviors in isolated astrocytes *in vitro* that are characteristic of the reactive phenotype see *in vivo*. EF exposure induces hypertrophy of the cell soma with increased expression of the cytoskeletal elements GFAP, vimentin, and nestin, as well as other proteins associated with reactivity. We found that EFs induce a marked increase in proliferation that peaks 48 hours after onset of exposure. Furthermore, EFs affect astrocyte migration, directing them toward the anode as early as 3 hours after field onset. Together, these unique observations demonstrate that the intensity and duration of the physiologic EFs found after injury *in vivo* are capable of driving reactive behaviors of astrocytes *in vitro*. This suggests that injury-induced EFs may be an important stimulus of reactive astrocytosis and represents an ideal target to induce a more regenerative response.

Title: Post-traumatic switch in constitutive toll-like receptor 4 modulation of dentate excitability

Authors: *A. A. KORGAONKAR, Y. LI, V. SANTHAKUMAR
Neurosci. and neurology, Rutgers the state university, Newark, NJ

Abstract: Brain injury a leading cause of acquired epilepsy and neurological disability in young adults, leads to early activation of immune responses and cellular and synaptic changes in the hippocampal dentate gyrus. We find a post-injury increase in dentate hilar neuronal expression of toll-like receptor4 (TLR4), a class of innate immune receptors implicated in enhanced hippocampal excitability in epilepsy. Here we examine if activation of TLR4 signaling after brain injury modulates dentate excitability *in vitro* and seizure thresholds *in vivo*. Wistar rats (25-27 day old) were subject to moderate (2 atm) lateral fluid percussion injury (FPI) or used as sham-controls (Gupta et al., 2012). The effect of TLR4 ligands (agonists, LPS-RS and TLR4 antibody and agonist, HMGB1) on perforant-path evoked granule cell population spike amplitude was examined in hippocampal slices 3 and 7 days FPI. A cohort of rats were administered LPS-RS (5ug) or vehicle (bolus hippocampal injection) 24 hrs after FPI and tested for changes in latency to kainic acid (5mg/kg, i.p.) induced seizures 30 days after FPI. In slices from control rats, TLR4 antagonists consistently increased (anti-TLR4: 19.35±51.45%) while HMGB1 suppressed (-60.91±13.42%) afferent evoked dentate population spike amplitude. Unlike controls, TLR4 antagonists decreased (anti-TLR4: -79.0±18.8%) dentate population spike amplitude after FPI indicating that TLR4 signaling contributes to the post-traumatic increase in dentate excitability. HMGB1 increased dentate excitability after FPI (83.77±14.36%) revealing a post-injury reversal of TLR4 effect on network excitability. Consistent with *in vitro* studies, LPS-RS treatment reduced the latency for kainic acid induced seizures in sham-controls and significantly prolonged seizure latency after FPI. Together, our *in vitro* and *in vivo* data demonstrate a constitutive effect of TLR4 signaling on dentate excitability. We identify a post-traumatic reversal in the direction of TLR4 modulation of excitability which contributes to early dentate hyperexcitability after brain injury. A single post-injury treatment with a TLR4 antagonist has a potential to prophylactically prevent lasting decreases in seizure threshold after brain injury. However, the ability of TLR4 antagonists to reduce seizure thresholds in controls needs to be considered while targeting TLR4 for therapy. Moreover, the mechanisms and physiological role of the novel constitutive and bi-directional effects of TLR4on dentate excitability, identified here, need further investigation.

Title: The effect of repeated binge alcohol combined with TBI on the subventricular zone microenvironment

Authors: *S. T. TON[1], I. C. VAAGENES[2], S.-Y. TSAI[2], D. J. SHEPHERD[1], V. A. HUSAK[2], D. C. NOCKELS[1], G. L. KARTJE[1,2]
[1]Loyola Univ. Chicago, Chicago, IL; [2]Res., Hines VA Hosp., Hines, IL

Abstract: We have previously found that a repeated dose of binge alcohol prior to traumatic brain injury (TBI) leads to worse recovery on a sensitive test of skilled forelimb function (Vaagenes et al., 2014). One means by which the brain may compensate for injury is in the mobilization of neural precursor cells. We therefore sought to determine the effect of binge alcohol at the time of TBI on subventricular zone (SVZ) and perilesional neural precursor cells. Adult, male rats were given daily doses of alcohol, either by injection (2gm/kg/i.p/day) or oral gavage (3gm/kg/day) for three consecutive days. One hour after the final dose, animals were given a TBI directed to the forelimb sensorimotor cortical area and sacrificed three weeks later. Brains were immunostained for proliferating cell nuclear antigen (PCNA) and doublecortin (DCX) to label neural precursor cells. We found that this short three day repeated dose of binge alcohol prior to TBI reduced the proliferation of neural precursor cells in the SVZ and perilesional area as well as decreased the differentiation of these cells into neurons. Furthermore, we found that the number of activated microglia as measured by ED-1 immunohistochemistry was reduced in the SVZ of TBI rats treated with binge alcohol compare to TBI alone. In addition to important immune functions, microglia also provide a supportive growth environment in the

SVZ through the release of various trophic factors. Neurotrophic factors play various roles in the regulation of neurogenesis after TBI; for instance, epidermal growth factor (EGF) and fibroblast growth factor (FGF) promote proliferation of neural stem cells while brain derived neurotrophic factor (BDNF) promotes survival of newborn neurons (Richardson et al., 2010). We are currently investigating changes in neurotrophic factor expression and signaling after binge alcohol and TBI in the SVZ microenvironment, and how this relates to recovery after brain damage.

Title: Heterogeneous TBI models reveal differential effects in the SVZ and divergent sonic hedgehog (Shh) signaling pathways in neuronal and oligodendroglial progenitors

Authors: A. J. MIERZWA[1,2], G. M. SULLIVAN[1,2], L. A. BEER[1,2], S. AHN[3], *R. C. ARMSTRONG[1,2]
[1]Dept Anatomy, Physiol. and Genet., USUHS, BETHESDA, MD; [2]Ctr. for Neurosci. and Regenerative Med., Bethesda, MD; [3]Eunice Kennedy Shriver Natl. Inst. of Child Hlth. and Human Development, Natl. Inst. of Hlth., Bethesda, MD

Abstract: The regenerative capacity of the CNS must be optimized to promote repair following traumatic brain injury (TBI) and may differ with the site and form of damage. In the adult CNS, Sonic hedgehog (Shh) maintains neural stem cells and promotes oligodendrogenesis. We examined whether Shh signaling contributes to neuronal (DCX) or oligodendroglial (NG2) progenitor responses to two distinct TBI models. Gli1 transcriptional activation indicates high levels of Shh signaling through the Smoothened receptor in the canonical pathway. Shh-responsive cells were heritably labeled *in vivo* using Gli1-CreERT2;R26-YFP bitransgenic mice with tamoxifen administration on days 2 and 3 post-TBI. All injuries were at the coronal level of

bregma to evaluate the response from cells in the subventricular zone (SVZ), the largest germinal zone in the adult mammalian brain. Mice were examined at 2 and 6 weeks post-TBI. In the first TBI model, injury to the cerebral cortex was produced with mild controlled cortical impact onto the overlying dura mater. YFP cells decreased in cortical lesions. Total YFP and YFP cells double-labeled with DCX increased in the SVZ, indicating Shh pathway activation in neural stem cells and neuroblasts. The alternate TBI model of impact onto the skull at bregma produced traumatic axonal injury in the rostral corpus callosum. YFP cells within the SVZ decreased at 2 weeks and then normalized by 6 weeks. In the corpus callosum, YFP cells were extremely rare, even after injury. YFP labeling was rarely found in NG2 progenitors, indicating a lack of Gli1 transcriptional activation in oligodendrocyte lineage cells. NG2 progenitors increased in the cortex, with a similar trend in the corpus callosum. To further test for Gli1 activation potential, Smoothened agonist (SAG) was microinjected into the corpus callosum to directly activate Shh signaling. YFP cells and NG2 progenitors increased in the SVZ but were not double-labeled, indicating an *in vivo* effect of Smoothened signaling without Gli1 activation in NG2 progenitors. Therefore, in all conditions, neuroblasts exhibited differential Shh pathway utilization compared to oligodendroglial progenitors. Furthermore, cortical versus white matter damage from TBI produced opposite responses of Shh-activated neural stem/progenitor cells within the SVZ. This work was supported by the Department of Defense within the Center for Neuroscience and Regenerative Medicine and by the National Multiple Sclerosis Society.

Title: Heme Oxygenase 1 and Lipocalin 2 as potential modulators of vascular disruption after traumatic brain injury

Authors: *N. H. RUSSELL[1], L. L. PHILLIPS[2]
[1]Dept. of Anat. and Neurobio., [2]Anat. and Neurobio., Virginia Commonwealth Univ., Richmond, VA

Abstract: Heme Oxygenase 1 (HO-1), the inducible form of Heme Oxygenase, degrades heme into biliverdin, CO, and iron. It is a heat shock protein, robustly induced by CNS vascular hemorrhage following traumatic brain injury (TBI). Notably, HO-1 releases highly oxidative iron, which can promote local pathology, as well as up-regulate transcription, potentially affecting neural plasticity during postinjury recovery. Lipocalin 2 (LCN2) is a scavenging/trafficking siderocalin, which traps bound iron and relocates it to intracellular functional sites. LCN2 also persistently binds and activates matrix metalloproteinase-9 (MMP-9), a secreted gelatinase which affects local injury/repair mechanisms. Microarray analysis revealed significant elevation of HO-1 and LCN2 mRNA in rat cortex and hippocampus after fluid percussion TBI, suggesting that HO-1 and LCN2 act in concert to influence recovery within these brain regions. We hypothesized that trauma-induced neuroplasticity at sites of vascular damage is mediated by a pathway involving focal HO-1 expression and iron generation, which then drives LCN2 induction and MMP-9 activation. Twenty four hours after moderate central fluid percussion TBI, HO-1 protein expression in cortex and hippocampus was documented by Western blot (Wb) and immunohistochemistry (IHC). In parallel imaging experiments, HO-1 and LCN2 were examined for co-expression. Wb analysis revealed that diffuse TBI elevated HO-1 by 153% in hippocampus, and 455% in cortex relative to sham injured controls, all statistically significant effects. Wide field immunofluorescence microscopy showed HO-1 elevation in white matter tracts and at the injury site, both areas known to exhibit hemorrhage and neurodegeneration after injury. Interestingly, HO-1 was also elevated in lateral cortex and hippocampal subsectors, regions not associated with hemorrhagic bleeds. Confocal imaging demonstrated primary HO-1 localization within a subset of GFAP positive astrocytes at 24 hr post injury, in both the lateral cortex and hippocampus. HO-1 was also localized within IBA1 positive microglia surrounding gross hemorrhage and necrosis. LCN2 IHC experiments in the same tissue revealed LCN2 and HO-1 co-expression in the same subset of reactive astrocytes. These results show that TBI induces focal HO-1 up-regulation at hemorrhagic sites and in regions without overt vascular disruption. This HO-1 response involves both astrocytes and microglia, and is correlated with local LCN2 increase. Ongoing mapping of postinjury HO-1 and LCN2 response will determine their potential molecular interaction during recovery and role in MMP regulation.

Title: Deep brain stimulation: underlying neural mechanisms for recovery from traumatic brain injury

Authors: *H. KATNANI, J. ARONSON, M. THOMBS, E. ESKANDAR
Dept. of Neurosurg., Massachusetts Gen. Hosp., Boston, MA

Abstract: In a previous publication (Katnani et al.; Society for Neuroscience Abstracts 2013) we described the enhanced functional recovery of mice in a sub-acute phase of traumatic brain injury (TBI) as a result of striatal stimulation. We found that brain injured mice receiving precisely timed stimulation performed significantly better then sham mice on a spatial memory task and also reached the same performance level of uninjured mice. In a follow-up study, we investigated potential neural mechanisms facilitated by stimulation that could underlie improved behavioral performance. Here we present results from an immunohistochemistry analysis, which first utilized c-fos expression to elucidate activated pathways, and second utilized specific neural markers for expression of neurogenesis and neuroplasticity in activated brain regions. In addition, whole transcriptome analysis was employed to broadly evaluate up-regulated genes caused by striatal stimulation in key regions associated with spatial memory such as the hippocampus, ventral striatum and prefrontal cortex. Evidence suggests that striatal stimulation can promote and cause proliferation in the brain, with neural proliferation observed in the subventricular zone. Furthermore, we speculate that these mechanisms facilitate the necessary neuroplastic changes to compensate for injured brain regions, thus allowing mice to overcome impairments at a faster rate and to a greater magnitude.

Title: Recovery of serotonin axons following a neocortical stab injury

Authors: *S. E. DOUGHERTY, D. J. LINDEN
Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Axon degeneration is a common occurrence in neurological disorders such as stroke and traumatic brain injury. While most of this axonal loss is as yet irreversible, some neuron populations have shown a propensity to recover their axonal arbors through regeneration (of injured axons) or compensatory sprouting (of spared axons). Serotonergic neurons display an enhanced capacity for axonal regeneration after acute injury. One potential explanation is the ability of serotonergic axons to survive and grow within hostile extracellular conditions. Previous studies have shown that serotonin axons can extend through otherwise nonpermissive environments including glial scars and within the subventricular zone. To assess serotonin axon degeneration, regeneration, and sprouting following acute brain injury, we used a neocortical stab model in a Slc6A4 (serotonin transporter) - soluble EGFP BAC transgenic mouse. One week after a cortical stab injury we are able to observe axonal damage and astroglial activation. There is a marked increase in GFAP staining surrounding the injury site throughout the cortical layers. This is concurrent with the appearance of bulbous fractured GFP staining suggesting the presence of degenerating serotonergic axons. At 10 weeks post-injury we observe an increase in axonal EGFP staining, including contiguous fibers extending across the damaged area, as well as a reduction in glial scar associated markers. In order to evaluate the dynamics of serotonergic axonal sprouting and regeneration, we are performing chronic *in vivo* two-photon imaging with a cranial window overlying the neocortex. These studies will reveal the dynamic nature of serotonin axonal regeneration and sprouting following a glial scar-forming injury and will provide insight into the process through which serotonergic axons overcome otherwise nonpermissive growth conditions.

Title: The role of estrous stage cycle on synaptic transmission and behavior in female mice following mild traumatic brain injury

Authors: *K. A. FOLWEILER[1,2], C. CRUZ[2], A. S. COHEN[2,1]
[1]Univ. of Pennsylvania, Philadelphia, PA; [2]Pediatrics, Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) affects over 1.5 million people in the United States each year with as many as 75% of cases considered mild TBI (mTBI) (Faul et al. 2010, Sosin, Sniezek and Thurman 1996). mTBI has been shown to lead to a wide array of long-lasting cognitive impairments including changes in working memory deficits. Despite prevalence and growing public concern, currently no effective therapies or treatments exist to attenuate neurological deficits resulting from mTBI. Females account for a significant portion of affected individuals; however, it is unknown whether recovery from injury is influenced by the levels of circulating ovarian steroid hormones (e.g., estrogens, progesterones) present in the brain depending on the menstrual cycle stage at time of insult. Therefore, the goal of this study was to assess the effects of female estrous cycle stage—the mouse correlate of the human menstrual cycle—on alterations in synaptic transmission and behavioral phenotype following mTBI. In order to model mTBI in mice we employed lateral fluid percussion injury (LFPI). LFPI is a commonly used rodent model of brain injury that reproduces many key features of human TBI including neuronal cell loss, gliosis, ionic perturbation and memory deficits (Dixon et al., 1987, McIntosh, 1987, 1989, Smith et al., 1991). At time of injury, mouse estrous cycle stages—estrus, diestrus, metaestrus, proestrus—were recorded. Six days following LFPI, we investigated changes in net synaptic efficacy in the hippocampus. We found a reduction in the Input/Output curves similar to that previously reported in brain injured male mice. That is, a decrease in the slopes of field excitatory postsynaptic potentials recorded in stratum radiatum of area CA1 were reduced in brain-injured mice across all cycle stages except for the estrous stage, which resembled the fEPSP slopes of sham controls**.** Furthermore, preliminary data from an elevated plus maze assessment suggests that there is little apparent injury effect on anxiety-like behavior in any of the cycle stages with the exception of the estrous stage (i.e., mice injured in estrous stage spent less time in the open arms of the maze compared to their sham counterparts). While it is unclear if the physiological alterations seen in hippocampal area CA1 are involved in observed behavioral changes, these results overall indicate that estrous cycle stage has an effect on synaptic transmission and behavioral outcome following mTBI.

Title: Changes in temporal and regional protein expression of peroxisome proliferator activated receptors (PPARs) after thoracic spinal contusive injury in rats

Authors: J.-H. OH, *Y. KIM, Y. YOON
Dept. of Physiol., Korea University, Col. of Medicine, Physiol., Seoul, Korea, Republic of

Abstract: Spinal cord injury leads to abnormal sensation and motor deficit below the level of lesion site that is caused by loss of myelination and cavity formation in the injured epicenter. Spinal cord is lipid-rich tissue owing to myelin sheath. Thus, lipid metabolism is important to regulate functions of the spinal cord. After spinal cord injury, inflammatory mediators such as eicosanoids are released and act as peroxisome proliferators that activate peroxisome proliferator activated receptors (PPARs), which play a key role in lipid metabolism and cellular differentiation. PPARs are classified into three isoforms (α, β/δ, γ) in the spinal cord. However, changing of their protein expression in the spinal cord after traumatic injury has not been demonstrated. Male Sprague-Dawley rats were anesthetized with ketamine/rompun mixture (1:4). Ten grams weight dropped from 6.25, 12.5 and 50 mm height onto the spinal cord of the 10^{th} thoracic vertebra level in rats after laminectomy using NYU device. We examined protein expression of PPAR-α, β/δ and γ in rostral, caudal, injured epicenter and L4-5 of the spinal cord with time after injury (6, 12, 24h, 3d, 1, 3 and 5 weeks). Patterns of PPAR-γ expression were similar among all of injured groups (6.25, 12.5 and 50 mm groups). PPAR-γ expressions were excessively increased from 6 hours and were maintained until 3 days after injury. After then, those were gradually returned to basal level. Expression of PPAR-γ was the greatest in the epicenter. Changing of PPAR-γ expression was spread around region, especially caudal direction that related to injury severity. Patterns of PPAR- β/δ expression were similar in both 6.25 and 12.5 mm groups, but this was appeared different pattern in 50 mm group. Expression of PPAR-β/δ in the caudal region was increased from 6 hours and was gradually increased over time after injury. In epicenter and rostral region, those were appeared from 3 days after injury. PPAR-α expression was increased until 3 days and was decreased from 1 week after injury at epicenter in a 6.25 mm group, while this was gradually decreased from 6 hours in a 50 mm group. However,

PPAR-α expression was not appeared relevant to difference of region, and was almost not changed at L4-5 region in all of injured groups. These results suggest that PPAR-γ is associated with pathophysiological mechanisms in the early phase, and PPAR-β/δ is associated with those mechanisms in the late phase after spinal cord injury. Expression of PPAR-γ and PPAR- β/δ seems to be related to the severity of injury. The present data serve as a reference for further study, which modulates neuroinflammation or myelination after spinal cord injury.

Abstract: Multiple efforts are currently underway to promote regeneration of long tract axons following spinal cord injury (SCI), specifically the corticospinal tract (CST). To understand the translational potential of emerging therapies for CST regeneration, parallel studies in small and large animal models are necessary. Here, we perform large-scale data-driven analytics coupled with stereological analysis of CST fiber density in rat and monkey SCI models to help identify multivariate features of CST-related functional recovery and assess species-specificity of these effects. Datasets for previously published studies in rats (Rattus norvegicus, n=13) and monkeys (Macaca mulatta, n=10) with cervical SCI and CST labeling were extracted from the Visualized Syndromic Information and Outcomes for Neurotrauma-SCI (VISION-SCI) database. Rats received graded bilateral cervical SCI (Infinite Horizon impactor severity 200 or 250 kilodyne) at cervical level 5-8 (C5-C8), and were tested for forelimb locomotion, gripping function; tissue sparing and CST fibers were quantified. Monkeys received unilateral hemisections at C7-C8, followed by monitoring for recovery in the activity chair and open-field, and quantification of tissue sparing and CST fibers. Stereological quantification was used to count labeled CST fibers in the spinal cord in both species. Syndromic analysis was performed using principal component analysis (PCA) to map species-specific multivariate patterns of functional recovery and CST sparing. A standardized dataset was created to combine matched measures (e.g. locomotion, gripping) and a separate PCA was performed to identify conserved patterns that may translate between species. Preliminary findings suggest the CST in rats contributes more to gripping function than general locomotion, whereas the CST in monkeys is involved in multiple skilled reaching, gripping and exercise cage tasks. A conserved syndromic measure was identified between rats and monkeys that were sensitive to injury, but not the effect of species. These results provide a proof-of-concept illustration that data-driven multivariate analytics can help identify translational outcome features to accelerate comparisons across species. However additional subjects, outcome measures, and injury paradigms in both species need to be assessed for cross-validation of these preliminary patterns.

Title: Magnetic spinal cord pulsation-cancelation injection system for region-specific vector and cell delivery: A preclinical study in naïve and spinally-injured minipigs

Authors: *M. MARSALA[1,2], S. JUHAS[2], M. HRUSKA PLOCHAN[1], D. DOLEZALOVA[1], A. MIYANOHARA[1], S. MARSALA[1], J. JUHASOVA[2], J. MOTLIK[2]
[1]Dept. of Anesthesiol., UCSD, La Jolla, CA; [2]Inst. of Animal Physiol. and Genet., Libechov, Czech Republic

Abstract: Background: Development of a simple, safe and easily accessible spinal injection system is critical for a successful transition of cell-replacement-based and gene therapy-based therapies into clinical practice. One of the critical limitations in performing a safe spinal cell/vector delivery is our ability to effectively eliminate a spinal cord pulsation during spinal injections, thus increasing the risk of secondary spinal cord injury. Here we characterize a safety profile of spinal magnetic injection system which is simple to use, can be effectively coupled with currently existing XYZ manipulators and effectively eliminates spinal cord pulsation effect during spinal injection. Methods: A spinal magnetic injection system was constructed by utilizing the 30G injection needle anchored between two expulsing magnetic field, thus permitting the generation of a pulsation-cancellation effect in spinally placed needle. The safety of the injection system was tested in : i) naïve non-injured minipigs and, ii) in previously L3 spinal segment-injured minipigs at 2 months after injury. After dorsal L2-L3 laminectomy animals (N=3 in each group) received spinal parenchymal injection of human embryonic stem cell derived neural precursors or human fetal spinal cord derived stem cells. After cell grafting animals survived for 4-6 weeks while being continuously immunosuppressed with Prograf (0.025/kg/12hrs). The presence of grafted cell was validated by immunofluorescence staining of transverse spinal cord sections with human-specific (hNUMA, HO14, hNSE, hSYN) and non-specific (DCX, MAP2, Chat) antibodies and analyzed with confocal microscopy. Results: In all animals a consistent presence of grafted cells in the targeted central gray matter was seen. Individual grafts were readily identified by using human-specific nuclear (hNUMA) staining. At 6 weeks after grafting an extensive axo-dendritic sprouting was seen in segments rostral and caudal the cell injection core. No injection-related injury (such as necrotic cavities, tissue displacement) was seen in any animal. A comparable cell engraftment was seen in both naïve and L3-segment-injured animals. Conclusion: These data indicate that this spinal injection system can effectively and safely be used for spinal delivery of cells or any injectable substances (vectors, drugs) in large animals and in human.

Title: Gastrointestinal peptide dysregulation in acute spinal cord injury

Authors: M. C. P. GERAEDTS, M. S. MCLEAN, *G. M. HOLMES
Neural & Behavioral Sci., Penn State Univ. Col. of Med., Hershey, PA

Abstract: Gastrointestinal (GI) dysfunction is a major physical and psychological burden for spinal cord injury (SCI) patients. We have shown that our model of experimental high-thoracic spinal cord injury (T3-SCI) mirrors the GI clinical presentation of neurotrauma patients, whereby T3-SCI shows diminished gastric emptying and dysmotility. The T3-SCI induced gastroparesis is due, in part, to an impaired vagally-mediated response to GI peptides. However, it is unknown whether nutrient-mediated peptide release from the GI tract is altered post-injury. We measured barrier integrity and GI peptide release from duodenal, ileal, and colonic explants of SCI and control rats at 1-day, 3-days, and 7-days post-surgery. Isolated intestinal explants were mounted in Ussing chambers, permitting measurement of transepithelial resistance (TER) and short-circuit current (ISC), and hormone secretion with or without apical glucose stimulation. 2 Hours after glucose stimulation, samples from the basolateral chamber where taken and stored at -80C until cholecystokinin (CCK), glucagon-like peptide 1 (GLP-1), and peptide YY (PYY) were measured using ELISA assays. Prior to glucose stimulation, T3-SCI had no effect on TER measurements, but the ISC was decreased in T3-SCI animals at 3-days and 7-days post injury. This suggests that SCI does not change the integrity or passive transport of intestinal tissue, but it decreases active ion transport through the tissue. CCK secretion from duodenal tissue was increased beginning 1-day post-injury in T3-SCI animals compared to control animals. GLP-1 release from ileum was increased in T3-SCI animals 7-days post injury, whereas in colon tissue there was no differences between groups. PYY secretion from ileum was increased in T3-SCI animals 3 and 7 days post injury, and also here, there was no difference in PYY secretion from colon tissue between groups. Surprisingly, apical stimulation of ileal and colonic tissue with glucose resulted in a decrease in TER and rapid tissue death in T3-SCI animals. Also, glucose stimulation had no stimulatory effect on GI peptide release from intestinal tissue isolated from control animals, but it decreased peptide secretion from intestinal tissue isolated from T3-SCI animals. We conclude that T3-SCI affects GI peptide secretion in several areas of the intestine. The basal peptide

secretion is elevated before glucose challenge, but after glucose challenge, the peptide secretion decreases in injured animals. Surprisingly, the control operated animals do not respond to the glucose challenge, suggesting that the impact of vertebral laminectomy may also play a role in the secretion of GI peptides.

Title: Metabolomic profile of cerebrospinal fluid and serum from acutely injured spinal cord patients

Authors: ***F. STREIJGER**[1], Y. WU[2], J.-M. MAC-THIONG[3], S. PARENT[3], S. CHRISTIE[4], C. BAILEY[5], L. LI[2], B. K. KWON[1,6]

Ctr., London, ON, Canada; [6]Dept. of Orthopaedics, Combined Neurosurgical and Orthopaedics Spine Program (CNOSP), Vancouver, BC, Canada

Abstract: Background: Therapeutic development for spinal cord injury (SCI) is severely hindered by the difficulty in conducting clinical trials, which to date have relied solely on functional outcome measures for patient enrollment, stratification, and evaluation. Not only are these measures insensitive, but also are impossible to perform in many SCI patients. Biological biomarkers that accurately classify injury severity and predict neurologic outcome can offer a paradigm shift in the way SCI clinical trials are conducted. **Objectives:** The objectives of this study are to: 1) characterize the temporal metabolomic profile of cerebrospinal fluid (CSF) and blood after SCI, and 2) determine the relationship between CSF and serum profiles to identify serum biomarkers that reflect the changes within the CSF. **Methods:** Matched blood and CSF samples were used from a unique Canadian prospective multi-center trial in which CSF and blood from acute SCI patients are being collected and banked (Canadian Multicenter CSF Pressure and Biomarker Study, or "CAMPER"). Importantly, these patients are recruited prospectively and thus the biological data can be matched with well-documented clinical

outcomes. We performed an untargeted metabolomic analysis using high-performance isotope labeling liquid chromatography mass spectrometry (LC-MS). **Results:** Analysis of the LC-MS data revealed over 900 unique metabolites within the blood and CSF. For many metabolites, the relative intensity was higher for CSF samples collected at later time points after injury (48 compared to 24 hours). We are currently in the process of examining CSF and serum samples collected from SCI patients with different AIS grades. Chemometric and statistical analyses will determine which key metabolic pathways or networks are significantly altered in SCI, the extent of the correlation between network changes and SCI pathology, and identify potential biomarker candidates within the metabolite profiles. **Conclusion:** Metabolomic analysis of CSF and serum will further our understanding of the pathophysiology of SCI and potentially lead to the identification of reliable biomarkers for SCI. As trauma to the spinal cord is most directly reflected in the surrounding CSF, a comparison between blood and CSF is particularly valuable from a clinical perspective to interpret which changes within blood are due specifically to the SCI.

Abstract: Introduction: Currently, there are no effective treatments available for patients with spinal cord injury (SCI). There is an urgent need for both the scientific development and clinical validation of novel therapies for acute SCI. Biomarkers would potentially provide a more

objective, biological basis with which to stratify injury severity than our current functional outcome measures. Furthermore, establishing biological markers that can be evaluated after SCI, and subsequent therapeutic interventions in both animal models and human patients would provide important guidance for the translation of novel treatments. Objective: The objective of this study is to perform genome wide analysis of microRNAs in pig blood and CSF and determine their utility as biomarkers for SCI. Our interest in microRNAs stems from their specific spatial, temporal and cellular-level expression, as well as their stability within blood (making it possible for blood samples to be utilized in order to measure markers specific to the injured central nervous system). Method: Female Yorkshire pigs underwent a T10 spinal cord injury using a weight drop contusion impactor followed by compression for 5 minutes. CSF and serum samples were obtained daily over a period of 7 days. Extracellular miRNAs were isolated and sequenced using the Illumina MiSeq system and the generated data was aligned using miRDeep2 and tested for differential expression with DESeq software. Results: Using next generation sequencing, we were able to detect the expression of 719 miRNAs in pig samples of CSF or serum at 24-hours post injury. Amongst the most highly expressed miRNAs in pigs were miR-486, miR-26, miR-181, miR-10, and miR-92. MiR-486 has been shown to play a significant role in regulating SCI pathology. A validated target of miR-486 is NeuroD6, a protein important for neuronal differentiation and oxidative stress response. MiR-26 has been identified as an astrocytic miRNA; miR-181 is a regulator of pro-inflammatory mRNAs such as tumor necrosis factor and IL-1β and miR-92 has been identified as a diagnostic biomarker for severe brain injury. Conclusion: Initial sequencing data confirms the presence of miRNA implicated in CNS trauma in CSF and serum sample collected from paralyzed pigs. This preclinical study in our pig model of SCI has provided the rationale for moving forward with further studies using extremely valuable CSF and serum samples collected from human patients with SCI. By establishing these biomarkers in the pig and determining similarities with human SCI, we foresee generating a panel of markers that can be used both preclinically and clinically to evaluate treatment response.

Title: Characterization of peripheral blood mononuclear cells in chronic spinal cord injury subjects

Authors: *O. BLOOM[1], A. PAPATHEODOROU[2], E. NIKULINA[2], A. STEIN[3]
[1]Feinstein Institute, Hofstra North Shore LIJ Sch. of Med., MANHASSET, NY; [2]Feinstein Inst. for Med. Res., Manhasset, NY; [3]Physical Med. and Rehabil., Hofstra North Shore LIJ Sch. of Med., Manhasset, NY

Abstract: Introduction: Traumatic spinal cord injury (SCI) affects more than 12,000 Americans annually. Acutely after traumatic SCI, intraspinal and peripheral inflammation exacerbates the primary injury zone and promotes secondary tissue damage. Less is known about inflammation in the chronic phase of SCI, but long-lasting changes in local and systemic immune function have been proposed to impact functional outcomes and secondary complications of living with SCI. For example, we recently discovered that the pro-inflammatory cytokine macrophage migration inhibitory factor (MIF) and other inflammatory mediators are elevated in the circulation of chronic SCI subjects (Stein et al Archives of Physical Medicine and Rehabilitation, 2013). Here, we are examining the hypothesis that chronic SCI subjects have additional immune system changes, including alterations in the distribution or activation of peripheral blood mononuclear cells (PBMCs). To test this hypothesis, the objective of this study was to profile populations of circulating PBMC subsets in chronic SCI and age/gender matched uninjured subjects. Methods: This prospective, IRB-approved, observational pilot study of adult SCI subjects was performed in an academic medical center. "Chronic" SCI was defined as > than 1 year from initial injury. PBMCs were isolated from blood by Ficoll density gradient. Multicolor flow cytometric analysis of PBMCs was performed to examine the number and percentage of B cells, T cells, and Treg cells. Results: Uninjured (N=4) and SCI (N=6) subjects included 1 female in each group. Uninjured and SCI subjects were of similar ages (mean±sem, range): (55±5, 43-64 and 57±3, 45-64 years) ($P<0.61$). Mechanisms of injury for SCI subjects were: Fall (n=2), Sports (n=4). SCI subjects had an ASIA Impairment Scale (AIS) grade A. In this small group of subjects, our initial analysis did not reveal any difference in the percentage of CD3-CD19+ B cells, CD3-CD19+CD27- naïve B cells, CD3+CD4+ T cells, CD3+CD8+ T cells, or CD4+CD25+ Treg cells. Studies are ongoing to examine these and more specific PBMC populations in additional subjects. Future studies will also examine potential alterations in the activation state or function of PBMC subsets in chronic SCI as compared to uninjured control subjects.

Title: In toto imaging of AAV-labeled axons after spinal cord injury using light sheet and confocal microscopy

Authors: *C. SODERBLOM, D.-H. LEE, P. TSOULFAS, J. K. LEE
Dept. of Neurosurgery, The Miami Project to Cure Paralysis, Univ. of Miami Miller Sch. of Med., Miami, FL

Abstract: Failure of axons to regenerate is the primary reason for paralysis after spinal cord injury (SCI). Thus, discovering mechanisms to promote axon regeneration has been an intense area of research. A technical challenge has been visualizing axon trajectory in the injured spinal cord that can provide clear origin-target information. Recent advances in tissue clearing methods have made it possible to overcome this hurdle, but all previous studies have been performed with transgenic mice in which the axons were prelabeled with green fluorescent protein (GFP). Thus, while these studies have provided a proof-of-concept, a more practical approach to investigating axon regeneration requires axon tracing. In this study, we labeled different axon tracts using adeno-associated viruses and performed tissue clearing to image the axons in toto using light sheet and confocal microscopy. Using mouse and rat models of SCI, our study demonstrates the promising potentials but also certain limitations in applying these methods to investigate axon regeneration.

Title: Detecting acute neuronal injury with diffusion MRI: A simulation study

Authors: *M. D. BUDDE
Neurosurg., Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Acute injury to axons and dendrites results in a systematic sequence of degeneration. The formation of focal enlargements and constrictions (i.e. beading) is thought to represent the earliest stage of Wallerian degeneration and is a nearly ubiquitous morphological feature of acute neuronal injury. Although the therapeutic implications of beading are unclear, beading represents a potential diagnostic and prognostic indicator of injury to the central nervous system. Beading is observed *in vitro* and *in vivo* experimental preparations in animal models, but a noninvasive method would have important clinical diagnostic implications. One advanced magnetic resonance imaging technique, diffusion tensor imaging (DTI), has been shown to be a sensitive marker of axonal and dendritic injury in numerous models of trauma and disease. However, DTI is not a specific marker of axonal injury in many situations, since it can be confounded by other tissue properties, such as multiple intersecting fiber tracts (i.e. "crossing-fibers"), or other pathologies, such as edema, inflammation, gliosis, and others. A novel diffusion MRI method, the double pulsed field gradient (dPFG), has been shown to be insensitive to the effects of crossing fibers and has the potential to specifically detect beading of axons and dendrites non-invasively with greater specificity than DTI. In this work, we simulated the DTI and dPFG experiments in geometrical models of normal and beaded axons in a variety of different fiber configurations. Whereas fractional anisotropy (FA), the most commonly used measure derived from DTI, is reduced in beaded axons, it is also reduced with edema and in crossing fibers. Thus, FA changes alone are ambiguous with respect to the underlying biology. On the other hand, a metric derived from the dPFG, eccentricity, is reduced as a consequence of beading, but is largely immune from edema and crossing fibers. Collectively, the results of the computational simulations demonstrate that the dPFG is a unique and specific marker of acute neuronal injury, which is likely to have important implications for clinical diagnosis in a variety of acute insults to the brain or spinal cord.

Title: Combined neurotrophin treatment promotes regeneration of multiple sensory modalities after dorsal rhizotomy

Authors: *L. KELAMANGALATH, X. TANG, Y.-J. SON, G. M. SMITH
Shriners hospitals Pediatric Res. Ctr., Temple Univ. school of Med., Philadelphia, PA

Abstract: Gene therapy offers a promising approach to provide neurotrophins at the injury site and thus enhance axonal regeneration after a nervous system injury. For investigating regeneration, we crush the L4/L5 dorsal roots and inject lentivirus into the spinal cord at the dorsal root entry zone (DREZ) of L4/L5 nerves immediately after injury. We have previously shown lentiviral expression of NGF and artemin at the dorsal root entry zone produces robust regeneration of calcitonin gene related peptide positive (CGRP+) axons. Artemin, but not NGF, produced a modest but significant regeneration of nonpeptidergic isolectin B4 positive (IB4+) axons. Surprisingly, artemin did not support regeneration of myelinated sensory afferents, as previously reported. In this study, we expressed GDNF or GDNF/Artemin at the DREZ using the lentiviral expression system. GDNF did not elicit regeneration of CGRP+ axons, but produced a significant regeneration of IB4+ axons and enhanced the regeneration of cholera toxin-B labeled myelinated sensory afferents across the DREZ. Combinatorial expression of GDNF and artemin showed further enhanced regeneration of IB4+ and CTB labeled myelinated axons, demonstrating a positive cooperativity between these factors. Thus, using a combination of lentiGDNF and lentiartemin, we were able to reconstruct multiple sensory axonal modalities anatomically. Physiologically, as the IB4+ axons respond to the high threshold input, only 50% of the GDNF group showed a return of thermal nociception. In contrast, the anatomical

regeneration of CTB labeled axons did not support any functional restoration, and appeared to remain within the dorsal horn. We evaluated the return of paw pressure sensation and proprioception using Ugo-Basil Analgesymeter and grid walk test and found no improvement. In a separate experiment, we were able to enhance regeneration of myelinated sensory afferents into lamina VIII by overexpressing Rheb within L4/L5 DRG neurons and concomitantly expressing neurotrophin NT3 at the DREZ. Rheb alone in the DRG did not induce any regeneration while expression of NT3 alone in the DREZ produced a superficial regeneration of these axons. Altogether, our data reinforces the importance of combinatorial approaches in enhancing CNS axonal regeneration.

Title: The effect of spinal cord injury on bladder-specific nodose ganglion neurons

Authors: *A. N. HERRITY[1], J. C. PETRUSKA[1,2], D. P. STIRLING[2,3], C. H. HUBSCHER[1]
[1]Anat. Sci. and Neurobio., [2]Neurolog. Surgery, [3]Microbiology and Immunol., Univ. of Louisville, Louisville, KY

Abstract: We have previously demonstrated in male rats anatomical evidence that the vagus nerve provides afferent innervation to the urinary bladder and that the extent of the vagal supply was similar to parasympathetic innervation from spinal sources (L6 DRG). The equivalent proportion of innervation to the bladder from both vagal and spinal sources may signify separate functional roles for these afferent fibers. To better understand the functional significance of bladder-specific neurons in the nodose ganglion (NG, sensory cell bodies of the vagus nerve), we examined their immunohistochemical profile in the naïve and chronically injured state using a complete transection model. We also examined spinal phenotypic differences in the L6 DRG as a comparison with the NG. In male Wistar rats, a subset of animals received a complete spinal cord transection at the level of T8. After a period of 5 weeks, the retrograde tracer, Fast DiI, was injected into the lining of the bladder and given 10 days for transport to the NG and DRG. The

NG and L6 DRG were processed for multi-label immunohistochemical analysis for the expression of P2X3 receptors and IB4 binding. Initial findings of the NG demonstrated, in the transected animals, a significant increase in the number of neurons expressing P2X3 and a significant decrease in the number of neurons binding IB4 compared to naïve controls. These results suggest both an inflammatory and stress response respectively may be occurring in NG neurons. In these two distinct NG subsets, we found that more than half of the neurons received bladder input in each group. Additionally, the NG demonstrated significantly greater bladder-specific/IB4+ neurons compared to the L6 DRG suggesting two distinct neurochemical profiles exist for visceral afferents between vagal and spinal sources. The high prevalence of bladder-specific neurons in the P2X3 and IB4 subsets demonstrates potential bladder transduction mechanisms through the vagus and its likely role in visceral nociceptive processing.

Title: Effects of repetitive transcranial magnetic stimulation on the functional recovery of patients with central cord syndrome

Authors: *J. HYUN[1,2,3], T. KIM[1], S. KIM[1]
[1]Rehabil. Med., Dankook Univ. Col. of Med., Cheonan, Korea, Republic of; [2]Dept. of Nanobiomedical Sci. & BK21 PLUS NBM Res. Ctr. for Regenerative Med., [3]Inst. of Tissue Regeneration Engin. (ITREN), Dankook Univ., Cheonan, Korea, Republic of

Abstract: The aim of this study was to delineate the effect of repetitive transcranial magnetic stimulation (rTMS) on the functional recovery of upper extremity in patients with central cord syndrome (CCS). Fourteen CCS patients were treated high frequency (20Hz) rTMS over the motor cortex for 5 days. All patients also received conventional occupational therapy during

rTMS treated period. Clinical evaluations including neurological assessment using International Standard for Neurological Classification of Spinal Cord Injury (ISNCSCI), hand functional assessments using the Jebsen hand function test and O'conner finger dexterity test were performed before rTMS initially and followed up 1 month after rTMS treatment. Diffusion tensor imaging and tractography of cervical spinal cord were also performed, and fractional anisotrophy (FA), apparent diffusion coefficient (ADC), imaginary crossing fiber numbers and the connection rate of fiber tracts were obtained in each patient. The motor score of upper extremity was improved during follow-up period of all treated side (100%) and more than half of non-treated side (75%) of CCS patients. The writing score of Jebsen hand function test were significantly increased more in treated side compared with non-treated side 1 month after rTMS treatment. The initial FA values of injured cervical spinal cord and the connection rate crossing injured cervical spinal cord in cervical spinal cord were correlated with the clinical motor score of upper extremities. There were no adverse effects during rTMS therapy and follow-up period. We tried to perform high frequency rTMS to CCS patients for the first time, and rTMS might enhance functional restoration, especially fine motor task performance of the upper extremity in CCS patients without any adverse effect.

Title: An animal model for spinal cord concussion and repeated injury

Authors: ***Y. JIN**, J. BOUYER, C. HAAS, I. FISCHER
Drexel Univ. Col. of Medicine, Dept of Neurobio. and Anat., PHILADELPHIA, PA

Abstract: Spinal cord concussions, which occur during vehicular accidents, falls, and sport activity, are characterized by a transient loss of motor and sensory function that usually resolves without permanent deficits. Unlike brain concussions, they have received little attention despite the potential for repeated injury leading to permanent neurological sequelae. Importantly, there are no models of spinal concussion to study the anatomical and functional sequelae of single or

repeated injury, and consequently, there is poor understanding of the short- and long-term consequences of such injuries. We have first examined the established mild thoracic contusion model utilizing the NYU impactor, but found that the severity of the injury was not compatible with the clinical presentation of spinal concussion. We subsequently developed a new model that shows transient deficits with minimal anatomical damage and used the model to study concussion and repeated injury. Rats received a very mild (50kdyn, IH impactor) contusion at C5 and were separated into two groups three weeks after the initial injury - C1, which received a second, sham surgery, and C2, which received a second injury at the same site. Animals received weekly behavioral tests - BBB, CatWalk, cylinder, and Von Frey. Analysis of locomotor activity by BBB demonstrated rapid recovery to near-normal function by 1wk after the first and second injury, which was confirmed using the more detailed CatWalk analysis. The cylinder test showed that single contusion did not induce significant deficits of the affected limb, but that repeated injury resulted in significant alteration in paw preference, with animals favoring the unaffected limb. Intriguingly, Von Frey analysis demonstrated an increased sensory sensitivity in the contralateral hindlimb in the C2 group vs. the C1 group. Anatomical analyses revealed that while the lesion volume of both groups was minimal, the area of spared white matter in the C2 group was significantly reduced 1-2 mm rostral to the lesion epicenter. Reactive astrocytes were present in both groups, with the majority found around the lesion epicenter in the C1 group, whereas the C2 group demonstrated increased reactive astrocytes extending 1mm caudal to the lesion epicenter. Macrophages accumulated within the injured, ipsilateral spinal cord, with significant increases 2-3mm rostral to the epicenter in the C2 group. Our model is designed to represent the clinical presentation of spinal cord concussion and highlight the susceptibility and functional sequelae of repeated injury. Future experiment will examine the temporal and spatial windows of vulnerability for repeated injuries.

Title: Lewis, Fischer 344 and Sprague-Dawley rats display differences in lipid peroxidation, motor recovery and neuronal survival after spinal cord injury

Authors: *H. MESTRE[1], M. RAMIREZ[2], E. GARCIA[1,2], S. MARTIÑÓN[2], Y. CRUZ[1], M. G. CAMPOS[2], A. IBARRA[1,2]
[1]Neuroimmunology, Univ. Anahuac Mexico Norte, Huixquilucan, Mexico; [2]Neuroimmunology, Proyecto CAMINA, Mexico City, Mexico

Abstract: Lewis (LW), Fischer 344 (F344) and Sprague-Dawley (SPD) are the rat strains that are most commonly used for spinal cord injury (SCI) research. However, these strains have subtle differences in physiological and immune responses. These variations could alter the morphological and functional recovery after SCI among strains. For this purpose we decided to evaluate one of the most detrimental events after SCI, lipid peroxidation (LP) and its effect on rubrospinal neuron (RSN) survival and functional locomotor recovery. Our study consisted of three experiments which all had three groups (LW, F344, and SPD; 78 animals): (1) the three strains (n = 8/group) were subjected to laminectomy of the T9 vertebrae (sham surgery) and 72 hrs after by-products of LP were quantified; (2) strains (n = 8/group) sustained a moderate spinal cord contusion at T9 (MASCIS impactor) and after 72 hrs, LP was quantified; (3) the three strains (n = 10/group) were subjected to SCI and were evaluated weekly using the BBB locomotor scale for 60 days. At the end of the follow-up period, subjects were randomly selected from each group (n = 4/group) for RSN survival analysis. Although LP-products were barely detected in sham-operated rats, F344 and SPD presented lower LP levels as compared to LW ones. The levels of LP after SCI in LW rats were significantly higher [406.81 ± 43.5 fluorescence units/g of tissue; mean ± standard deviation (SD)] in comparison with either F344 (233.69 ± 41.98) or SPD rats (220.40 ± 14.20; $P < 0.01$, one-way ANOVA followed by Tukey's test). The BBB score of LW rats was also significantly lower (3.2 ± 0.3; mean ± SD) than the one demonstrated by F344 (4.9 ± 0.8) or SPD animals (5.1 ± 0.7; $P < 0.001$, repeated measure one-way ANOVA followed by Bonferroni's test). RSNs were barely detected in LW rats; they showed a mean of 12 ± 5 surviving cells (% from sham-operated rats: 5.1 ± 2; mean ± SD), while F344 and SPD showed 30 ± 7 (%: 10.4 ± 2) and 38 ± 5 (%: 12.6 ± 4) respectively. The present findings are of relevant interest to SCI research since strain differences must be considered for future investigations, especially those evaluating LP or motor recovery after SCI.

Title: The role of mTOR and STAT3 in the intrinsic growth of rubrospinal neurons

Authors: *K. M. KEEFE, Y. LIU, G. SMITH
Neurosci., Temple Univ., Philadelphia, PA

Abstract: It is well known that regeneration in the mature central nervous system (CNS) is rare. In order to repair damage with sufficient vigor to re-establish functional connections, the neuronal cell body must be able to turn on genes needed to form new growth cones, produce proteins and growth factors, and elongate and repair damaged axons. Adult CNS neurons are particularly resistant to this type of activation, but there is evidence to show that these 'growth programs' can be stimulated in the right circumstances. In this study, we explore upregulation of growth programs in rubrospinal neurons via stimulation of the mammalian target of rapamycin (mTOR) and signal transducer and activator of transcription 3 (STAT3) pathways. It is thought that directly priming neurons with a transcriptional activator such as STAT3 combined with induction of protein translation mediated though mTOR activation will produce a robustly active growth state. This is accomplished via injection of adeno-associated viruses (AAVs) encoding ras homolog enriched in brain (AAV-Rheb), a direct positive regulator of mTOR, and AAV-STAT3, unilaterally into the red nucleus of a female rat, followed by a unilateral hemisection of the thoracic spinal cord level 8 contralateral to the injection site. At 5 weeks post-injury, we found that animals injected with AAV-Rheb/AAV-STAT3 show greater incidence of regrowth such as sprouting, abnormal axon morphology, and growth into and beyond the lesion site when compared to controls injected with AAV-GFP. This study highlights the importance of mTOR and STAT3 in axonal growth of the rubrospinal tract after injury.

Title: Effect of the ketogenic diet on expression of anti-inflammatory genes in a rodent model of SCI

Authors: *X. WU[1], O. JANG[1], J. ZHU[1], J. LIU[1], W. TETZLAFF[1,2], F. STREIJGER[1]
[1]ICORD, Vancouver, BC, Canada; [2]Zoology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Introduction: Recently, we demonstrated in an animal model of SCI that a low carbohydrate, high fat ketogenic diet (KD), starting 4 hours following injury improves both gross and fine forelimb function and enhanced neuroprotection. Importantly, after returning to a standard diet after 12 weeks of KD treatment, the improved forelimb function remained stable. Although this study emphasizes an important effect of food on functional recovery after SCI, further work is necessary to determine the mechanisms of action. As the underlying mechanisms KD become better understood, it will be possible to develop alternative strategies that produce similar or even improved therapeutic effects and could potentially have significant impact on improving thewellness of individuals living with SCI. **Objectives**: The objective of this study is to determine the temporal anti-inflammatory effects of KD using a rat model of SCI. **Methods**: To test study this, a cervical hemicontusion injury model in rats was used. Starting 4 hours after SCI, animals were fed either a regular carbohydrate-based rodent diet, or 2) a KD diet with ratio of fat to carbohydrate and protein of 3:1. To examine the effect of KD on inflammation, we used microarray methods to examine gene expression 2 days, 7 days, and 6 weeks after SCI. **Results**: Microarray analysis showed that many inflammation-related genes were robustly changed in the cervical spinal cord of KD treated animals at 2 days, 7 days and 6 weeks after injury. Notably, the expression changes of genes involved in inflammation were largest at 6 week post-injury. Among the 152 genes, 23.0% (35/152) of them encode protein associated with inflammatory response and 15.1%(23/152) with immune cell trafficking. Immunohistochemistry and western blotting techniques are currently being performed to confirm the microarray data. **Conclusion**: Our data provide some insights into the complex cascade of cellular changes in the spinal cord induced by KD, some of which may contribute to its protective effect after SCI. KD treatment of injured rats result in prominent changes in genes encoding proteins involved in inflammatory signal pathways. Hence regulation of inflammatory response could be one of the principal mechanisms of KD-induced neuroprotection following SCI.

Title: Bilateral contusion-compression model of incomplete traumatic cervical spinal cord injury

Authors: *N. FORGIONE[1], S. K. KARADIMAS[1,3], W. FOLTZ[4,2], K. SATKUNENDRARAJAH[1], A. LIP[3], M. G. FEHLINGS[1,3]

Abstract: Approximately two thirds of traumatic spinal cord injuries (SCIs) result in incomplete lesions; the majority of these injuries occur in the cervical spinal cord causing devastating neurological impairments. Despite a defined need, we lack a clinically relevant injury model that replicates the pathomechanisms of this injury, and that can be used to test potential therapies. To address this key knowledge gap, we characterized a contusion-compression model in rats that generates a bilateral, incomplete injury. We described the effects of moderate (18 gram) clip-compression injury at cervical level C6 over an 8-week recovery period. First, we quantitatively assessed the effects of injury on gray and white matter sparing, lesional tissue, and cavity formation at 2, 4, 6 and 8 weeks post-injury. Next, magnetization transfer (MT) and T2-weighted magnetic resonance imaging (MRI) were used to analyze lesion dynamics *in vivo*. Our next goal was to assess neurobehavioral recovery in C6 injured rats. We used BBB, Catwalk, and grip strength to test forelimb and hindlimb motor function. Overall, these analyses showed that while motor function was significantly reduced in injured animals, there was sparing and recovery. Sensory evoked potentials (SEPs) recorded from the forelimb demonstrated decreased amplitude and increased latency at 8 weeks post-injury. Hoffman (H) -reflex recorded from the hindlimb was indicative of increased spasticity, thus recapitulating below-level spasticity seen in clinical SCI. The sparing of motor function accompanied by improvements over time mimic the symptoms seen in humans with incomplete cSCI. Therefore we have developed a clinically relevant model of cSCI that will contribute to improved success in the translation of putative therapies.

Title: Identification of genes related to ketogenic diet-induced beneficial functional and neuroprotective effects following SCI

Authors: *W. TETZLAFF[1,2], J. ZHU[2], S. CEN[2], J. LIU[2], A. HAEGERT[3], S. LE BIHAN[3], F. STREIJGER[2]
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Intl. Collaboration On Repair Discoveries (ICORD), UBC, Vancouver, BC, Canada; [3]Lab. for Advanced Genome Analysis, Vancouver Prostate Ctr., Vancouver, BC, Canada

Abstract: Introduction: The current dietary recommendations for the management of spinal cord injury (SCI) focus mostly on food that has high carbohydrate and low fat content. However, data from our own lab suggest that such carbohydrate-based diets may actual dampen neurological outcome following SCI. Contrary to our current clinical practice, we reported that feeding a low carbohydrate, high fat diet, a so-called ketogenic diet (KD), improved reaching ability that involves fine manipulation of the distal muscles of the digits and supination. Furthermore, we initiated KD not until 4 hours after injury and this time window of intervention differs from the majority of drug treatments for SCI, which have been studied with only little to no delay, which is not realistic in the overwhelming majority of acute SCI patients. **Objective:** As of today, the mechanisms of the beneficial effects of KD following in SCI are unknown. Therefore, the goal of this study is to identify differentially expressed genes that may underlie the KD-induced functional and neuroprotective effects using micro-array techniques. **Methods:** To identify the effects of KD on the overall pattern of mRNA expression after acute SCI, we collected tissue from rats injured with the Infinite Horizon spinal cord impactor at the C5 level. SCI rats were treated with either SD or KD for 48 hours, 7 days or 6 weeks. 200 ng of total RNA was used and labeled using the Low Input Quick Amp Labeling Kit. Gene expression profiles were analyzed using direct hybridization assay (Illumina). Ingenuity Pathway Analysis software was used to identify molecular pathways and networks. **Results:** KD affects the gene expression of many astrocyte and endothelium-derived vasoactive mediators such as Endothelin Converting Enzyme (ECE), the highly sensitive, vasodilatory PGE2 receptor and cytochrome P450 monooxygenases (CYP2b19). Furthermore, we observed downregulation of phospholipase A2 (PLA2G4E) and prostaglandin receptors (PTGER1 & PTGFR) in the spinal cord of KD treated

SCI-rats, genes that have a diversity of biological functions. These results prompted us to analyze the effects of these genes in KD-induced beneficial effects. Selected RT-PCR and western blotting confirmations are currently being performed and will be presented. **Conclusion:** Overall, the results of our study provide an initial picture of the molecular mechanisms. As the underlying mechanisms of dietary approaches such as the ketogenic diet become better understood, it will be possible to develop alternative strategies that produce similar or even improved therapeutic effects and could potentially have significant impact on neurological outcome following acute SCI.

Title: The relevance of hyaluronidase-4 and astrocytes in a rat spinal cord hemisection model

Authors: *Y. SHIMIZU[1], T. OKUDA[1], N. KAWAHARA[1], N. KATO[2], Y. ISHIGAKI[3], T. MATSUMOTO[1]
[1]Orthopaedic Surgery, [2]Physiol., [3]Med. Res. Inst., Kanazawa Med. Univ., Uchinada, Ishikawa, Japan

Abstract: [Purpose] Chondroitin sulfate proteoglycans (CSPGs) are known as an axon reproduction inhibitor that is derived from the reactive astrocyte in the glial scar. Our previous study revealed that these CSPGs remain constant in the injured part in the rat spinal cord contusion model. In the hemisection model, by constrast, CSPGs expression reaches its peak 3 weeks after the hemisection and decreases thereafter. The Chondroitinase ABC (ChABC) of bacterial origin is known as exogenous digestive enzymes of CSPGs. CSPGs decrease when the ChABC is administered to the injured part of the spinal cord contusion model. The decline of CSPGs expression in a hemisection model may be attributed to a gradual expression of an endogenous enzyme with the chondroitinase activity. Hyaluronidase-4 (Hyal-4) is reported as a mammalian enzyme which specifically breaks down chondroitin sulfate (CS) containing GAG chains. Our data so far demonstrated a co-localization of reactive astrocytes and Hyal-4 in the region surrounding the site of CSPGs expression in the hemisection model, suggesting that

reactive astrocytes produce Hyal-4. Thus, this presentation aims at examining how Hyal-4-positive regions overlap with expression of CSPGs and the astrocyte marker GFAP. [Methods] Experiments were conducted in female Sprague-Dawley rats (10-week-old) with spinal cord hemisection. Frozen sections of the injured spinal cord were prepared after perfusion with 4% paraformaldehyde on day 4 or at 1, 2, 3, 4, 5 or 6 weeks post hemisection. Immunofluorescence studies were performed using the following primary antibodies: CS56 for CSPGs, anti-Hyal-4 antibody for Hyal-4 and anti GFAP antibody for astrocytes. The secondary antibodies were conjugated with Alexa 488 or Alexa 594. Images were acquired using BZ-9000(KEYENCE). [Results] The majority of the GFAP-positive area overlapped with the Hyal-4-positive region, and GFAP expression was located to a much lesser extent in the CS56-stained area near the injured site. Furthermore, some of the GFAP-expressing cells were Hyal-4-positive.[Conclusions] The data agreed with the previous finding that reactive astrocytes produce CSPGs. We also suggested that reactive astrocytes express Hyal-4. We propose that reactive astrocytes may fine-true the micro-enviroment around the injured site by regulating production of both CSPGs and its endogenous digesting enzyme Hyal-4 as well.

Title: Inter-regional intrinsic brain activity effects in pediatric spinal cord injury

Authors: *L. KRISA[1], M. MULCAHEY[1], D. MIDDLETON[2], F. MOHAMED[2], T. ZEFFIRO[3]
[1]Thomas Jefferson Univ., Philadelphia, PA; [2]Temple Univ., Philadelphia, PA; [3]Neurometrika, Potomac, MD

Abstract: Purpose: To evaluate cerebral inter-regional functional reorganization in children with different levels of spinal cord injury (SCI) using intrinsic activity connectivity measures. **Methods:** We measured changes in cerebral inter-regional correlation in six female and 12 male participants with SCI, average age 16.3 years, during two fMRI sessions gathered 2-48 hours apart. During each session participants were instructed to keep their eyes open while maintaining fixation. The resulting time series were processed to mitigate effects of head motion and other sources of physiological noise. After spatial normalization functional connectivity of selected sensorimotor regions were quantified using seed-voxel analysis in complete (AIS A) and incomplete (AIS B, C, and D) SCI participants. **Results:** We observed effects on inter-regional connectivity related to the level of SCI (paraplegia versus tetraplegia), with primary motor cortex on both sides showing increased coupling with extrastriate visual cortex with damage at cervical compared to thoracic levels. **Conclusion:** Inter-regional functional connectivity assessment is a practical and sensitive technique to characterize the cerebral effects of SCI in children. Inter-regional correlations of intrinsic cerebral activity reveal increased coupling in visual and motor cortical regions related to the level of damage.

Title: Spinal cord injury-induced plasticity in sensory nociceptive processing and autonomic function

Authors: K. K. MARTIN, D. J. NOBLE, S. HOCHMAN, *S. M. GARRAWAY
Physiol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Spinal cord injury (SCI) results in several devastating effects which typically include the impairment of sensory and autonomic function. For instance, both the development of pain and compromised respiratory function are critical consequences of SCI. Despite the prevalence of these maladaptive conditions, the underlying mechanisms are poorly understood. Also, although previous reports have suggested that there are parallels in impaired sensory and autonomic signaling, a thorough investigation into their interactions after SCI has not been

shown. To examine sensory-autonomic dysfunction after SCI, we used adult Long Evans rats with a T8 moderate contusion injury (IH Impactor, 150 kdyne) or sham surgery to compare SCI-induced plasticity in respiratory rate and induced pain responses. Beginning 24 hours after injury, we recorded respiratory rate and movement related behaviors using highly sensitive non-contact electric field sensors (EPIC, Plessey Semiconductors). Recordings were obtained before, during and after behavioral pain tests which included the measurement of hind-paw mechanical allodynia (withdrawal response to von Frey filaments), brush-induced at-level mechanical allodynia and nociceptive tail-flick latency. Because changes in respiratory rate represent a physiological autonomic response to pain, results of this study will provide an important integrative dimension to pain plasticity not typically studied after SCI. Preliminary results show that SCI rats have a higher basal respiratory rate that is maintained for several weeks after injury. Moreover, unlike sham rats, SCI rats increased their respiratory rates in response to mechanical stimulation, consistent with an observed mechanical allodynia. Studies are underway to further relate SCI-induced allodynia to changes in autonomic function, including heart rate and cardiorespiratory synchronization.

Title: The effect of intrapspinal microstimulation parameters on movement thresholds in normal and spinal cord-injured rats

Authors: *S. B. FROST[1], C. L. DUNHAM[2], S. BARBAY[2], D. W. MCNEAL[2], D. KRIZSAN-AGBAS[1], M. K. WINTER[3], D. J. GUGGENMOS[2], R. J. NUDO[2]
[1]Molec & Integrat Physiol, [2]Ctr. on Aging, [3]Kansas Intellectual and Developmental Disabilities Res. Ctr., Univ. Kansas Med. Ctr., KANSAS CITY, KS

Abstract: This study was conducted to determine the effect of various intraspinal microstimulation (ISMS) parameters on the minimum current required to evoke a visible joint movement (i.e., movement thresholds) in normal and spinal cord-injured (SCI) rats. Experiments were carried out in four adult, male, Fischer 344 rats using commercial laboratory equipment (*Tucker Davis Technologies*). Subjects consisted of two normal (uninjured) rats and two rats that had received a 250 kDyn contusion injury to the thoracic spinal cord at level T8-T9. SCI rats demonstrated a severe deficit after injury (BBB avg 10) and were recovered at least four weeks prior to the ISMS procedure. During this procedure, a silicon-based microelectrode array (*NeuroNexus Technologies*) with stimulus site impedance in the range of 120–140k at 1kHz was inserted into the spinal cord at the lumbar level. Each stimulus site position ranged from ~500–2,800μm below the surface of the posterior spinal cord, with the medio-lateral position ~250–1,500μm lateral to the midline. All electrophysiological experiments were conducted under ketamine anesthesia. Both monophasic (with passive discharge) and biphasic current pulses were used to determine the relative efficacy of each ISMS mode for evoking hindlimb movements. In each rat, movement thresholds were determined in at least 60 sites. The ISMS responses typically consisted of movements of the hip, knee, ankle or toes, with movement thresholds typically ranging from ~14–25μA. While monophasic anodic pulses resulted in slightly lower movement thresholds compared to monophasic cathodic pulses, there was no significant difference between these conditions. There was a trend toward lower thresholds with higher frequencies using anodic pulses, but these differences were also not significant. In a normal rat, movement thresholds using biphasic cathodic leading stimulation were significantly lower when using a 13 or 5 pulse train compared to single pulse train. However, even when using a single pulse, the movement thresholds averaged only 16 +/- 3.2μA. Average hindlimb biphasic stimulation movement thresholds were 15.7 +/- 1.1 μA and 18.7 +/- 0.9 μA in a normal and SCI rat, respectively. While movement thresholds in the SCI rat were statistically significantly higher, the actual difference was quite small (< 3μA). These results demonstrate that ISMS current thresholds for evoking hindlimb movement remain low in a rat model of spinal cord injury.

Title: Delivery of autologous neurotrophin-producing fibroblasts promotes locomotion in the chronic spinal cat

Authors: *A. J. KRUPKA[1], J. DASHKOVA[2], I. FISCHER[1], M. A. LEMAY[2]
[1]Neurobio. & Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Bioengineering, Temple Univ., Philadelphia, PA

Abstract: Adult cats show limited locomotor capabilities following spinal transection. With body-weight support training, the animals recover stepping ability with weight-bearing plantar foot placement. We previously found that delivery of neurotrophins via xenografts of genetically modified rat fibroblasts promotes a similar motor recovery without training. Similar results were obtained in rodents using direct injection of viruses into the cord. Viral delivery raises clinical concerns regarding recombinant genetics, and xeno/allografts require immunosuppression that increases cancer risks. Furthermore, none of these studies has investigated the effects of delayed onset of neurotrophin delivery on recovery. Our study utilized autologous fibroblasts modified to express the neurotrophins BDNF and NT-3 grafted into the spinal cord following a complete transection at T11-T12. Fibroblasts were grafted at the time of injury, 2 weeks after injury, or 6 weeks after injury. Recovery of bipedal stepping on a treadmill was evaluated before and after injury and grafting. Kinematic evaluation indicated that grafting promoted recovery of treadmill stepping in the experimental groups. While control cats could only perform limited stepping at low (<=0.4m/s) speeds, grafted cats recovered stepping at all speeds up to 0.8m/s. Recovery was seen in many grafted cats as early as 3 weeks after injury, and all but one grafted cat were capable of stepping by 5 weeks after grafting. This recovery remained 12 weeks after grafting. Histological evaluation showed no regeneration through the lesion. We conclude that neurotrophin producing autografts are effective at promoting stepping even when delivered in a chronic spinal cord injury model.

Abstract: The development and subsequent translation of effective therapies for spinal cord injury (SCI) is hampered by the paucity of information about the biology of injury in human patients, and the lack of biomarkers that could facilitate clinical trials. Such biomarkers of SCI would be helpful for precisely classifying the injury severity, predicting neurologic recovery, and providing surrogate outcome measures for evaluating the biological effects of novel therapies. Previously, we utilized ELISA techniques to identify 6 biomarkers of injury severity in CSF from acute SCI patients. To expand the breadth of this analysis and potentially identify additional biomarkers, we conducted a targeted proteomics analysis of human CSF samples utilizing advanced mass spectrometry techniques. Acute ASIA A, B, and C SCI patients were enrolled in a prospective clinical trial in which CSF samples were obtained through indwelling intrathecal catheters at 24, 48 and 72 hours post-injury. The injury levels ranged from C4 to T11. Further, CSF from 6 non-SCI patients undergoing lumbar laminectomy/discectomies was also tested. A targeted proteomics approach was employed using multiple reaction monitoring (MRM) mass spectrometry to measure the levels of more than 100 proteins across all patients. The specific proteins evaluated were selected based on previous analyses of human CSF from patients with other neurologic conditions such as traumatic brain injury, stroke, Alzheimer's, and Parkinson's disease. Method development was performed on Agilent 6460 and 6490 triple quadruple mass spectrometers, using synthetic proteotypic peptides corresponding to the previously discovered proteins of interest. The MRM assays developed provided the highest sensitivity transitions for a given peptide, the highest selectivity for a given protein, short analysis times and minimal sample volumes. From 283 optimized peptide candidates, 75 were found to be present in human post-SCI CSF test samples. These were combined into a single analysis method, allowing the quantitation of these low level proteins in human CSF in one experiment. In this study, we utilized an immune-depletion strategy in which 14 major high-abundance proteins are removed by commercially available multi-affinity columns, which enable

effective detection of unique low abundance proteins. We are currently in the process of examining the human CSF and serum samples at various time points after SCI. The insights from this study will help scientific researchers develop clinically applicable therapies for human patients, and provide clinical researchers with tools that will facilitate the testing of novel therapies.

Abstract: Introduction: To date, expeditious surgical removal of impinging bone fragments after traumatic spinal cord injury (SCI) is one of the few treatment options available for the management of acute SCI. Intuitively, removing extradural compression reduces pressure and restores cord perfusion. But while surgical decompression may provide relief of extradural pressure, the cord itself typically continues to swell, indicating a potential increase in intraparenchymal pressure. Indeed, we have recently demonstrated in a porcine model of SCI that intraparenchymal pressure continues to increase even after spinal cord decompression. The biological basis and physiologic consequences of such swelling are poorly understood. Therefore, the goal of the present study is to determine how intraparenchymal pressure changes in the cord as swelling occurs, and the resultant effect on spinal cord blood perfusion. **Method:** Miniature Yucatan pigs received a contusive SCI at T10/11, using a controlled weight drop device followed by 1-hr of sustained compression. Fibre-optic pressure sensors and laser

Doppler flowmetry probes were implanted caudally into the spinal cord at 2 and 4 cm from the injury site. The cord pressure (CP) and blood flow (BF) were continuously monitored for up to 7-days. **Results:** After a contusion/compression injury, the CP and BF adjacent to the injury site (2 cm) instantaneously increased and decreased, respectively. Decompression caused the CP to return to baseline and the BF to transiently increase above baseline, a hyper-perfusion effect. The CP then increased rapidly over the next 4 hours while the BF, returned back to baseline levels. Over the 7-day sampling period, the CP remained at an elevated state while the BF fluctuated around baseline levels. Further from the injury site (4 cm), the CP and BF changes were far less pronounced during the injury, compression and decompression periods. However, 3 hours after decompression, the CP began to rise while the associated BF decreased below baseline. Unlike the CP at the 2 cm site, the 4 cm site CP, while it remained elevated above baseline over the 7-day sampling period, it exhibited greater fluctuations. The BF at the 4 cm site also fluctuated more than the BF closer to the injury site and its direction of changed tended to oppose that of its associated CP. **Conclusion:** Our data demonstrates that following SCI, the intraparenchymal pressure of the spinal cord re-accumulates within hours of decompression. Additionally, our data suggests that the pressure changes in the spinal cord may have a deleterious effect on cord blood perfusion, but further investigation is warranted to better elucidate this dynamic relationship.

Title: Olfactory ensheathing cells and fibroblasts differ their modification of the lesion site after complete spinal cord transection

Authors: R. R. KHANKAN[1], K. G. GRIFFIS[2], D. N. PEREZ[2], J. R. HAGGERTY-SKEANS[2], H. ZHONG[2], R. R. ROY[2], V. R. EDGERTON[2], *P. E. PHELPS[2]
[1]Molecular, Cell. & Integrative Physiol., [2]Integrative Biol. and Physiol., UCLA, Terasaki Life Sci. Building, Los Angeles, CA

Abstract: To better understand the growth-promoting potential of olfactory ensheathing cells (OECs), we transplanted transgenic eGFP-expressing OECs or skin fibroblasts (FBs) 1 mm above and below a complete T8 spinal cord transection. This short-term study compared how OECs and FBs modify the injury site at 1, 2, and 4-weeks post-lesion and analyzed 5-6 rats per cell type at each time-point. The size of the lesion core was smaller in OEC than in FB-treated rats at 1-2 weeks, but lesion sizes did not differ by 4-weeks post-injury. OECs migrated from the injection site into the lesion core as streams of cells organized into networks that intermingled with astrocytes, whereas FBs formed only a solid sheet of cells that did not integrate into the GFAP-positive glial scar. Despite the limited number of surviving transplanted cells, we evaluated the extent of neuronal survival and axon sparing near the GFAP scar border. Neurons were located closer to the scar border and more serotonergic axon bundles crossed the scar border in OEC than in FB-treated spinal cords at 1-2 weeks post-transection. We next asked if microglia and macrophage expression of ionized calcium binding adapter molecule-1 (Iba1) differed in its distribution and interactions with OEC and FB transplants. The intensity of Iba1-immunoreactivity in the lesion core of OEC and FB-treated groups was similar. Iba1 reactivity, however, was lower in OEC than FB-treated spinal cords at the glial scar border and within the rostral and caudal stumps. These data imply that OECs modulate the immune response after a spinal cord injury and that these immunological interactions enhance neuronal survival and axon sparing.

Title: The roles of CCAAT/enhancer binding protein delta (CEBPD) in astrogliosis after spinal cord injury

Authors: *S.-M. WANG[1], N.-E. CHIU[2], J.-Y. HSU[3], J.-M. WANG[4]
[1]the institution of bioinformatics and biosignal transduction, The Inst. of Basical Med. Sci. of Natl. Abstract: Spinal cord injury (SCI) is a devastating disease that results in disruption of microstructure in the cord and is followed by limited neuronal regeneration and functional recovery. After SCI, astrocytes, the most abundant glial cells in the central nervous system, become reactive and hypertrophy. Increased number of reactive astrocytes leads to astrogliosis which can be observed in a variety of chronic neurological and neuroinflammatory diseases. Moreover, astrogliosis causes the formation of irreversible glia scarring that blocks axonal regeneration. One potential candidate that affects the behavior of reactive astrocytes is the transcription factor CCAAT/enhancer binding protein delta (CEBPD), which is responsive to inflammatory factors such as tumor necrosis factor alpha (TNF-α) and interleukin 1 beta (IL-1β) in many inflammation-related diseases. To test the hypothesis that CEBPD modulates astrogliosis after SCI, we assessed a number of wound healing events using wild-type and CEBPD-knockout mice subjected to a moderate contusive injury at the mid-thoracic spinal level. We found that CEBPD was expressed by reactive astrocytes along the lesion border starting from 7 days after injury. CEBPD-deficient mice showed significantly reduced glial scar formation and increased residual white matter around the lesion compared with the wild-type mice 28 days after injury. In addition, CEBPD-deficient mice exhibited better recovery of motor function than the wild-type controls. Interestingly, CEBPD was associated with increased astrocytic expression of matrix metalloproteinase-3, suggesting a promotive role of CEBPD in astrocyte migration. Taken together, our results suggest that CEBPD may facilitate astrocyte migration and, thus, astrogliosis after SCI in mice.

Title: Spinal injury-induced spasticity in complete Th9 transection model in rats: Modulation by spinal glycine transporter 2 antisense oligonucleotide

Authors: *K. KAMIZATO[1], M. MARSALA[1], C. MAZUR[2], O. KAKINOHANA[1]
[1]UCSD, La Jolla, CA; [2]Isis Pharmaceuticals Inc., Carlsbad, CA

Abstract: BACKGROUND: Imbalance between presynaptic excitation and inhibition after spinal injury plays a key role in the progressive increase in spinal reflexes and the appearance of spasticity. Glycine is a major inhibitory neurotransmitter in the central nervous system. The extracellular concentrations of glycine are regulated by Na+/Cl(-)-dependent glycine transporters (GlyTs), which are expressed in neurons (GlyT2) and adjacent glial cells (GlyT1). The goal of the present study was to assess the effect of GlyT2 inhibition on the spasticity response in animals with chronic transected spinal cord injury-induced muscle spasticity. METHODS: All animal studies were carried out under protocols approved by the Institutional Animal Care and Use Committee at UCSD. Adult Sprague-Dawley (SD) rats (female 200-300 g) had Th9 spinal segment transected to induce muscle spasticity. The presence of spasticity was defined as exacerbated EMG response recorded from the gastrocnemius muscle after applying progressively increased paw pressures using von Frey filaments (0.6-26 grams). After baseline spasticity measurement, animals received a single lumbar intrathecal bolus of GlyT2 antisense oligonucleotide (GlyT2-ASO;) or control antisense oligonucleotide (Cont-ASO). Before and after treatment the presence of spasticity response was measured in 1-week intervals for up to 4 weeks. RESULTS: In spastic animals receiving intrathecal injection of GlyT2-ASO, a progressive decrease in measured surface EMG activity after paw tactile stimulation was seen with the maximum effect measured at 2 weeks after injection ($p<0.05$). A significant anti-spastic affect was still present at 3 weeks after treatment, but was no longer present at 4 weeks. CONCLUSIONS: These data show that suppression of spinal GlyT2 activity may represent a novel therapy for modulation of chronic spinal injury-induced muscle spasticity.

Title: Immune responses following transplantation of expanded autologous schwann cells for spinal cord injury in minipigs

Authors: *A. J. SANTAMARIA[1], F. D. BENAVIDES[1], L. G. GUADA[1], Y. NUNEZ[2], A. BROOKS[1], J. P. SOLANO[2], J. D. GUEST[1,3]

Abstract: Introduction: Autologous Schwann cells (aSC) from sural nerves are being derived, expanded, and purified in cGMP compliant cell cultures and tested in a Phase 1 human clinical trial after spinal cord injury (SCI), [ClinicalTrials.gov Identifier: NCT01739023]. Preclinical studies used aSC in minipigs and primates, and either syngeneic SC in rodents or human SC + immune suppression in rodents. Here we report aSC transplants associated with substantial lymphocytic immune response in Yucatan minipigs and in one primate but not in rodent studies. Formation of lymphoid follicular structures has been reported in a mouse model after SCI, and in humans with MS but not following cell transplantation for SCI. Prior experiments utilized GFP-transfected cells except the rodent study with human cells. We thus tested two hypotheses: 1) the lymphocytic response is directed at the "foreign" green fluorescent protein. 2) ex-vivo expanded aSC are capable of MHC-restricted antigen presentation. Methods: To assess for the specificity of the lymphocytic response, female Yucatan minipigs underwent left hemi-contusion injuries at T6, T9 and T12. A nerve was extracted to derive aSC, each animal's preparation was divided into a GFP-transfected and non-transfected preparation. The cells were prepared in a manner similar to that for the clinical trial. The aSC were cryopreserved at passage 1 and later thawed and expanded to passage 2 for transplantation directly into the injury cavities 7 weeks after SCI: T6-non-transfected aSC, T12-GFP-transfected cells, T9-only a pial penetration was made, no cells were delivered. The concentration was 100,000 cells/µl and the volume delivered that which filled the injury cavity. Two months after transplantation, the animals were perfused. Results: In prior cohorts we observed the presence of perivascular lymphocytic infiltration as early as 1 day post-transplant and this response was only identified in 1/12 non-transplanted control animals. The injury sites occupied by transplanted aSC showed the formation of lymph-node like structures with germinal centers detected as early as 28d, and as late as 218d post-transplantation. CD3 positive lymphocytes were prominent in the paracortical and interfollicular zones of the formations. Staining for BCL-2 was used to exclude neoplastic growth. Transplanted aSC expressing myelin proteins were identified surrounding the nodal structures. Conclusions: Transplantation of ex-vivo purified aSC leads to a chronic organized lymphocytic response in the spinal cord of minipigs. It is important to determine the immunological mechanisms underlying this response and if they are unique to this species.

Title: Clinical and Surgical Predictors of Perioperative Complications in patients with degenerative cervical myelopathy: Results from the multicenter, prospective AOSpine International study on 479 patients

Authors: *L. TETREAULT[1], N. ALSHAFAI[2], P. COTE[3], M. FEHLINGS[2]
[1]Univ. of Toronto, Oakville, ON, Canada; [2]Toronto Western Hosp., Toronto, ON, Canada; [3]Univ. of Ontario Inst. of Technol., Toronto, ON, Canada

Abstract: Introduction: Surgery for the treatment of cervical spondylotic myelopathy (CSM) is not without associated morbidity. By identifying important clinical and surgical predictors of complication development, clinicians can recognize their high-risk patients and institute appropriate prevention plans. This study was designed to identify important clinical and surgical predictors of perioperative complications in patients with degenerative cervical myelopathy. Material/Methods: Over a three-year period, 479 patients diagnosed with degenerative cervical myelopathy and treated surgically were enrolled in the prospective CSM-International study at sixteen global sites. A panel of physicians reviewed all adverse events and classified each one as related to CSM, related to surgery or unrelated. Univariate analyses were performed to determine demographic and surgical differences between patients who suffered a perioperative complication and those who did not. A final complication clinical prediction rule was developed using multiple logistic regression. Results: Eighty patients experienced 92 perioperative complications, yielding an incidence of 16.7%. Patients with complications were on average older (58.00±10.75) and had a higher BMI (26.62±4.50) compared to those without complications (56.04±12.12, 25.60±4.55), although these relationships did not reach significance. Univariately, the major clinical risk factors for perioperative complications were a diagnosis of OPLL, the number of comorbidities pre-operatively, diabetes, and co-existing gastrointestinal or cardiovascular disorders. There was no difference in the rate of complications between anterior or posterior approaches (p=0.744). Patients undergoing a 2-stage approach, however, were at a greater risk of perioperative complications than those treated with either

anterior or posterior surgery. Finally, patients with complications had a longer operative duration (198.41±92.30 min) than those without complications (173.98±77.02 min) (p=0.014). A final prediction model consisted of seven predictors: diabetes (OR=2.35), age (OR=1.02), operative duration (OR=1.003), two stage surgery (OR=20.37, p=0.012), OPLL (OR=1.82), gastrointestinal co-morbidities (OR=2.53) and body mass index (OR=1.06). Conclusion: Patients are at a higher risk of perioperative complications if they are older, have myelopathy secondary to OPLL, suffer from diabetes or gastrointestinal disorders, have a higher BMI and if they are treated by two-stage surgery or have a long operative duration.

Title: Chemical warfare nerve agent induced gene expression alterations in blood: Indications for CNS-driven systemic injury

Authors: C. C. ROTHWELL[1], A. A. MELBER[1], C. S. HOFMANN[1], J. W. SEKOWSKI[2], *H. M. HOARD-FRUCHEY[1]

Abstract: Chemical warfare agents continue to be a persistent military and civilian concern on the battlefield and at home during the war against terrorism. Exposure to organophosphate chemical warfare agents such as soman, sarin, and VX results in alteration of cholinergic pathways. These agents bind to and disrupt the function of acetylcholinesterase, causing a variety of symptoms including miosis, excessive secretion, convulsions, seizure, and death. Although studies on the effects of chemical nerve agents began during the World War II era, the molecular mechanisms of these toxic agents are not well characterized. To characterize the systemic effects of VX at the molecular level, we used microarray analysis to identify gene expression changes in

whole blood samples. Adult male Sprague-Dawley rats were exposed to 0.4, 0.7, or 1.0 x LD_{50} VX (i.v.), and trunk blood was collected at 1, 2, 4, 8, or 24 h post-exposure. Total RNA was isolated and processed for mRNA and microRNA hybridization to Affymetrix GeneChip HT RG-230 PM and miRNA 3.1 array plates. For mRNA, principal component analysis (PCA) identified dose as the greatest source of variability within the dataset. Analysis of variance (ANOVA) was performed to identify nerve agent-induced changes in gene expression for 1 x LD_{50} VX over time. Using these data, pathways significantly affected were identified. Genes differentially expressed in response to VX exposure mapped to canonical pathways containing inflammatory and immunological molecules and molecules involved in cellular energy production. For microRNA, PCA identified time as the major source of variability within the dataset. Data analysis for the microRNA and integration with the mRNA dataset is ongoing. Characterizing the mRNA and miRNA expression changes within identified pathways may identify new systemic therapeutic targets for development of medical countermeasures as well as new biomarkers for diagnosis of chemical warfare nerve agent exposure. **Disclaimer:** The views expressed in this poster are those of the author(s) and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government. Title: Development of an aging rat model of nerve agent exposure for the evaluation of medical countermeasures

Authors: *M. C. MOFFETT, A. R. FURMAN, J. E. SCHWARTZ, M. F. STONE, G. E. GARCIA, L. A. LANGE
USAMRICD, Aberdeen Proving Ground, MD

Abstract: Older individuals are among one of the fastest growing populations in recent years and may be particularly vulnerable in the event of a terrorist attack using chemical weapon nerve agents. This project was designed to evaluate the susceptibility of aged rats to soman (GD) toxicity, including GD-induced seizures, neuropathology, and behavioral deficits. Male F344 rats 2 (adult) and 18 months (aged) of age were implanted with telemetry devices and exposed to GD (22-88 µg/kg). Whole blood cholinesterase was measured at multiple time points following GD exposure. Spatial memory acquisition was assessed using the Morris water maze (MWM) starting on post-exposure day (PED) 14. Brains were collected three weeks after exposure for pathological analysis. Aged rats showed a significantly greater sensitivity to the toxic effects of GD compared to adult rats. Although impairments in the MWM were observed in the aged compared to adult rats, there were no observed GD-induced spatial memory impairments following exposure. This was most likely due to the high mortality rate in the adult and aged animals that displayed EEG seizures. The majority of animals that survived to be tested in the MWM did not display seizures and did not have significant neuropathology. In the second experiment adult and aged rats were exposed to approximately equitoxic doses of GD (88 and 66 µg/kg respectively) and treated with atropine sulfate (2 mg/kg, im), the oxime HI-6 (93.6 mg/kg), and diazepam (10 mg/kg). Preliminary evaluation of medical countermeasures showed an effective reduction of mortality rates in both the adult and aged rats.

Title: Omic approaches identify lipid disturbances in mice exposed to Gulf War agents at a chronic 16 months post-exposure time-point

Authors: *L. ABDULLAH[1,2], J. EVANS[1], J. REED[1], G. CRYNEN[1], H. MONTAGUE[1], A. GONZALEZ[1], M. CROCKER[1], S. BAUMANN[3], Z. ZAKIRVA[1], T. EMMERICH[1], R. PELOT[1], G. AIT-GHEZALA[1,2], M. MULLAN[1], F. CRAWFORD[1,2]
[1]Roskamp Inst., SARASOTA, FL; [2]James A. Haley VA Hosp., Tampa, FL; [3]Agilent Technologies, Santa Clara, CA

Abstract: Introduction: Gulf War Illness (GWI) continues to affect 25% of veterans who were deployment to the 1991 Gulf War (GW). The clinical presentation of this illness includes central nervous system (CNS) symptoms, such as cognitive problems and anxiety. To date, CNS pathobiology associated with chronic symptoms of GWI remains largely unknown, making it difficult to identify effective therapies. Therefore, identification of disturbed biological pathways associated with chronic GWI pathology is important for the development of appropriate treatments. Aim: Given the complex clinical presentation of GWI, we applied omic (lipidomics, proteomics and metabolomics) approaches to examine biological changes at 16-months post-exposure to GW agents. Methods: Nine-week old male C57BL6 mice were administered GW agents (pyridostigmine bromide [PB] and a pesticide permethrin [PER]) or control (DMSO) once daily for 10-days via intraperitoneal injections. Neurobehavioral testing was performed at 16-months post-exposure and then brain samples were collected for neuropathological and omic analyses. Lipidomics was performed using liquid chromatography/mass spectrometry (LC/MS) with in-source collision-induced dissociation on a LTQ mass spectrometer. Metabolomic analyses were conducted on trimethylsilyl derivatized samples by electron ionization gas chromatography (GC)/MS using a GC/QTOF mass spectrometer. Proteomic studies were performed using iTRAQ labeling with LC/MS/MS on a Q Exactive Orbitrap mass spectrometer. Results: Compared to controls, a significant decrease in several major phospholipid (PL) classes was observed in exposed mice. Ether PLs that are synthesized in peroxisomes were increased in exposed mice relative to controls. Metabolomic studies showed a decrease in free fatty acids in exposed mice vs. controls. Proteomic analyses showed that proteins that are involved in lipid degradation within lysosomes were modulated following exposure to GW agents. These omic changes corresponded with cognitive impairment and astroglia activation in the brains of exposed animals. Conclusion: These studies suggest an examination of peroxisomal and lysosomal function in laboratory models of GWI as likely candidates for novel targets to treat the CNS symptoms of GWI.

Title: Testing for dose-dependent effects on object- and location memory following clinically relevant whole brain irradiation in adult rats

Authors: *D. R. RIDDLE[1,3], M. E. FORBES[1], M. PAITSEL[1], J. D. BOURLAND[2]
[1]Dept. Neurobio. and Anat., [2]Radiation Oncology, Wake Forest Sch. of Med., Winston-Salem, NC; [3]Biomed. Sci., Western Michigan Univ. Homer Stryker M.D. Sch. of Med., Kalamazoo, MI

Abstract: Whole brain irradiation (WBI) effectively treats brain tumors and metastases but many patients who survive > 6 months suffer cognitive decline due to normal tissue injury. The underlying mechanisms are not established and results of studies of brain irradiation in animal models are highly variable. We recently reported on a study of Fischer 344 x Brown Norway F1 rats irradiated at 3 or 17 mo-of-age with 40 Gy fractionated WBI (fWBI, 2 x 5 Gy/wk for 4 wk, BED 106.7 Gy) and then evaluated using novel object recognition (NOR) and novel object location (NOL) tasks from 3 to 12 mo after fWBI. These analyses revealed no effect on location memory but a radiation-induced, early-delayed deficit in object memory that was modest, transient and evident only in rats irradiated as young adults. Given the limited cognitive effects in that study, the mixed results of other studies, and recognition that rodents are more radioresistant than humans, another cohort of rats was treated at 3 mo-of-age with either sham irradiation, 40 Gy fWBI (8 x 5 Gy, BED 106.7), or 48 Gy fWBI (8 x 6 Gy, BED 144 Gy) and then evaluated longitudinally with the NOR and NOL from 1.5 to 12 mo after treatment. Analysis of discrimination ratios (DR) in the NOR with 6 min, 30 min, or 4 hr delay revealed no radiation-induced deficits at any time point following fWBI with 40- or 48 Gy. The average DR in the NOR 6 and NOR 30 remained stable in all groups from 1.5 to 12 mo after treatment, while the average DR in the NOR 4 hr declined in all groups starting at ~6 mo and was at chance levels by 12 mo. Measures of location memory from the NOL with 6 min and 4 hr delays were more variable than measures of object memory, were better with the shorter delay, and appeared unaffected by fWBI at either dose. Although novel object- and novel location discrimination appeared unaffected, fWBI altered some measures of activity during testing. The latency to begin exploring objects during the sample and test phases of the NOR was increased in rats receiving 40 Gy fWBI; surprisingly, rats receiving 48 Gy were more like sham irradiated control rats in

that measure. Irradiation with 40 but not 48 Gy also increased the average latency to enter the center zone of the testing arena during initial open field habituation at 4 wk after fWBI. Irradiation (regardless of dose) decreased the speed of movement during testing in the NOR, particularly in the first few mo after treatment. The results of this and previous studies of radiation-induced cognitive changes emphasize the need for continued investigation and validation of rodent models of radiation-induced brain injury, which are critical for developing new therapies for treatment-induced cognitive dysfunction in cancer survivors.

Title: Cognitive defects and tau protein alterations in adult mice following neonatal low dose co-exposure to radiation and ketamine

Authors: *S. BURATOVIC[1], B. STENERLÖW[1], A. FREDRIKSSON[1], S. SUNDELL-BERGMAN[2], P. ERIKSSON[1]
[1]Uppsala Univ., Uppsala, Sweden; [2]Swedish Univ. of Agr. Sci., Uppsala, Sweden

Abstract: Ionizing radiation (IR) is widely used in medicine for treating tumours, including tumours in the central nervous system, and for imaging techniques e.g. computed tomography (CT). Ketamine is an anaesthetic agent commonly used in children undergoing repeated anaesthesia in radiotherapy of tumours but also as sedative agent in CT diagnosis. Although its great benefits in medicine awareness has been raised about possible negative consequences from low dose exposure to IR during brain development and also the effects a co-exposure situation with IR and ketamine might have on the vulnerable developing brain. In previous studies we have indicated that IR as well as ketamine can induce persistent neurotoxic effects in mice, manifested as reduced cognitive function and altered levels of the neuroproteins CaMKII, GAP-

43 and tau, when exposure occurs during a defined critical phase of brain development. The present study was conducted to explore developmental neurobehavioural and neuroprotein effects in mice co-exposed to IR and ketamine during neonatal brain development. Male neonatal NMRI mice were exposed to a single 7.5 mg/kg b.w. dose of ketamine s.c. on postnatal day 10. One hour following ketamine exposure the mice were placed in plastic dishes and irradiated to a single dose of 50, 100 or 200 mGy from a 137Cs source at a dose rate of 0.2 Gy/min (Rudbeck laboratory, Uppsala University). Mice were also exposed to only ketamine or IR for equivalent doses as co-exposed mice. Control animals were exposed to 0.9% saline (10 mg/kg b.w.) s.c. or placed in plastic dishes and sham irradiated. At 2- and 4-months of age the animals were tested for spontaneous behaviour in a novel home environment. At 5-months of age the animals were tested in a Morris water maze (MWM). Two weeks after the MWM mice were euthanized and dissected for further analyses of proteins CaMKII, GAP-43, synaptophysin and tau in cerebral cortex and hippocampus. Animals co-exposed to IR and ketamine developed an altered cognitive function, manifested as a lack of habituation capacity, in a dose-response related manner. In the MWM animals co-exposed to IR and ketamine showed an impaired memory and learning capacity. Furthermore, in mice co-exposed to IR and ketamine and showing reduced cognitive function in the behavioural tests levels of tau protein was increased in cerebral cortex. This study shows that co-exposure to IR and ketamine can interact and aggravate developmental neurotoxic effects manifested as impaired habituation, learning and memory ability, indicating reduced cognitive function, in a dose-response related manner and at doses where the sole agents alone don't have any impact on the measured variables.

Title: Reduced carbachol-induced β/γ oscillations in CA3 region of hippocampus after post-natal contamination of uranium in adult rat

Authors: *C. DINOCOURT, J. STEFANI, C. ELIE, P. LESTAEVEL, I. DUBLINEAU, P. GOURMELON
IRSN, Fontenay Aux Roses, France

Abstract: During period of brain development, heavy metals can induce developmental neurotoxic effects. Uranium (U) is naturally present in the environment since it is a component of the earth's crust. Civilian and military industries increase U concentration in the soil and underground water. Therefore populations may be chronically exposed by ingestion of drinking water or food. Previous studies have shown that U is present in brain and alters behavior. In young rat exposed to U from birth through drinking water, object recognition memory was decreased and was associated with a reduction of ACh concentration and AChE activity in the entorhinal cortex. The objective of this study is to assess whether gamma range oscillations induced by cholinergic agonist could be involved in the deficit of learning and memory. Synchronous network activity was recorded in the hippocampus of rats contaminated from birth during 6 months by depleted uranium (DU) at 10 and 40mg/l and non-contaminated rats. We analyzed β/γ oscillations (20-80Hz) induced by the cholinergic agonist, carbachol (CCH) in CA3 region of hippocampus slices. Bath application of CCH (20μM) generates fast rhythmic activity with a frequency in β range and a secondary in the γ range in slices from non-contaminated as well as contaminated animals. The peak frequency of these oscillations is not different between non-contaminated and contaminated animals. However, our results show less powerful of β range oscillations in animals contaminated at 40mg/l compared to control animals. Indeed, none of the slices from animals contaminated at DU40 displays a power higher than 50μV2/Hz. In contrast, 83% of slices from control rats and 83% of slices from rats contaminated at DU10 show a power higher than 50μV2/Hz. Since fast-spiking interneurons are necessary for the generation of γ range oscillatory synchronization, analysis of parvalbumin-containing interneurons has been investigated. Number of parvalbumin-positive cell bodies is not reduced in CA3 region. No difference has been observed in the distribution of synaptic terminals of these interneurons in contaminated animals compared to control animals. In conclusion, these results show a decrease of gamma range oscillations without change of peri-somatic interneuron network. These suggest that synchronous oscillations could be disturb by chronic exposure of U and thus could result in cognitive deficits. Further experiments have to be performed, especially on basal neurotransmission and excitability as well as interneuron network.

Title: Is neurogenesis altered after chronic internal contamination of uranium during brain development?

Authors: *M. LEGRAND[1], C. IBANEZ[1], P. LESTAEVEL[1], J. STEFANI[1], N. FLORES[1], P. ERIKSSON[2], C. DINOCOURT[1]
[1]IRSN, Fontenay Aux Roses, France; [2]Uppsala Univ., Uppsala, Sweden

Abstract: Uranium (U) is a heavy metal naturally found in the environment. Its many uses in civil or military technologies give cause of concern about human health risks. A lot of studies highlight the effects of uranium on cerebral functions such as cognitive tasks. For example, contamination via drinking water in adult rats induced spatial memory impairment and sleep/wake cycle disturbance. Decrease of object recognition memory has also been showed after post-natal exposure to U. Neurogenesis is known to be involved in learning and memory defects. Therefore, we analysed the effects of depleted uranium (DU) on neurogenesis during brain development in an *in utero* model of internal contamination. Pregnant rats were contaminated by drinking water at DU 40 and 120 mg/L during gestation and lactation. At embryonic stages (E13, E18) and post-natal stages (PND 0, PND 21) we examined the structural morphology of the brain by Nissl staining, the cell proliferation by BrdU immunostaining and the cell death by Fluorojade staining. Our results show that DU does not generate major organogenesis deficits in the telencephalon of embryos and in the dentate gyrus of young rats. In animals contaminated by U at 40mg/L, no significant change in cell proliferation and cell death is observed at each time point. However, these processes are impaired in animals contaminated by U at 120mg/L. At E13, results show a decrease of BrdU staining in cortical neuroepithelium in contaminated embryos without modification in cell death. In contrast, at E18, an increase of BrdU staining is observed in hippocampal neuroepithelium. At this stage, results also show a decrease of fluorojade-positive cells in cortical neuroepithelium. At PND 0, the number of Fluorojade-positive cells decreases in the dentate gyrus but no modification of cell proliferation was noted. Finally at PND 21, quantitative analysis shows a decrease of BrdU positive cells in the dentate gyrus of hippocampus of contaminated rats. In conclusion, these results show that *in utero* contamination by U leads to changes in cell proliferation and cell death processes during brain development. These could have an impact in the next steps of neurogenesis (differentiation, migration, synaptic connectivity) and could consequently result in defects on the organization of neuronal network. So, these results suggest that chronic exposure to U in embryonic life could lead to behavior disorders in adulthood. More experiments have to be performed to study the other processes of neurogenesis such as gene and protein expressions of specific markers of differentiation and migration.

Title: The effect of aging on neural stem / progenitor cell populations after radiation

Authors: ***Z. CHENG**[1,2], Y.-Q. LI[1], S. WONG[1,2]
[1]Sunnybrook Res. Inst., Toronto, ON, Canada; [2]Inst. of Med. Sci., Univ. of Toronto, Toronto, ON, Canada

Abstract: Aging is associated with decreased neurogenesis in the dentate gyrus (DG), and cranial radiation treatment (RT) is known to ablates DG neurogenesis. Aging may further compound the development of severe and irreversible cognitive dysfunction after RT. Inhibition of neurogenesis is considered to be an important underlying mechanism of RT-associated cognitive deficits. It has been reported that the extent of post-RT reduction in neurogenesis is diminished with aging. Here, we investigated the influence of aging on changes in neural stem cells and neural progenitor cells (NPCs) in DG after RT. METHODS Male mice aged 2, 4, 6, 12, and 18 months old were given 0 or 5 Gy. Newborn cells were labeled with a bromodeoxyuridine (BrdU) incorporation assay 4 weeks post-RT. The brains were harvested and fixed 4 weeks after BrdU. The newborn neurons, type I (putative neural stem cells), and type II cells in the DG were identified using immunohistochemistry with specific phenotypic markers and estimated by stereological methods. Two-way ANOVA was used to analyze the results. RESULTS In the DG, the total number of newborn cells (BrdU+) decreased with aging ($p < 0.0001$; 448 ± 89 at 2 months, 8.5 ± 8.5 at 18 months) and after RT ($p = 0.0007$; 68% reduction at 2 months, 33% reduction at 18 months). The number of newborn neurons decreased with aging ($p < 0.0001$; 191 ± 88 at 2 months, 4.5 ± 4.5 at 18 months) and after RT ($p < 0.0001$, 53%, 43%, 60%, 14%, and 100% reduction at 2, 4, 6, 12 and 18 months respectively). The interaction between age and RT was significant ($p = 0.0019$). The number of newborn type I ($p = 0.0001$; 90 ± 18 at 2 months, 8.5 ± 8.5 at 18 months), total type I ($p = 0.002$; 8271 ± 120 at 2 months, 4493 ± 592 at 18 months), and total type II cells ($p = 0.001$; 472 ± 90 at 2 months, 280 ± 14 at 18 months)

decreased with aging. RT decreased the number of total type I cells ($p = 0.01$; 33% reduction at 2 and 18 months). RT did not have a significant influence on the number of newborn type I and total type II cells when adjusted for age. CONCLUSION The age-related decline in neural stem cells and NPCs may contribute to the age-related decline in newborn neurons. The loss of putative neural stem cells after RT may contribute to the post-RT decline in neurogenesis, and the extent of post-RT decline in neural stem cells and newborn neurons do not seem to be more severe with aging.

Title: Anatabine ameliorates cognitive impairment and neuropathological deficits in a mouse model of Gulf War Illness

Authors: *G. AIT-GHEZALA[1,2,3], Z. ZAKIROVA[1,2,3], B. MOUZON[1,2,3], M. TWEED[1,2,3], D. PARIS[1,2,3], V. MATHURA[1,2], F. CRAWFORD[1,2,3], M. MULLAN[1,4]
[1]Roskamp Inst., SARASOTA, FL; [2]The Open University,Walton Hall, Milton Keynes,, Buckinghamshire MK7 6AA,, United Kingdom; [3]James A. Haley Veteran's Hospital, 13000 Bruce B. Downs Blvd., Tampa, FL; [4]Rock Creek Pharmaceuticals,, Sarasota, FL

Abstract: Gulf War Illness (GWI) is a multisymptom chronic illness with a central nervous system (CNS) component, symptoms of which include cognitive impairment such as memory and neurological deficits, fatigue, and musculoskeletal problems, as well as immune and inflammatory dysfunction, as key consequences of exposure post deployment to the Persian Gulf War. There are ample data that suggest that exposure to Gulf War (GW) agents, such as pyridostigmine bromide (PB) and pesticides such as permethrin (PER), were key contributors to the etiology of GWI. We have previously demonstrated that C57BL6/J mice at 5 months post exposure to GW agents early in life develop late-onset cognitive impairment, and neuropathological changes marked by an elevation of neuroinflammatory markers. This model of chronic consequences of acute exposure to GW agents is thus relevant to the veterans currently

suffering with GWI as their exposure occurred over 20 years ago. We have previously shown *in vitro* and *in vivo* the efficacious anti-inflammatory properties of Anatabine, a minor tobacco alkaloid also present in plants of the Solanacea family, which displays a chemical structural similarity with nicotine (Paris et al., 2013). In the current study we investigated whether daily oral administration of Anatabine (2o mg/kg) could be used to mitigate neuroinflammation, and ameliorate cognitive impairment and neuropathological deficits observed in our mouse model of GWI. Behavioral analyses of learning and memory were performed in control and GW agent exposed mice at 5 months post-exposure, at the end of behavior assessment, a treatment or placebo began and the mice were assessed again 1 and 2 months post treatment with Anatabine. Our results demonstrate that 2 months post treatment with Anatabine we were able to rescue the neurobehavioral deficits we previously observed in these mice. Immunohistochemical (IHC) analyses are ongoing in brain sections from these animals. Thus, Anatabine is a promising potential therapeutic that may be used alleviate some of the symptoms experienced by GW veterans today. Title: Galantamine as an effective pre-treatment countermeasure against high doses of soman: Comparison with pyridostigmine efficacy

Authors: *Y. ARACAVA[1], E. F. R. PEREIRA[1], M. LANE[1], R. J. CLARK[1], G. W. BASINGER, Jr.[2], E. X. ALBUQUERQUE[1]

Abstract: Organophosphorus (OP) nerve agents have resurged recently as deadly weapons used in Middle East conflicts and as means to spread terror among civilians. By irreversibly inhibiting acetylcholinesterase (AChE), they lead to life-threatening cardio-respiratory arrest and status epilepticus-like seizures. It is known that the toxicity of the nerve agent soman cannot be readily counteracted by the available treatments, especially when dealing with doses higher than 2xLD50. Here, we compared the effectiveness of pre-treatment with galantamine vs. pyridostigmine against 2x and 3xLD50 soman in both male and female guinea pigs. Thirty min prior to the s.c. injection of soman, guinea pigs were treated i.m. with galantamine, pyridostigmine or saline. Post-soman treatment consisted of the muscarinic receptor antagonist atropine (0.5 mg/kg) and the AChE reactivator 2 PAM (25 mg/kg), both given at 1 min post-soman, and midazolam (2.2-2.8 mg/kg) administered 5 min post-seizure onset. Animals challenged with 2xLD50 soman received one post-treatment cocktail, whereas those challenged with 3xLD50 received the post-treatment cocktail three times at 1.5 h intervals. At 24 h post-soman injection, we evaluated the effectiveness of the treatments to prevent lethality, blood and brain AChE inhibition, and neurodegeneration (assessed with Fluoro-Jade B, FJ-B, staining). Against 2xLD50, pre-treatment with galantamine (6-10 mg/kg) afforded 100% protection from lethality; 71% and 0 % of the animals survived when pre-treated with pyridostigmine (0.026 mg/kg) and saline, respectively. Against 3xLD50, pre-treatment with 8, 10 and 12 mg/kg galantamine afforded 67, 71 and 100% survival, respectively, whereas pre-treatment with pyridostigmine and saline resulted in 38% and 14% survival, respectively. Clinical signs of intoxication had slower onset, lower severity, and shorter duration in galantamine- than in pyridostigmine- or saline-pretreated animals. Large numbers of FJ-B-positive cells were seen in numerous brain regions of most of the pyridostigmine- and saline-pretreated guinea pigs, whereas cell death was absent in the brains of soman-injected guinea pigs that had been pre-treated with galantamine. Finally, brain and blood AChE activity were more preserved among soman-injected rats that had been pre-treated with galantamine than among those pre-treated with pyridostigmine or saline. Thus, our results reveal that lethality and neurotoxicity induced by supra-lethal doses of soman is effectively counteracted by pre-treatment with galantamine in conjunction with post-treatment with atropine, 2-PAM, and diazepam.

Title: Effects of galantamine post-treatment on nerve agent-induced EEG changes and lethality of rats

Authors: *E. A. ALEXANDROVA, Y. ARACAVA, J. D. PESCRILLE, L. D. RICHARDSON, B. GUSHEN, E. F. R. PEREIRA, E. X. ALBUQUERQUE
Div. of Translational Toxicology, Dept. Epidemiology & Publ. Hlth., Univ. Maryland Sch. of Med., Baltimore, MD

Abstract: Control of seizure activity resulting from overactivation of the brain cholinergic system due to irreversible acetylcholinesterase (AChE) inhibition by the organophosphorus (OP) nerve agents sarin and VX is essential to improve survival and limit brain damage. Here, we analyzed cortical EEG recordings from rats exposed to 1.2xLD50 sarin or VX to determine if inclusion of galantamine in a post-OP exposure treatment regimen consisting of the muscarinic receptor antagonist atropine and the AChE reactivator 2-PAM reduces OP-induced seizures and lethality. To this end, cortical EEG was telemetrically recorded for 24 h from rats injected with 1.2xLD50 of sarin or VX and immediately post-treated with atropine (0.5 mg/kg)-plus-2-PAM (25 mg/kg) and galantamine (0.3, 1.0, or 3.0 mg/kg) or saline. After the treatment with atropine, 2-PAM, and saline, 73% of the sarin-injected rats survived and 54.5% developed seizures. The total EEG power of the convulsing rats increased significantly, primarily due to a nearly 50-fold increase in the power of the low-frequency delta band (0.5-4 Hz); the power of the high-frequency gamma band (32-50 Hz) increased only 12 times during first hour of seizures and then gradually decreased to 68% below baseline at the end of experiments. In the EEG of sarin-injected rats that did not convulse, the total power and the delta power density were decreased (40-45%) shortly after the sarin challenge. At the same time, the gamma band power increased up to 85% in the first 3 h after injections. The EEG and survival of sarin-challenged rats that were post-treated with 0.3 or 1 mg/kg galantamine were comparable to those of rats that had been post-treated with saline. Increasing the dose of galantamine to 3 mg/kg increased survival of sarin-injected rats to 88% and significantly reduced to 12% the incidence of seizures. In this group, the gamma band power density remained 62% above the baseline level at 20 h after sarin. All animals that were challenged with VX and post-treated with atropine, 2-PAM, and saline survived and only 28% developed short periods of seizures. In non-convulsing rats, VX induced more profound changes than sarin in the power density of the delta (~65% decrease) and gamma (~2.2-fold increase) bands. Inclusion of galantamine in the post-treatment regimen reduced to 17% the incidence of seizures among VX-challenged rats. These results demonstrate a strong

relationship between seizure occurrence and the simultaneous changes of energy in gamma and delta bands shorty after OP exposure. They also reveal that galantamine associated with atropine and pralidoxime effectively protects animals against OP-induced seizure and lethality.

Title: Prenatal exposure to Chlorpyrifos leads to reduced msk expression in the dentate gyrus: Implications for regulation of histone acetylation

Authors: ***S. W. TODD**[1], W. R. RANDALL[2], E. F. R. PEREIRA[1], E. X. ALBUQUERQUE[1]
[1]Div. of Translational Toxicology, Dept. Epidemiology and Publ. Hlth., [2]Dept. Pharmacol., Univ. of Maryland Sch. Med., Baltimore, MD

Abstract: Chlorpyrifos (CPF) is an organophosphorous insecticide that is used worldwide. Sub-acute exposure to CPF during pregnancy has been correlated with increased incidence of cognitive dysfunction in children [Neurotoxicol Teratol 34:534, 2012]. While the acute toxicity of CPF results primarily from its ability to irreversibly inhibit acetylcholinesterase (AChE), the enzyme that hydrolyzes the neurotransmitter acetylcholine, the mechanisms underlying the neurological deficits induced by prenatal exposure to sub-acute levels of CPF are poorly understood. Recent studies have demonstrated that (i) decreased histone acetylation in the hippocampus reduces the activation of genes that are related to cognitive function [Nature 447:178, 2007] and (ii) injection in the hippocampus of a drug that increases histone acetylation improves cognition in a mouse model of Alzheimer's disease [Science 328: 753, 2010]. These findings relate well to studies that identify histone acetylation as a requirement for the formation of fear memory [Cell 156:261, 2014]. The present study was designed to test the hypothesis that prenatal exposure to sub-acute levels of CPF leads to a decreased expression of mitogen- and stress- activated kinase (MSK) protein as well as a reduction in the levels of acetylated histones in the whole hippocampus. Among many substrates, MSK is a primary activator cAMP

Response Element Binding (CREB) protein, which can directly acetylate histone residues [Mol Cell Biol 21:476, 2001] and as a result, increase the expression of genes needed for memory consolidation [Neuropsychopharmacology Rev 38:62, 2013]. To test this hypothesis we exposed guinea pigs to CPF (25 mg/kg/d, sc) or peanut oil during the final 10 days of pregnancy. On postnatal day 80, brains were harvested from offspring and processed for western blots and immunohistochemistry. Total MSK protein expression in the dentate gyrus via immunohistochemistry and levels of acetylated histone H3 in the whole hippocampus via western blot were significantly decreased in male guinea pigs that had been prenatally exposed to CPF. Disruption of the epigenome may contribute to the neurological deficits observed in those who have been developmentally exposed to sub-acute levels of CPF.

Title: *In utero* exposure to the pesticide chlorpyrifos leads to augmented gabaergic synaptic transmission and gliosis in the guinea pig hippocampus

Authors: *R. D. BURKE, E. X. ALBUQUERQUE, E. F. R. PEREIRA
Div. of Translational Toxicology, Dept. of Epidemiology and Publ. Hlth., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Epidemiological studies have reported that the incidence of cognitive deficits is markedly high among children exposed *in utero* to organophosphorus pesticides, including chlorpyrifos (CPF) [Neurotoxicol Teratol 34:534, 20121]. Studies of animal models have suggested that cognitive impairments induced by prenatal exposure to CPF may result from disruption of the functional integrity of the hippocampus [Brain Res 1474:19, 2012]. Because increased GABAergic activity is known to induce cognitive impairments [Psychopharmacology 145:213, 1999], we hypothesized that GABAergic transmission in the CA1 field of the hippocampus increases as a result of prenatal exposure to CPF. To test this hypothesis, we

recorded inhibitory and excitatory postsynaptic currents (IPSCs and EPSCs) from CA1 pyramidal neurons in hippocampal slices from adult male guinea pigs that were born to dams injected with CPF (25 mg/kg/day) or vehicle (peanut oil) during the last ten days of gestation. This CPF dose regimen caused no overt signs of maternal toxicity and resulted in ca. 40% red blood cell acetylcholinesterase inhibition in newborn guinea pigs. Spontaneous and miniature IPSC frequencies were higher in CPF-exposed than in control guinea pigs, while spontaneous and miniature EPSCs were comparable between treatment groups. Western blotting performed on protein extracts from the hippocampi of guinea pigs used in the electrophysiological experiments revealed that prenatal exposure to CPF had no significant effect on the expression of cellular markers of specific interneuron populations and reduced the expression of glutamic acid decarboxylase, an enzyme that catalyzes GABA synthesis. As such, the enhanced GABAergic transmission in the hippocampus of CPF-exposed animals is unlikely due to an increased number of interneurons and/or increased synthesis of GABA. However, expression of glial fibrillary acidic protein, an astrocyte marker, was significantly increased in the hippocampus of the guinea pigs that had been prenatally exposed to CPF. Given earlier reports that astrocytes promote the development of inhibitory synapses in the hippocampus [J Neurosci 25:3638, 2005], it is tempting to speculate that gliosis takes place and leads to an increase in GABAergic transmission that, in turn, contributes to the cognitive impairments observed later in life following prenatal exposure to CPF.

Title: Corticosterone enhances chlorpyrifos-induced neuroinflammation

Authors: *J. P. O'CALLAGHAN[1], K. A. KELLY[1], D. B. MILLER[1], S. M. LASLEY[2]
[1]NIOSH, Centers For Dis. Control and Prevention, MORGANTOWN, WV; [2]U Illinois Coll Med., Peoria, IL

Abstract: Elevated expression of proinflammatory mediators in the CNS serves as the basis for normal and pathophysiological neuroinflammation. For example, the enhanced expression of proinflammatory cytokines and chemokines such as TNF-α, IL-1β, IL-6 and CCL2 may underlie

the general malaise termed sickness behavior as well as depression and can affect and contribute to a risk of neurodegeneration in affected individuals. Chemical exposures that increase the degree or duration of proinflammatory responses in the CNS may lead to more severe symptoms and consequences of neuroinflammation. Our prior data indicate that acute exposure of the C57Bl6/J mouse to the irreversible cholinesterase inhibitor, diisopropylfluorophosphate (DFP), results in a neuroinflammatory response in multiple brain regions, as evidenced by enhanced expression of a large variety of proinflammatory cytokines over a 12-hr post exposure period. Surprisingly, treatment with anti-inflammatory glucocorticoid, corticosterone (CORT), enhanced rather than suppressed DFP-induced neuroinflammation. These findings suggested that CORT might serve as a stressor surrogate to "prime" the neuroinflammatory response to workplace and environmentally relevant exposures to organophosphates, such as the widely used pesticide, chlorpyrifos (CPF). Here, we administered CPF (8 mg/kg, i.p.) with and without prior CORT (400 μg/ml in the drinking water for 4 days) to C57Bl6/J male mice. As with DFP, CPF alone caused neuroinflammation (increases in mRNA for TNF-α, LIF, CCL2 and OSM) at 6 hrs. post dosing. These effects were markedly enhanced by the prior exposure to CORT and broadened to include another cytokine (IL-1β). These findings suggest that stressors experienced by pesticide applicators and other workers exposed to CPF will contribute to a neuroinflammatory response of yet to be characterized duration or severity. Abstract: Galantamine, a reversible acetylcholinesterase inhibitor currently approved for treatment of Alzheimer's disease, has emerged as an effective antidote against the toxicity of organophosphorus (OP) nerve agents, including sarin (Albuquerque et al., PNAS 103: 13220, 2006). Here, we analyzed the pharmacokinetic profile of galantamine in young adult male rats that received the following treatments: (i) galantamine (1, 3, or 6 mg/kg, im); (ii) atropine (0.5 mg/kg, im)-plus-pralidoxime (25 mg/kg, im) followed 10 min later by diazepam (0.072 mg/kg, im) and galantamine (1, 3, or 6 mg/kg); or (iii) 0.8xLD50 sarin followed 1 min later by atropine-plus-pralidoxime and 10 min later by diazepam and galantamine (3 mg/kg). Blood was collected at various time points from a jugular vein catheter into heparinized ependorf tubes. Plasma concentrations of galantamine were determined by means of high-performance liquid chromatography as described in Albuquerque et al. (2006). The area under the plasma concentration vs. time curve (AUC), half-life (1/2), maximum plasma concentration of galantamine (Cmax), and time to reach Cmax (Tmax) were evaluated through noncompartmental pharmacokinetic analysis using the software Kinetica 5.0 (Adept Scientific Ltd, Herts, UK). Table 1 shows the values of these parameters for each dose of galantamine. Treatment of the rats with drugs used in the standard care of OP intoxication, specifically the muscarinic receptor antagonist atropine, the cholinesterase reactivator pralidoxime, and the anticonvulsant diazepam, had no significant effect on the pharmacokinetics of galantamine. Likewise, the pharmacokinetics of galantamine was not affected by exposure of the rats to 0.8xLD50 sarin. These findings are far-reaching for the evaluation of galantamine as a potential neuroprotecting agent against the immediate and delayed toxicity of sarin, as they demonstrate that the *in vivo* disposition of galantamine is not affected by ancillary standard-care therapies normally used to halt the acute cholinergic crisis induced by sarin or by sarin itself.

	Galantamine (mg/kg, im)		
	1	3	6
Cmax (µg/ml)	0.41 ± 0.10	0.92 ± 0.28	1.78 ± 0.55
Tmax (min)	5.92 ± 3.02	8.33 ± 4.92	10.5 ± 5.22
AUC (µg/ml.min)	29.7 ± 6.43	58.3 ± 12.8	133.6 ± 33.0
t1/2 (min)	51.2 ± 27.7	63.2 ± 27.3	77.2 ± 24.2

Table 1. Pharmacokinetics of galantamine in adult male rats. Data are mean ± SD of results from 10 animals per treatment.

Title: Long-lasting histone acetylation of pyramidal neurons are detected in the hippocampus of young adult guinea pigs exposed *in utero* to the organophosphorus pesticide chlorpyrifos

Authors: *W. R. RANDALL[1], E. F. R. PEREIRA[2], E. X. ALBUQUERQUE[2]
[1]Pharmacol., [2]Div. of Translational Toxicology, Dept. of Epidemiology and Publ. Hlth., Univ. Maryland Sch. Med., Baltimore, MD

Abstract: Abstract: Organophosphorus (OP) pesticides such as chlorpyrifos (CPF) and malathion are among the most heavily used pest control agents worldwide. Epidemiological data indicate that OP pesticides are toxic to the developing human brain. In-utero exposure to OP pesticides has been linked to delayed mental development in young children as well as autism spectrum disorders and attention deficit hyperactivity. Although acute toxicity of OP pesticides results primarily from the rapid inhibition of acetylcholinesterase, the delayed toxicity is more likely related to long-term changes in gene expression. We hypothesize that *in utero* exposure to CPF alters epigenetic mechanisms, particularly histone modifications, that induce changes in the expression of genes known to control higher brain functions. To test this hypothesis, we used guinea pigs, a precocious rodent that mimics many characteristics of human OP intoxication. Pregnant guinea pigs were injected subcutaneously once daily with 25 mg/kg CPF or with peanut oil (the CPF vehicle) for 10 days starting on gestation day 50-53. Guinea pigs generally delivered their pups at GD65-67. On post-natal day 80, animals were euthanized and their brains were removed and processed for immunohistochemistry using antibodies to acetylated histones and histone deacetylase2 (HDAC2). Levels of acetylated histone H2B and acetylated histone H3 were altered in pyramidal cells of the hippocampal CA1 region in animals developmentally exposed to CPF *in utero* than in CA1 pyramidal cells of the controls whose mothers were given peanut oil diluent. Previous studies indicated that the expression of p38 kinase was significantly higher in the brains of animals developmentally exposed to CPF than in the brains of control animals. This is noteworthy because p38 is one of the kinases that activates mitogen- and stress-activated kinases 1 and 2 (MSK1/2), which have been identified as a principal histone H3 kinase and in mediating histone H3 acetylation. Together these results suggest that exposure to CPF during early development produces epigenetic modifications in the acetylation of histones H2B

and H3, possibly though activation of histone H3 acetylase through p38 signaling that could lead to long-term changes in gene expression accompanying the neuronal abnormalities observed in the deficits in cognition.

Title: Comparison of brain injury following soman exposure by inhalation and subcutaneous injection

Authors: *R. K. KAN, J. A. LEUSCHNER, B. J. WONG, M. W. PERKINS, T. L. DAO, J. L. DEVORAK, L. J. SHUMWAY, A. M. RODRIGUEZ, A. M. SCIUTO

Abstract: The most likely route of exposure to the chemical warfare nerve agents (CWNAs) is inhalation. Animals subcutaneously injected to a convulsive dose of the CWNA soman developed severe brain damage in different regions of the limbic structure. The present study was designed to compare the magnitude of brain injury following inhalation and subcutaneous exposure to the CWNA soman. Untreated, non-anesthetized rats were exposed to 600 mg X min/m^3 of soman vapor containing perfluorohexane (PFH). Control rats were exposed to PFH. Rats designated for subcutaneous exposure were pretreated with HI-6 (125 mg/kg, ip) 30 min prior to soman challenge (180 ug/kg, sc). At 1 min after soman injection, rats were given atropine methylnitrate (AMN; 2.0 mg/kg, im). HI-6 and AMN were given to increase survival without affecting the development of convulsions. Control rats received HI-6, saline instead of soman and AMN. All 24 hr survivors were anesthetized and perfused with saline, followed by 10% formalin. Brains were cut into 3 mm slices and then processed in paraffin. Serial sections were cut at 5 μm and then stained with hematoxylin and eosin for neuropathological evaluation. Rats that developed convulsions after inhalation and subcutaneous exposure had severe brain injury in the piriform cortex, amygdala, thalamus, dentate hilus and neocortex. Rats that did not convulse were free of neuropathology. The results indicate that regardless of route of exposure,

soman causes convulsions and brain injury. In addition, our results solidify the notion that convulsions are a primary pathogenic factor of brain injury since no brain injury was observed in non-convulsing rats. Both exposure routes are suitable for studying CWNA-induced neurological toxicity and brain injury and evaluating potential countermeasures.

Title: MicroRNA expression profiling reveals mRNA regulating specific signaling pathways in ventral hippocampus following nerve agent exposure

Authors: *J. M. PIZARRO[1], T. L. DAO[2], J. A. LEUSCHNER[2], S. W. KASKI[2], L. J. SHUMWAY[2], C. R. BRAUE[2], R. K. KAN[2]

Abstract: The ventral hippocampus has been shown to be more susceptible to seizure and nerve agent-induced neuropathology than the dorsal hippocampus. Therefore, the ventral hippocampus is the ideal brain region in which to study the role of microRNA and identify the microRNA-mRNA signature involved in soman-induced brain injury. Rats were pretreated with HI-6 (125 mg/kg, ip) 30 min prior to soman injection (180 ug/kg, sc). At 1 min after soman challenge, rats were given atropine methylnitrate (2.0 mg/kg, im) to reduce peripheral toxicity. At 1 hr, 3 hrs, 6 hrs, 12 hrs and 24 hrs after the onset of convulsions, rats were anesthetized, and the ventral hippocampi were dissected for investigating mRNA targets of differentially expressed miRNAs. The results showed an upregulation of a distinct set of miRNAs at different times after the onset of soman-induced convulsions. Among the significantly differentially expressed miRNAs, miR-16, miR-21, miR-29b, miR-30e, miR-34a, miR-124, miR-135b, miR-140, miR-142-3p, miR-181c, miR-212, miR-215, miR-411, and miR-503 were upregulated and are associated with the

regulation of neuronal death. In addition, a number of miRNA target genes were identified to be involved in calcium, chemokine, cytokine-cytokine receptor interaction, MAPK, mTOR, neurotrophin, p53 and Toll-like receptor signaling pathways. The interplay between miRNAs and their mRNAs involving neuronal death and the above signaling pathways could be important in soman-induced brain injury development. This study is the first to investigate the role of miRNAs and their mRNA targets in the pathogenesis of brain injury after exposure to the chemical warfare agent soman

Title: Effects of genetic liability to schizophrenia on intrinsic functional connectivity in the language network

Authors: ***S.-Y. KIM**[1], J.-W. HUR[2], Y. YOON[1], C. LEE[1], J. KWON[3]
[1]Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of; [3]Dept. of Neuropsychiatry, [2]Seoul Natl. Univ. Hosp., Seoul, Korea, Republic of

Abstract: Language dysfunction is one of the core features of schizophrenia (Li et al., 2009). Abnormal language processing in schizophrenia has also been demonstrated at the neural level, including aberrant neural connectivity between inferior frontal (Broca's area) and superior temporal (Wernicke's area) gyri in the patients. Using resting-state functional magnetic resonance imaging (rs-fMRI), the current study investigated effects of genetic liability to schizophrenia on intrinsic functional connectivity of the language network. Twenty nine patients with first-episode psychosis (FEP), 26 healthy individuals with genetic high risk to schizophrenia (GHR), and 51 age-matched healthy controls (HC) underwent rs-fMRI scans. For members of the GHR group, the Family Interview for Genetic Studies was used to investigate their family history of psychiatric disorders, and a quantitative measure of genetic liability was calculated for each participant to model likely exposure to genetic risk for schizophrenia (i.e., genetic liability

scale: GLS). Rs-fMRI scans were analyzed using CONN toolbox of SPM8 to determine intrinsic functional connections between brain regions. Broca's area (i.e., the pars opercularis and pars triangularis of the inferior frontal gyrus (IFG)) was utilized as a seed region to examine functional connectivity of the language network in each participant. The results showed strong functional connectivity between the seed area and language-related brain regions in HCs, including the bilateral IFG and the bilateral superior and middle temporal gyri (STG and MTG). Critically, we found significant hypo-connectivity between Broca's area and other language-related regions in both FEP and GHR groups compared to HCs. Specifically, patients showed significantly reduced connectivity between Broca's area and bilateral fronto-temporal areas. Compared to HCs, the GHR group showed significant hypo-connectivity between Broca's area and Wernicke's area in the left hemisphere. Importantly, a multiple regression analysis with the GLS as an independent factor in the GHR group revealed a significant effect of genetic liability to schizophrenia on functional connectivity between these two language areas: the greater the genetic liability in a GHR individual, the lesser the connectivity between Broca's area (BA44/45) and Wernicke's area (BA37) ($r=-.62$, $R^2=.38$, $p<.001$). In conclusion, the current findings suggest that aberrant functional connections in the left hemisphere language pathway may underlie an inherited vulnerability for schizophrenia, independent of medication or clinical symptom status.

Title: Exploring neuropathological deficits and new drug targets for major psychiatric disorders using the Stanley Neuropathology Consortium datasets and RNA-Seq data

Authors: *S. KIM
Stanley Med. Res. Inst., Rockville, MD

Abstract: The Stanley Neuropathology Consortium Integrative Database (SNCID, http://sncid.stanleyresearch.org) is a data-mining tool that includes 3586 neuropathological data sets as well as raw RNA-Seq data measured in two sample collections. The data can be used to further understand the aetiology of major psychiatric diseases and to potentially identify new

drug targets for these disorders. The two collections include the Neuropathology Consortium, which consists of 15 well-matched cases in each of four groups: schizophrenia (SCH), bipolar disorder (BPD), depression (MD) and unaffected controls (UC), and the Array Collection, which consists of 35 cases in each of three groups: SCH, BPD and UC. We reanalysed the neuropathological markers in multiple brain regions to identify those abnormalities that are shared between psychiatric disorders and those that are specific to each disorder. We then performed gene co-expression network analyses to identity the co-expression modules associated with each disease and also with abnormal markers in the hippocampus using the RNA-Seq data. Of the 2672 consortium collection data sets, 254 showed a significant abnormality in at least one disorder as compared to UCs. In the cortex, perineuronal oligodendrocytes and related markers were significantly altered in all three groups; SCH, BPD and UC whereas, the density of parvalbumin-containing neurons and related markers were significantly altered in just SCH and BPD, as compared to UCs. In the hippocampus, reelin-containing neurons and related markers were abnormal in the all three disease groups, whereas the density of parvalbumin-containing neurons and related markers were altered in SCH and BPD only. Co-expression modules that included immune and inflammation related genes were associated with SCH and BPD but not with MD. The immune/inflammation modules were also associated with the density of parvalbumin-containing neurons. The increased expression of immune and inflammation-related genes in the hippocampus may contribute to the deficits in the parvalbumin-containing neurons in SCH and BPD. The data further supports the possibility that drugs that impact the immune/inflammation system may be beneficial for the treatment of SCH and BPD.

Title: Cis-acting regulation of a novel AS3MT transcript by a genome-wide supported risk variant for schizophrenia

Authors: *M. LI, R. TAO, A. E. JAFFE, F. ZHANG, C. LI, J. E. KLEINMAN, T. M. HYDE, J. SHIN, D. R. WEINBERGER
Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: Background: Recent meta-analyses of genome-wide association studies for schizophrenia have reported strong associations of single nucleotide polymorphisms (SNPs) spanning Chromosome 10q24.32, in an about 757.5 kb genomic region covering numerous genes. However, little is known regarding the molecular mechanisms of the risk association. The top significant associated SNP rs7085104 is located about 500bp upstream of the classic translation start site of the arsenic (+3 oxidation state) methyltransferase (AS3MT) gene. This SNP has also shown associations with bipolar disorder (BPD) and major depressive disorder (MDD). **Methods:** Using RNA-Seq techniques (Hi Seq 2000, 80-120M 100 bp paired end reads) in the dorsolateral prefrontal cortex (DLPFC) of postmortem human brain tissue from normal controls (N=167), patients with schizophrenia (N=107), BPD (N=22) and MDD (N=96), and normal fetal brain (N=25) from a mixed race sample. **Results:** The SNP rs7085104 was significantly associated with AS3MT gene-level expression in healthy controls ($p<1.0\times10\text{-}4$). No other genes in the LD region showed significant expression associations with rs7085104. Furthermore, we identified novel junction reads within AS3MT, spanning from exons 1 to 4, but missing exons 2 and 3 (named junctiond2d3). The risk allele was associated with higher junctiond2d3 expression ($p<1.0\times10\text{-}3$), which is consistent with the diagnostic association of higher expression in patients ($p<1.0\times10\text{-}3$). In silico analysis predicted a truncated AS3MT transcript lacking exons 2 and 3 (denoted AS3MTd2d3), with a novel KOZAK sequence and translation start site in exon 4, which may encode a shortened protein lacking 102 amino acids. **Conclusions:** Our data suggest that the genetic risk variants in Chr.10q24.32 have potential cis-regulatory transcriptional effects on AS3MT,and more specifically, the truncated transcript AS3MTd2d3, which should be explored in future biological studies

Title: The DNA methylation profiles of the brain-derived neurotrophic factor (BDNF) gene are potent diagnostic biomarker in psychiatric disorders

Authors: *M. FUCHIKAMI[1], S. OKADA[1], S. YAMAWAKI[1], S. MORINOBU[2]
[1]Hiroshima University, Dept. of Psychiatry, Hiroshima, Hiroshima, Japan; [2]Dept. of Neuropsychiatry, Kochi Univ., Nankoku, Japan

Abstract: Major depression, because of its recurring and life-threatening nature, is one of the top 10 diseases for global disease burden. Major depression is still diagnosed on the basis of clinical symptoms in patients. The search for specific biological markers is of great importance to advance the method of diagnosis for depression. We examined the methylation profile of 2 CpG islands (I and IV) at the promoters of the brain-derived neurotrophic factor (BDNF) gene, which is well known to be involved in the pathophysiology of depression. We analyzed genomic DNA from peripheral blood of 20 Japanese patients with major depression or schizophrenia, and 18 healthy subjects to identify an appropriate epigenetic biomarker to aid in the establishment of an objective system for the diagnosis of depression. Methylation rates at each CpG unit was measured using a MassArray® system (SEQUENOM), and 2-dimensional hierarchical clustering analyses were undertaken to determine the validity of these methylation profiles as a diagnostic biomarker. Analyses of the dendrogram from methylation profiles of CpG I, but not IV, demonstrated that classification of healthy subjects and patients at the first branch completely matched the clinical diagnosis. At the next branch, classification of depression and schizophrenia by methylation profiles of CpG I, was also in complete accordance with the clinical diagnosis. Despite the small number of subjects, our results indicate that classification based on the DNA methylation profiles of CpG I of the BDNF gene may be a valuable diagnostic biomarker for psychiatric disorders.

Abstract: Psychotic disorders such as schizophrenia and bipolar disorder are quite common, affecting 2% of the general population. However, there is yet no satisfying explanation for the biological mechanisms underlying these disorders, due to the extraordinary complexity of the brain and the difficulties inherent in studying human neurophysiology. Applying Induced Pluripotent Stem (iPS) cell technology creates the unique opportunity to study neural cell cultures of individual patients. Our goal is to establish iPS-derived neural cell cultures from families with a high incidence of psychotic disorders and compare their intrinsic neuronal properties and network properties. To avoid heterogeneity caused by the wide range of manifestations of these diseases, we focus our efforts on families. Moreover, we have established a robust neural differentiation protocol that results in mature neurons and glial cells that together form a spontaneously active network confirmed by electrophysiology and confocal imaging. In parallel, high resolution exome sequencing is performed on DNA isolated from blood samples of patients and their healthy family members to find a genetic correlate of the disease in these families.

Title: Identifying targets of neuropsychiatric disease-associated transcription factors TCF4 and ZNF804A

Authors: *V. L. REINHART, S. XI, N. MATLUCK, C. SCHUBERT, T. A. LANZ
Pfizer, Cambridge, MA

Abstract: Large numbers of candidate genes and risk loci are emerging from recent GWAS and *de novo* exome sequencing studies for schizophrenia. Among them, several transcription factors have been strongly implicated by multiple lines of genetic evidences, including common variation, de novo mutations, rare variants, and copy number variation. However, the functions of these transcription factors are largely unknown. Identifying their direct targets may provide biological context and help uncover convergent pathways for these disease-associated genes, as well as facilitate the interpretation of differential gene expression observed in post-mortem brain samples from patients. The present study sought to uncover neuronal targets of two such transcription factors: transcription factor 4 (TCF4) and zinc finger protein 804A (ZNF804A). Myc-tagged constructs for each gene were over-expressed in HEK cells, and fixed lysates were analyzed by ChIP-sequencing against myc and RNApolII to identify the transcription factor binding motif and actively translating targets of the transcription factors. In parallel, viral shRNA constructs were developed against each gene and used to transduce rat primary cortical neurons at 7 DIV. After 14 DIV, total RNA was extracted and analyzed by RNA-sequencing. Genes overlapping in both the ChIP-sequencing and RNA-sequencing datasets were analyzed using Ingenuity Pathway Analysis, and select genes were validated in replicate neuronal experiments by qRT-PCR. TCF4 targets included several genes involved in actin dynamics (e.g. LIMK1, PAK4, MYLK), ERK signaling (e.g. MAPK3). Pathway analysis highlighted inflammatory cascades for both TCF4 and ZNF804A knockdown in primary neurons. Pathway analysis, gene targets and binding motifs for both transcript factors will be presented in full. Our data suggest that these GWAS-associated transcription factors impact pathways previously observed to be dysregulated in post-mortem brains from subjects with schizophrenia.

Med., Univ. of Oslo, Oslo, Norway; [8]Div. of Mental Hlth. and Addiction, [9]Med. Genet., Oslo Univ. Hosp., Oslo, Norway

Abstract: In polygenic traits and diseases, such as schizophrenia (SCZ), individual genetic loci account for only a very small portion of the phenotypic variance. Therefore, in addition to increasing the sample size, a key to improved yield from SCZ genome-wide association studies (GWAS) is the application of refined statistical methods, providing greater power for detection of small genetic effects, for a given sample size. To this end, we have recently developed a novel statistical methodology that improves power for gene discovery in GWAS by using a priori information about relative "enrichment" of statistical association based on genomic annotations (1). Application of this approach to summary statistics from the published Psychiatric Genomics Consortium SCZ GWAS indicated approximately three-fold increase in gene discovery over standard methods. The analysis revealed gene loci spanning multiple biological themes including numerous receptors for neurotransmitters and ion channels. Each gene has been discovered individually and independently of its function. The presence of hits across different neurotransmitter systems and channels for various ions begs the question of whether these hits reflect independent mechanisms, or are tied together through common biological pathways and

functions. To address this question, we have examined the identified gene loci for the presence of putative elements of previously described “neurotransmitter integration network” (2). Our results show that many of these genes indeed are mapped onto a common network, where the signaling cascades triggered by activation of GPCRs can modulate ion channels and ionotropic receptors. This may be achieved by activation of the intracellular kinases and phosphatases ensuring the appropriate level of excitability, and thus neuronal output, given the intensity and modality of the input. Taken together, the spectrum of molecular risk factors identified in our study supports the concept of SCZ as an “associative” disorder: a breakdown in the communication across different slow and fast neurotransmitter systems through intracellular signaling pathways. This emergent model may unify a number of currently competing hypotheses, e.g., Dopaminergic, Glutamatergic, Calcium and (a more general) Second Messenger Hypothesis and explain why effective antipsychotic drugs have a “rich pharmacology”, i.e. affinity for several receptors. 1.Schork AJ, et al. Title: No abnormal hexanucleotide repeat expansion of C9ORF72 in Japanese schizophrenia patients

Authors: *Y. YOSHINO[1,2], Y. MORI[2], S. OCHI[2], S.-I. UENO[2]
[1]Neuropsychiatry, Toon, Japan; [2]Neuropsychiatry, Ehime Univ. Grad. Sch. of Med., Ehime, Japan

Abstract: Abnormal hexanucleotide repeat expansion of C9ORF72 is known to cause neurodegenerative disorders such as frontotemporal dementia. Additionally, patients with psychotic symptoms are more likely to have abnormal hexanucleotide repeat expansion than are patients without them. We investigated the hexanucleotide repeat sizes of C9ORF72 in 466 Japanese schizophrenia patients. We found no abnormal hexanucleotide repeat expansion. In

conclusion, C9ORF72 may not be responsible for schizophrenia susceptibility in the Japanese population.

Title: Blood homocysteine and schizophrenia evaluated by a Mendelian randomization analysis

Authors: ***M. KINOSHITA**[1], S. NUMATA[1], A. TAJIMA[2], A. NISHI[1], I. IMOTO[2], T. OHMORI[1]
[2]Dept. of Human Genet., [1]The Univ. of Tokushima Grad. School/ Inst. of Hlth. Biosci., Tokushima/Tokushima, Japan

Abstract: Objective: Observational studies have potential limitations, such as confounding, reverse causation, associative election bias, and attenuation by errors (Davey Smith and Ebrahim, 2005). Mendelian randomization, which used genetic variants as instrumental variables for exposures to overcome these problems, is a method for assessing causal relationship in epidemiological studies (Taylor et al., 2013). We recently demonstrated that increased blood homocysteine levels may be associated with an increased risk of developing schizophrenia in the Japanese population by conducting the Mendelian randomization approach (Nishi et al., 2014). However, it is still unclear that the association of blood homocysteine levels and a risk of schizophrenia in the world-wide population. In this study, we investigated the association between blood homocysteine levels and schizophrenia in the world-wide population by conducting Mendelian randomization based on the MTHFR C677T polymorphism (rs1801133). Methods: To estimate the association between rs1801133 and schizophrenia, we performed a meta-analysis of 33 case-control studies with the random-effect model by ‘metafor’, an R package. A total of 10,734 cases and 14,036 controls were included in this meta-analysis. Results: The pooled per-allele odds ratio (OR) for schizophrenia was 1.1 (95% CI = 1.04-1.17; p = 1.5 x 10-3, in the random-effects model) with significant heterogeneity (I2 = 48.1%; $p < 0.05$). The funnel plot analysis indicated no evidence of publication bias in this meta-analysis ($p > 0.05$). In the Mendelian randomization analysis, we found a significant effect of homocysteine on schizophrenia risk, representing an OR of 1.82 (95% CI = 1.26-2.66; p = 1.6 x 10-3) for

schizophrenia per 1-SD increase in homocysteine, when using a pooled estimate of per-allele standardized β coefficient (0.16) of the effect of rs1801133 on homocysteine from a recent meta-analysis of genome-wide association studies comprising 44,147 individuals. Conclusions: Our study indicated that elevated blood homocysteine levels may increase the risk of schizophrenia in the world-wide population. Further replication studies will be needed in larger samples using multiple genetic variants.

Title: Messenger and microRNA expression profiling in neurons and oligodendrocytes in schizophrenia and Parkinson's disease

Authors: *S. A. MAUNEY[1], K. C. SONNTAG[2,3], T.-U. W. WOO[1,3,4]
[1]Lab. for cellular neuropathology, [2]Psychiatry, McLean Hosp., Belmont, MA; [3]Psychiatry, Harvard Med. Sch., Boston, MA; [4]Psychiatry, Beth Israel Deaconess Med. Ctr., Boston, MA

Abstract: The human brain is an extraordinarily complex structure consisting of heterogeneous subsets of neurons that mediate distinct aspects of information processing. Disturbances of these neurons compromise the functional integrity of the connectional architecture of the brain, resulting in various psychiatric and neurological disorders. To explore how the molecular integrity of various neural subtypes might be compromised in psychiatric and neurodegenerative diseases, we determined the mRNA and miRNA expression profiles of pyramidal, parvalbumin (PV)-immunoreactive, and dopamine neurons, and oligodendrocytes in schizophrenia (SZ) or Parkinson's disease (PD), and ascertained the convergence and specificity of the transcriptional networks and signaling cascades that are altered in these disorders In pyramidal neurons from the

superior temporal cortex in SZ, we found differentially expressed mRNAs that belong to the transforming growth factor beta and the bone morphogenetic proteins signaling pathways. In the PV neurons from the same region, differentially expressed transcripts were associated with WNT, NOTCH, and PGE2 signaling and transcription factors such as LHX6, in addition to genes that regulate cell cycle and apoptosis. In PD dopamine neurons of the substantia nigra, there was a predominant down-regulation of mRNAs, including PARK gene family members and genes associated with programmed cell death, mitochondrial dysfunction, neurotransmitter and ion channel receptors, as well as an upregulation of transcripts that are involved in neuronal survival mechanisms. We also assessed oligodendrocytes from SZ subjects, which exhibited a distinct expression pattern that is consistent with dysregulation of cell cycle events. In addition to the mRNA expression profiles, we identified a set of differentially expressed miRNAs in both SZ and PD. Enrichment analysis of their predicted targets or from negative correlation analyses, revealed an association of miRNAs with dysregulated signaling pathways, raising an interesting possibility that dysfunction of neurons or oligodendrocytes in SZ and PD may in part be mediated by a concerted dysregulation of gene network functions as a result of the altered expression of miRNAs. Our data show mostly distinct, but also overlapping dysfunctional gene and miRNA networks between different neural cell populations in SZ and late stage PD, and provide a platform for future downstream analyses aiming to understand the disease-specific and shared molecular processes of individual neuronal dysfunction in these disorders.

Title: Clusterin immunoreactivity in the cerebral cortex in subjects with schizophrenia

Authors: *K. M. ATHANAS[1], S. DASDELEN[1], T.-U. W. WOO[1,2,3]
[1]Lab. for Cell. and Mol. Neuropathology, McLean Hosp., Belmont, MA; [2]Dept. of Psychiatry,

Beth Israel Deaconess Med. Ctr., Boston, MA; [3]Dept. of Psychiatry, Harvard Med. Sch., Boston, MA

Abstract: Clusterin is a multifunctional disulfide-linked heterodimeric chaperone protein that is involved in many biological processes. Several studies have found clusterin dysregulation to contribute to a number of disorders, from tumorigenesis to neurodegenerative states, such as Alzheimer's disease, by acting to either promote or inhibit oxidative stress, apoptosis, synaptic plasticity, amongst other functions. Because of our recent observations that the mRNA that encodes clusterin was upregulated by more than 2-fold in both pyramidal and parvalbumin-containing inhibitory neurons in the cerebral cortex in schizophrenia, in this study, we address the hypothesis that clusterin protein expression will also be increased in subjects with schizophrenia. In a cohort of postmortem brains from 20 schizophrenic and 20 demographically matched normal control subjects obtained from the Harvard Brain Tissue Resource Center, we immunohistochemically visualize the cellular localization of clusterin in the dorsolateral prefrontal cortex (Brodmann's area 9) and primary visual cortex (Brodmann's area 17). Qualitative examination reveals that clusterin is expressed in various cell types, including both pyramidal and non-pyramidal neurons in addition to glial cells across all cortical layers. Quantification of the densities of clusterin-immunoreactive cell subtypes is underway. Findings of this study will determine if clusterin expression is disturbed in schizophrenia and will thereby shed light on the possible mechanistic link between this protein and known pathophysiological processes of the illness, such as oxidative stress, cellular injury and synaptic deficit.

Title: Serine Racemase (SRR) and schizophrenia risk: Functional genomic characterization of schizophrenia GWAS risk variants

Authors: *R. BIRNBAUM[1], F. ZHANG[2], T. M. HYDE[2,3], J. E. KLEINMAN[2], D. R. WEINBERGER[1,4]

[1]Lieber Inst. For Brain Develop., Baltimore, MD; [2]Lieber Inst. for Brain Develop., Baltimore, MD; [3]Psychiatry, Neurology, Neurosci., [4]Psychiatry, Neurology, Neuroscience, Inst. of Genet. Med., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Background: Converging evidence supports the hypothesis that N-methyl-D-aspartate(NMDA)-type glutamate receptor hypofunction is pathogenic in schizophrenia. D-serine, a co-agonist required for full activation of the NMDA receptor, is synthesized by serine racemase. Recently SRR rs423957 was reported to be associated with schizophrenia in a PGC meta-analysis (p-value =5.69x10-8, OR=1.1) (Ripke et al Nat Gen 2013). The current analysis investigated the main effect of the risk associated SNP and correlated SNPs on SRR abundance by RNA Sequencing methodology. We also investigated the effect of the risk associated SNP and correlated SNPs on antipsychotic drug response. **Methods**: RNA sequencing was performed on post-mortem PFC grey matter for 101 Caucasian controls (27 females, 38 +/- 23 years, 74 males, 36 +/-18 years) and 64 SCZ cases (13 females, 53+/- 18 years, 51 males, 42 +/- 13 years). Samples were enriched with PCR to create a cDNA library for high throughput sequencing. Pair-end reads of cDNA sequences were aligned the human genome reference (TopHat v2.0.4). Genotype effect on time to discontinuation of medication, the primary outcome measure in the CATIE study, was determined using the Cox proportional hazards ratio model, while controlling for age, sex, duration of illness, and drug clearance. **Results**: SRR DLPFC expression was reduced in schizophrenia cases compared to controls ($F(1,117)=1.2$, $p=0.035$). The risk SNP rs423957 was associated with decreased SRR abundance in CAUC controls (p-value=0.03) and in CAUC schizophrenia samples (p-value=0.0023), and SNPs in LD with rs423957 showed highly significant association with SRR abundance. For an alternative proxy SNP in LD ($r2=0.89$) with the GWAS SNP, there was a hazard ratio of 2 for the minor allele in a pharmacogenetic analysis of time to discontinuation of antipsychotic medication. **Conclusions**: The current results of decreased SRR mRNA associated schizophrenia confirm previous reports of decreased D-serine associated with schizophrenia. The cis-eQTL effect of the PGC risk SNP and of variants in LD with it, suggest a putative mechanism of risk. Risk variant association with other intermediate phenotypes, including neuroimaging and cognition phenotypes, pertinent to schizophrenia risk, is ongoing.

Title: Maternal infection in mice leads different DNA methylation and gene expression between male and female offspring

Authors: *Z. YU[1], R. FUNAYAMA[2], K. UENO[3], N. NARIAI[3], K. KOJIMA[3], C. ONO[1], Y. KASAHARA[1], Y. KIKUCHI[1], M. NAGASAKI[3], K. NAKAYAMA[2], H. TOMITA[1,4]
[2]Div. of Cell Proliferation, Grad. Sch. of Med., [3]Div. of Biomed. Information Analysis, Tohoku Med. Megabank Organization., [4]Tohoku Med. Megabank Organization, [1]Tohoku Univ., Sendai, Japan

Abstract: Background: Evidence suggests that both genetic and environmental factors are associated with schizophrenia. Environmental components, such as maternal immune responses to infection during pregnancy have been considered a risk factor for schizophrenia. Previous mouse studies showed that maternal immune challenge induced schizophrenia-related abnormal behavior in adults offspring. Additionally, postmortem studies have reported the alterations in gene expression and DNA methylation in schizophrenia. Taken together, maternal infection may influence genetic expression and DNA methylation during postnatal brain development, which involve in the pathogeneses of schizophrenia. Purpose: To investigate the transcriptional regulations affected by maternal immune challenge in fetal brain by microarray and ChIP-seq, which remains throughout development and cause behavioral abnormality in adult. Methods: Poly I:C or PBS was administered to pregnant mice (C57BL/6) every 6 consecutive days from E14 to E19. The offspring were separated from their mothers after 3 weeks and divided into 4 groups: `Poly I:C-female`, `Poly I:C-male`, `PBS-female` and `PBS-male` -mice groups. After behavioral evaluations, total RNA from prefrontal cortex of adults offspring were applied on Illumina Mouse WG-6 V2 Beadchips to analyze mRNA expression profiling. Methylated DNA was isolated from prefrontal cortex using MethylMiner Methylated DNA Enrichment Kit. Illumina Genome Analyzer IIx was used to analyze DNA methylation profiling. Sequenced reads were mapped to the mouse genome (UCSC mm9), and target genes-associated peak calls were determined with MACS and GREAT software. Results and conclusion: Gender difference was observed in PPI study; Poly I:C-male mice showed decreased %PPI only in 71 dB ($P<0.05$), whereas Poly I:C-female mice showed significantly decreased %PPI in all of 68 dB ($P<0.01$), 71 dB ($P<0.001$) and 77 dB ($P<0.001$). Specific gene expression profiles and methylation patterns were identified in both of Poly I:C-male and -female mice comparing with its PBS-control, respectively. Poly I:C-female mice showed more genes transcript alterations and DNA hypermethylation than male counterparts. Data suggest molecular mechanisms underlying the impact of maternal immune response to the fetal brain, which is preserved until adult and causes behavioral abnormality in gender-specific manner.

Title: No evidence of association of schizophrenia-risk genotype in rs1625579 with expression of mir137 in postmortem human prefrontal cortex

Authors: N. FENG, V. IMAMOVIC, *B. K. LIPSKA
NIH/NIMH, BETHESDA, MD

Abstract: A large genome-wide association study identified a locus on chr 1p21.3, rs1625579, located in the intronic region of MIR137 host gene, as strongly associated with schizophrenia, and later with autism spectrum disorder. In subsequent studies, a risk-associated common allele (T) was shown to predict the severity of cognitive deficits in schizophrenia, regional brain activity, and changes in brain structure. We sought to determine the effects of rs1625579 on molecular phenotype by analyzing expression of MIR137 mRNA in the dorsolateral prefrontal cortex (DLPFC) of 286 subjects (198 controls and 88 patients with schizophrenia), ranging in age from birth through old age (over 80 years old). We also examined separately the effect of diagnosis in 231 adult subjects (over 18 years old, 143 controls and 88 subjects with schizophrenia). RNA was extracted using miRNeasy Kit (QIAGEN). Reverse transcription was conducted using specific miRNA primers (ABI). TaqMan qPCR assay measured MIR137 expression levels that were normalized to a geometric mean of U6 and U44 small nucleolar RNA (snoRNA). The genotypes at rs1625579 were obtained using Illumina BeadArrays (1M). We used analysis of covariance (ANCOVA) with genotype and diagnosis as categorical variables, and age, sex, pH, postmortem interval (PMI) and RNA integrity (RIN) as covariates. We also conducted ANCOVA with race (157 African Americans and 71 Caucasians) and genotype as independent variables. Expression of MIR137 mRNA slightly decreased with age throughout the lifespan in all subjects ($r=-0.35$, $p=0.0000$), and in controls and schizophrenia patients when analyzed separately ($r=-0.36$, $p=0.0000$, and $r=-0.22$, $p=0.03$, respectively). There was no significant effect of genotype at rs1625579 in all subjects ($F=0.3$, $p=0.7$) and when in controls

were analyzed separately (F=1.5, p=0.2). There was also no significant effect of diagnosis (F=0.08, p=0.8) on expression of MIR137 mRNA, and no significant genotype by diagnosis interaction. Moreover, we did not detect a significant effect of race, and there was no race by genotype interaction on MIR137 mRNA expression (F=0.3, p=0.8). In conclusion, we did not find a difference in MIR137 expression between controls and patients with schizophrenia or a significant effect of genotype at rs1625579 on MIR137 mRNA expression in the DLPFC. The molecular mechanisms underlying clinical association with schizophrenia remain elusive.

Title: Common variants for schizophrenia ascertained through genome-wide association with a cognitive endophenotype

Authors: ***A. B. ZHEUTLIN**[1], R. G. FORTGANG[1], K. M. HAUT[1], F. W. SABB[2], R. M. BILDER[3], N. FREIMER[4], E. D. LONDON[4], T. D. CANNON[1]
[1]Psychology, Yale Univ., New Haven, CT; [2]Interdepartmental Program for Neurosci., [3]Psychology, [4]Psychiatry, Univ. of California - Los Angeles, Los Angeles, CA

Abstract: Background: Schizophrenia is highly heritable, but also genetically complex and heterogeneous, likely involving 1000s of common variants. Common variant effect sizes for any complex measure (e.g., schizophrenia, intelligence) are often too small to pass genome-wide significance, even employing extremely large samples. One approach to overcoming this lack of power is to create a polygenic risk score combining risk across SNPs (including those not meeting genome-wide thresholds for significance) and weighted individually by their effect sizes. Here, we directly tested whether polygenic variants associated with an endophenotype for schizophrenia - verbal memory performance - in healthy controls also predict memory performance in patients with schizophrenia. We also explicitly tested the implications of the

common variant, common disease model by examining the relationship between endophenotype-generated scores and schizophrenia-related risk scores in the same sample. **Methods:** Healthy controls ($N = 900$) and schizophrenia patients ($N = 58$) completed the California Verbal Learning Task, a list-learning measure of verbal memory. A bootstrapping analysis of associations between CVLT performance and common variants was run (100 iterations) in the control sample and multiple cut-points (SNPs present in 70, 80, and 90 of 100 associations) were used to calculate CVLT polygenic scores. Schizophrenia risk scores were calculated using variants identified by the Psychiatric Genomics Consortium in a large, case-control sample. **Results:** For two of the three replication/resampling cut-points, scores derived from weights based on the control sample revealed significant associations with CVLT performance in patients with schizophrenia. Lower schizophrenia risk scores were associated with higher CVLT polygenic scores (CVLT scores and performance are positively correlated) at all three replication/resampling cut-points in patients with schizophrenia. **Conclusions:** Polygenic memory scores reflecting variation in CVLT performance in healthy controls significantly predicted CVLT performance in a small sample of schizophrenia patients. This is the first demonstration, to our knowledge, of polygenic scores derived from an endophenotype-based, genome-wide association study in schizophrenia successfully predicting the same phenotype (i.e., memory performance) in an independent sample. Furthermore, the relationship between schizophrenia risk scores and CVLT-derived scores provides the first genome-wide, molecular genetic evidence of the shared etiology between episodic memory performance and schizophrenia.

Title: Exploring the genome in three dimensions in the prefrontal cortex: Discovering the functional relevance of non-coding regions of the genome

Authors: *A. C. MITCHELL[1], P. ROUSSOS[1], V. POTHULA[1], A. LESSARD[2], S. AKBARIAN[1]
[1]Psychiatry, Icahn Sch. of Med. at Mount Sinai, New York City, NY; [2]Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Less than 1.5% of the human genome encodes protein. However, vast portions of the human genome are transcriptionally and epigenetically regulated. Many noncoding regulatory DNA elements are thought to regulate the spatial organization of interphase chromosomes. Chromosomal 'loopings', for example, are pivotal for the orderly process of gene expression. They enable distal regulatory enhancer or silencer elements to interact directly with proximal promoter and transcription start sites potentially bypassing many kilobases of interspersed linear genomic sequence. To date very little is known about the regulation of these supranucleosomal structures in brain nuclei. Methods: We introduce chromosome conformation capture (3C) for brain and compare higher-order chromatin structures at schizophrenia risk loci. Results: We show that chromosome conformation capture, a widely used approach to study higher-order chromatin, is applicable to tissue collected postmortem, thereby informing about genome organization in the human brain. We highlight loops positioned at H3K4me3 marks at HLA-DRB9, HIST1H2BJ, and CACNA1C. Furthermore, we introduce circular chromosome conformation capture (4C) to detect looping interactions between specific loci and across the genome. Conclusions: We provide evidence that chromosomal loopings exist between schizophrenia risk loci at H3K4me3 marks between (1) genes, (2) intergenic SNPs and transcription start sites, and (3) transcription start sites and intronic SNPs in postmortem prefrontal cortex. Chromosomal loopings are often accompanied with the presence of histone marks. H3K4me3 ChIPseq data shows that these marks are altered at intergenic and intronic loci in schizophrenia, suggesting that intergenic chromosomal loopings may be altered in schizophrenia. We predict that the exploration of three-dimensional genome architectures and function will open up new frontiers in human brain research and psychiatric genetics and provide novel insights into the epigenetic risk architectures of regulatory noncoding DNA. This research is funded by the Brain and Behavior Research Foundation and the National Institutes of Mental Health.

Title: Association of a GWAS schizophrenia risk DRD2 locus (an established antipsychotic target) with inefficient DLPFC activation during fMRI in healthy controls and in schizophrenia

Authors: *E. RADULESCU[1], Q. CHEN[1], J. H. CALLICOTT[2], V. S. MATTAY[1], D. R. WEINBERGER[1]
[1]Lieber Inst. For Brain Develop., Baltimore, MD; [2]Clin. Brain Disorders Br., Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: Background: The D2 receptor gene (DRD2) is the only gene so far that encodes for a known antipsychotic drug target. Recent Genome-Wide Association Study (GWAS) results based on the Psychiatric GWAS Consortium (PGC) data found an association at the DRD2 locus with risk for schizophrenia. While the D2 receptor protein is an established drug target, we tested the association of the DRD2 locus (using a significant single nucleotide polymorphism- SNP, rs2514218) with a previously validated intermediate phenotype of schizophrenia [1]-right dorso-lateral prefrontal cortex (DLPFC) activation during a working memory fMRI paradigm. Methods: 128 healthy volunteers and 58 individuals with schizophrenia (DSM-IV-TR), genotyped for DRD2 rs6589377, a proxy ($r2>0.8$) for rs2514218 (the SNP significant in the GWAS data), participated in an fMRI working memory study (Nback). The subjects were matched for performance during the 2-back condition (accuracy $\geq$ 70%). Individual first-level GLM contrast images (2-back > 0-back) were analyzed within the SPM8 ANCOVA (genotype, diagnosis = between-subjects factors; age, IQ, performance, reaction time: covariates). Results were corrected for multiple comparisons at the whole-brain level and within pre-defined DLPFC regions. Results: We found a statistically significant association of rs6589377 with prefrontal engagement: the highest activation in the right DLPFC (consistent with a phenotype of inefficiency) was found for GG (homozygotes for minor-risk allele) > AG > AA (homozygotes for major allele) (cluster peak at MNI: 30 42 39, R-BA9, Z score=4.40, $p<0.001$ FWE corrected for multiple comparisons). This effect was even more pronounced in the schizophrenia individuals. No genotype x diagnosis interaction was observed. Conclusions: Our findings support the functionality of the significant DRD2 locus variation at a brain system level. Our results also support the idea that intermediate biological phenotypes associated with risk for schizophrenia may be valid biomarkers for evaluating potential antipsychotic effects of novel therapeutic agents. Title: PDE10A isoform heterogeneity and expression within the human striatum

Authors: C. MACMULLEN, K. VICK, R. PACIFICO, *R. L. DAVIS, Prof
Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Bipolar Disorder (BD) is a neuropsychiatric disorder characterized by severe mood swings that affects nearly 5.7 million American adults according to the National Institute of Mental Health. Genetic studies have associated the cAMP signaling pathway phosphodiesterase PDE10A to this disorder. PDE10A inhibitors are also under intense study as novel therapeutics for neuropsychiatric disorders. Two annotated isoforms of PDE10A, PDE10A2 and PDE10A1, differ only in alternately spliced 5' exons. These exons are separated by a large intron known to possess twelve common SNPs and eight rare SNVs associated with BD. To learn more about the genetic organization of this gene region, 5' RNA Ligase Mediated Rapid Amplification of cDNA Ends (RLM-RACE) as well as high throughput RNA sequencing studies of human striatal brain tissue were employed to uncover novel splice isoforms of PDE10A. Anti-peptide antibodies were generated to these PDE10A isoforms and their cellular distribution within mouse cortical and striatal neurons was explored using immunocytochemistry. The interactions of these isoforms were also analyzed by over-expressing the proteins in HEK293 cells. Finally, isoform specific antibodies were used in immunoprecipitation assays to illustrate the presence of these proteins within non-psychiatric disease control striatal tissue. These studies extend our current knowledge of PDE10A isoform diversity within the human striatum. They also highlight novel targets to pursue for developing anti-psychotic drug therapies.

Title: Polygenic risk scores for schizophrenia predict hippocampal function

Authors: *Q. CHEN, V. S. MATTAY, E. Y. XIAO, R. E. STRAUB, D. R. WEINBERGER
Lieber Inst. For Brain Develop., Baltimore, MD

Abstract: Introduction: In recent years, polygenic risk profile scores (RPS) are being increasingly used to indirectly measure the collective genetic effect of many weakly associated markers on the risk for a neuropsychiatric disorder and for their modulatory role on neural circuits. Modeling RPS can help to investigate the polygenic component in a trait involving markers with small effects across the whole genome or certain gene-set genetic components (ISC 2009). In the current study we used RPS to study whole genome effect on a previously validated intermediate phenotype of schizophrenia, namely altered hippocampal engagement during a simple declarative memory task. Methods: Two hundred and five healthy volunteers underwent BOLD fMRI (3T) during a simple declarative memory task (SDMT), which included incidental encoding and retrieval of visual scenes. For both the encoding and retrieval sessions, the scenes were presented in a blocked fashion, with 4 blocks of neutral scenes and 4 blocks of visual scenes alternating with 9 blocks of resting state (fixation cross hair). In the current study, we focused on the encoding phase for neutral scenes only (Rasetti & Mattay et al. 2014). RPSs were calculated for each individual as the weighted sum of the number of reference alleles on preselected markers based on PGC GWAS study (ISC 2009). Scoring thresholds include 5E-8, 0.0000001, 0.0001, 0.001, 0.01, 0.05, 0.1, 0.2, 0.5, and 1, and association testing was conducted in SPM8. Results: We found a significant inverse association between RPS and hippocampal activation for scoring thresholds of 0.01 and above. Association p values ranged from p=0.001 to p=0.003 (uncorrected). At the threshold of 0.01, RPS (24597 markers were included) accounted for 4.83% of the variance in right hippocampal activation. Conclusions: Our results show that polygenic risk profile scores for schizophrenia significantly correlated with altered hippocampal function. The relationship of higher RPS with decreased hippocampal function is consistent with our previous finding of decreased hippocampal engagement during a simple declarative memory task in patients with schizophrenia and their siblings when compared to healthy volunteers (Rasetti & Mattay et al.2014). This finding implies that a polygenic risk score approach can be used to explore the influence of the cumulative effect of risk genes on brain function, in particular on how risk genes collectively modulate neural circuits and confer risk for schizophrenia.

Title: Functional characterization of L-type Calcium channel gene CACNA1C variants implicated in mood disorder genome wide association studies

Authors: *S. S. BHAT[1], R. J. SMITH[1], M. PRASAD[2], Y. CHANG[2], T. D. GOULD[3]

Abstract: The CACNA1C gene encodes the alpha-pore forming subunit of the Ca2+ channel CaV 1.2 (L-type voltage gated). Multiple genome wide association studies (GWAS) have indicated significant association between single nucleotide polymorphisms in CACNA1C and mood disorders, as well as schizophrenia. All such SNPs are located in intron 3 and therefore do not alter protein structure. Their biological implications and role in altering disease susceptibility remain unknown. The goal of this study was to analyze functionality of these genetic changes. We hypothesized that these associated SNPs, or other variants in linkage disequilibrium (LD) with them harbor regulatory elements that affect CACNA1C expression. We bioinformatically identified evolutionarily conserved regions within Intron 3 of CACNA1C, one of which contains 2 SNPs in LD with a GWAS significant SNP and putative binding sites for multiple transcription factors. Because this particular conserved region might play a regulatory role in CACNA1C expression, we cloned this intronic sequence, containing major and minor alleles of the 2 SNPs, into reporter gene vector and assessed their ability to for transcription activation in HEK293 cells and neuronal cell line SH-SY5Y. Our data showed that haplotype consisting of the minor alleles of both SNPs lead to significantly higher expression of the reporter gene. These data indicate that the putative regulatory region affects reporter activation in an allele specific manner. The data provides basis for focused study of intron 3 of the CACNA1C where all the CACNA1C mood disorder GWAS signals reside. We expect that further functional characterization of CACNA1C regulatory elements will lead to an improved understanding of the molecular mechanisms underlying pathophysiology of psychiatric disorders as modulated by CACNA1C genotype

Mutua Terrassa, Univ. Hosp. Mutua Terrassa, Biomed. Res. Ctr. in Mental Hlth. Network (CIBERSAM),, Barcelona, Spain

Abstract: Schizophrenia is a mental disorder with severe consequences that has a lifetime risk of about 1% and heritability estimated at up to 80%. In order to characterize gene candidates and to obtain functional information regarding the molecular bases of the disease, mRNA from blood was sequenced using an Illumina Genome Analyzer GAIIx. 200 genes with significant differential expression after adjusting for multiple testing (Padj Value <0.05) were found in the 22.278 human genes analyzed. 37 genes out of the 200 differential expression genes (19%) have been already included in the GWAS catalog2, a slight enrichment regarding the 17% fraction of GWAS associated genes. Among these 200 genes, ADAMTS2 has the lowest Padj value

(1.3236E-69) and it has been related with attention deficit hyperactivity disorder (time of onset).3 Three other differentially expressed genes have been associated to schizophrenia in the GWAS: CSMD1 associated with schizophrenia among other traits4 and EHF associated with response to antipsychotic treatment and volumetric brain 5,6. RFX2 is not reported but includes an intronic SNP with a P value = 3.5x10-6 which ranks in position 89 among the P values of a schizophrenia and bipolar disorder GWAS meta-analysis.7 According to GeneRIF repository , 9 out of the 200 differentially expressed genes have been related to schizophrenia: GRIK3, LPL, S100B, SLC12A1, SNCA, SYN2, TUBB2A, SELENBP1, CSMD1. Levels of S100B have been reported to be increased in schizophrenia which is consistent with our observation of significantly higher expression of the gene in schizophrenics. Also, lower copy number of SELENBP1 in schizophrenics has been reported, which is consistent with the significant lower expression levels we observe in schizophrenics. Functional analyses of the differentially expressed genes using the tool FatiGO from the package Babelomics indicated a significant enrichment in 9 Gene Ontology biological processes (Padj Values <0.05). These processes are mainly related to protein processing and inflammatory and immune response. There are 20 differential expression genes involved in the immune, inflammatory response and the response to wounding, 15 of these genes are upregulated and 5 downregulated in schizophrenia.

Title: Epigenetic factors can dysregulate the GABA cell phenotype in schizophrenia

Authors: ***S. SUBBURAJU**, A. J. COLEMAN, F. M. BENES
Program in structural and Mol. Neurosci., Mailman Res. Center, McLean Hosp., Belmont, MA

Abstract: GABAergic dysfunction in schizophrenia (SZ) is associated with a marked decrease in the expression of GAD67 in interneurons found in the stratum oriens (SO) of sector CA3/2 of the hippocampus (HIPP). A microarray-based gene expression analysis of laser microdissected (LMD) human hippocampus has suggested that GABA neurons in the SO of CA3/2 may contain a network of differentially regulated genes that are involved in GAD67 regulation. Several of these genes may contribute to the highly significant decrease of GABAergic activity at the SO-CA3/2 locus in SZ. To validate the role of this network in GAD67 regulation, both *in vitro* and *in vivo* studies in which shRNAi and lentiviral vectors have been used to explore how changes in the expression of GAD67 may be influenced by two other genes, HDAC1 and DAXX, that have been specifically implicated in the proposed network could potentially influence the expression of GAD67. Toward this end, knockdowns of HDAC1 and DAXX expression were induced both *in vitro* (in HiB5 cells with a GABAergic phenotype) and *in vivo* (in GABA cells of the SO of CA3/2 following selective stereotaxic infusions of the vectors). Suppression of HDAC1 and DAXX expression was associated with a highly significant increase of GAD67 expression; however, neither gene was associated with changes in the expression of its respective co-repressor (i.e. DAXX or HDAC1, respectively). Viral vector knockdowns of both HDAC1 and DAXX did, however, induce significant changes in the expression of other putative GAD67 regulatory genes, such as Runx2 and PAX5. Taken together, these findings suggest that both HDAC1 and DAXX are components of a complex network of genes identified in GABAergic neurons at a key locus of the trisynaptic pathway where significant abnormalities have been observed in patients with SZ. HDAC1 and DAXX are known co-repressors of methylation reactions at CpG islands and may be contributing to transcriptional regulation of GAD67 expression. In summary, these experiments have provided validatory information suggesting that there is a complex network of interactive genes that play a complex role in both normal and abnormal GABA cell function in the hippocampus.

Title: A serotonin-dependent mechanism is essential for the protracted antidepressant-like effect of ketamine in a rat model of depression

Authors: *K. G. DU JARDIN[1], N. LIEBENBERG[1], H. MÜLLER[1], B. ELFVING[1], C. SANCHEZ[2], G. WEGENER[1]
[1]Translational Neuropsychiatry Unit, Dept. of Clin. Med., Aarhus Univ., Aarhus, Denmark; [2]External Sourcing, Lundbeck Res. USA, Inc., Paramus, NJ

Abstract: Ketamine, a non-competitive NMDA receptor antagonist, produces an antidepressant effect within two hours that persists for more than one week in treatment-resistant patients. Likewise, ketamine exhibits a rapid and protracted antidepressant-like effect in a genetic model of depression, Flinders Sensitive Line (FSL) rats. The mechanisms mediating the antidepressant effect of ketamine are not well understood, however, the FSL rat model may offer opportunities to gain new mechanistic insights. Since cognitive deficits are common in depression, and FSL rats display reduced memory performance compared to their control strain, Flinders Resistant Line (FRL), FSL rats may constitute a valid platform to study cognitive aspects of depression. Moreover, numerous studies support that serotonin (5-HT) is implicated in antidepressant responsiveness and regulation of memory function. Thus, the objective was to assess the impact of endogenous 5-HT tone on ketamine's protracted antidepressant-like effect and any protracted effect on memory function by comparing its effect in rats with normal 5-HT tone to 5-HT depleted rats. FSL rats were pretreated with the irreversible tryptophan hydroxylase inhibitor, p-chlorophenylalanine (pCPA; *IP* 150 mg/kg/day), or saline once daily for three consecutive days. On the following day, the FSL rats were acutely treated with ketamine (*IP* 15 mg/kg) or saline. Saline/saline-dosed FRL rats were included as controls. Ketamine's effects on recognition memory and its antidepressant-like activity were assessed in the object recognition test (24 hours after ketamine) and the forced swim test (48 hours after ketamine), respectively. In the object recognition test, control FSL rats exhibited a significantly lower memory performance than control FRL rats. Neither, pretreatment with pCPA nor treatment with ketamine affected the memory performance of the FSL rats. In the forced swim test, control FSL rats displayed a significantly higher immobility than control FRL rats. Saline pretreatment combined with ketamine treatment significantly reduced the immobility of the FSL rats, whereas pCPA pretreatment alone did not affect immobility. However, pCPA pretreatment significantly prevented the antidepressant-like effect of ketamine treatment. In conclusion, 5-HT depletion prevented the protracted antidepressant-like effect of ketamine without affecting the depressive-like phenotype of FSL rats. These results suggest that ketamine elicits its antidepressant-like effect via a 5-HT-dependent mechanism. Neither ketamine nor 5-HT depletion affected the memory performance of FSL rats. Additional behavioral data will be presented.

Title: Time-dependent metabolomic profiling of Ketamine drug action reveals hippocampal pathway alterations

Authors: K. WECKMANN, C. WEBHOFER, C. LABERMAIER, M. MÜLLER-SITZ, *M. KIMURA, C. W. TURCK
Max Planck Inst. of Psychiatry, Munich, Germany

Abstract: Psychiatric diseases including Major Depressive Disorder (MDD) have a high morbidity and constitute an ever increasing burden for societies. At present most clinically used antidepressants are targeting monoaminergic reuptake mechanisms. However, a limited efficacy and a delayed onset of therapeutic response combined with several side effects make them less than ideal drugs. Approximately one third of patients are suffering from treatment resistant depression (TRD) and do not respond to commonly used antidepressants. Reasons for the delayed therapeutic effect and TRD remain elusive. To improve antidepressant drug efficacy, one line of research has focused on the *N*-methyl-*D*-aspartate receptor (NMDAR) and its signaling pathways. Ketamine blocks the NMDAR with profound effects on downstream signaling cascades. Unlike monoamine reuptake inhibitor (SSRI) Ketamine improves depressive symptoms within hours and is particularly effective in patients suffering from TRD. Psychomimetic side effects have so far prevented Ketamine's routine use in the clinic as a first-line drug. In order to develop alternative fast-acting drugs with a similar mode of action on the glutamatergic system, but with fewer side effects, a detailed understanding of the molecular events elicited by Ketamine treatment is essential. Alterations affecting the metabolome are a reflection of modified pathway activities in response to drug treatment. In the present study C57BL/6 mice were treated with a single injection of Ketamine with the aim of identifying hippocampal cellular pathway alterations and biomarker candidates. In addition, we have compared affected pathways and biomarkers between Ketamine and SSRI treatment. We applied a targeted polar metabolomics profiling platform and studied the time course of metabolite level changes and their contribution to the antidepressant-like effect of Ketamine. *In silico* pathway analyses revealed profound alterations of several hippocampal pathways. Interestingly, already two hours after a single injection of Ketamine many TCA cycle metabolites were significantly altered and 14 hours after Ketamine treatment most of the glycolytic metabolites were

significantly downregulated. Both these pathways are also affected by chronic the SSRI Paroxetine, albeit 24 days after treatment. This study provides new insights into Ketamine's mode of action and sheds light on pathways that are affected downstream of the NMDAR.

Title: Large-scale network effects of sub-anesthetic ketamine on macaques: New insight into the glutamatergic system for mood disorders

Authors: Q. LV[1], L. YANG[1], Z. WANG[1], G. LI[2], Z. SHEN[1], W. YU[1], Q. JIANG[1], B. HOU[1], J. PU[1], H. HU[1], *Z. WANG[1]
[1]Inst. of Neurosci., Shanghai, China; [2]Dept. of Anesthesia, Zhongshan Hosp., Shanghai, China

Abstract: Recently a single sub-anesthetic dose of ketamine has been shown to produce a rapid (within hours) antidepressant response that lasts for 1-2 weeks, which is extremely attractive for novel pharmacological strategy. Although preclinical studies have begun to investigate the various signaling pathways of NMDA receptor blockade, what are the relevant brain circuits that underlie the fast and efficacious action of this agent remains largely unknown. To systematically identify the global network change, we combined the resting-state functional magnetic resonance imaging (fMRI) and graph theoretical analysis to quantitatively examine the topological features of the coherent brain activity. In a randomized, placebo-controlled, crossover design, healthy macaque monkeys (n = 9) received a single-dose administration of saline and ketamine (0.5 mg/kg) respectively, spaced at least 1-month apart. Resting-sate fMRI scans were scheduled ~18 hours after the agent administration and conducted on a Siemens Trio 3T scanner with an enhanced gradient insert AC88. We observed significant difference in global small-world metrics between ketamine and saline groups. Both characteristic path length ($p < 0.001$) and the normalized characteristic path length ($p < 0.01$) of the brain network were increased by ketamine, while the clustering coefficient ($p < 0.01$), local efficiency and global efficiency were

significantly decreased ($p < 0.001$). Nodal strength and network-based connectivity analysis revealed large-scale down-regulation of functional connectivity in the monkey brain after single-dose administration of ketamine, prominently at several key structures in the cortico-striatal-limbic pathways. This finding suggests key targets in the brain reward circuitry that may underlie the rapid, efficacious therapeutic outcome of ketamine.

[1]Neurosci., [2]Discovery Sci., Janssen Res. & Development, L.L.C., San Diego, CA; [3]Clin. Pharmacol., Janssen Res. & Development, L.L.C., Titusville, NJ; [4]Clin. Research-CNS, Janssen Res. & Development, L.L.C., San Diego, CA

Abstract: Ketamine is a non-competitive, non-subtype selective *N*-methyl-D-aspartate (NMDA) receptor antagonist. In addition to its well-known use as an anesthetic and analgesic, sub-anesthetic doses of ketamine have also been reported to produce rapid (≤ 2 hrs) and sustained (for days) antidepressant effects in depressed patients. It is also effective in a variety of antidepressant-sensitive behavioral tests and experimental models of depression. In order to better understand the mechanisms through which ketamine's rapid antidepressant effects are mediated, we conducted a pharmacokinetic study in rat using a dose range frequently used in preclinical mechanistic studies. We administered (±) ketamine subcutaneously at 1, 5 and 10 mg/kg as well as intravenously at 1 and 5 mg/kg, sampling plasma at 5 min through 8 hours for subcutaneous administration and 2 min through 8 hours for intravenous administration. Ketamine displayed a shorter half-life and conversion rate to the metabolite, norketamine, in rat compared to published data in human. C_{max} after subcutaneous administration at 1 mg/kg was 189 ng/mL

(0.8 μM), 730 ng/mL (3.1 μM) at 5 mg/kg and 2399 ng/mL (10.1 μM) at 10 mg/kg. C_{max} after intravenous administration was 377 ng/mL (1.6 μM) at 1 mg/kg and 2784 ng/mL (11.7 μM) at 5 mg/kg. Comparing the C_{max} observed in these studies, only the 1 mg/kg, s.c. group was near the estimated C_{max} of ~183 ng/mL (0.8 μM) reported by Zhao et al. (2012) following 40-minute infusion of 0.5 mg/kg ketamine in patients with treatment-resistant bipolar depression. Based on the literature and our own internal observations, 1 mg/kg, (whether s.c. or i.p.) generally is ineffective at producing anti-depressant-like efficacy in preclinical studies; whereas, 2.5 mg/kg or higher (frequently 10 mg/kg) is generally required. From these data, we conclude that at Cmax concentrations achieved in most preclinical studies demonstrating anti-depressant-like efficacy, significant activity at targets besides NMDA receptors, including dopamine D2 receptors, nicotinic receptors and hyperpolarization-activated cyclic nucleotide-gated (HCN) channels, may contribute to the observed effect. Based on the available information published on the brain:plasma ratios in rodents and humans (~3-6:1) together with the differences in plasma C_{max}, the dose regimens used in most preclinical studies also likely have activity at additional brain targets besides NMDA receptors compared with the likely brain targets affected in human studies with ketamine.

Title: Acute ketamine treatment induces long lasting behavioral effects in anxio-depressive mice

Authors: *A. M. GARDIER, I. MENDEZ-DAVID, T. PHAM, D. DAVID
Faculte De Pharmacie, Chatenay-Malabry, France

Abstract: Ketamine, a non competitive, glutamatergic NMDA receptor antagonist that binds to the phencyclidine site within this ionotropic Ca2+ channel, displays a rapid antidepressant effect: several double-blind placebo-controlled clinical trials suggested that a single ketamine dose (a 0.5 mg/kg intravenous dose < its anesthetic effect) induced a rapid (within 72 hrs after ketamine) and persistent (for 1 week) antidepressant activity in treatment-resistant depressed patients. This rapid antidepressant response may require an increase in mammalian Target of Rapamycin (mTOR)-dependent expression of BDNF in the prefrontal cortex. Measurements of ketamine effects in animal models of depression (chronic mild stress; chronic corticosterone administration) have been sparse. Most of the studies used animal tests of the antidepressant-like activity (Forced Swim Test, FST for example). Sub-anesthetic ketamine dose (3 mg/kg or below) caused this response in mice. However, some negative results were obtained after acute ketamine injection (0.5 to 12.5 mg/kg) in naïve, non-stressed rodents. Firstly, we performed a full characterization of the putative anxiolytic/antidepressant-like activity of ketamine (10 mg/kg, i.p) in male BALB/cJ mice 24 hours after its administration using the Open Field (OF), Elevated Plus Maze (EPM), Novelty Supressed Feeding (NSF), FST and Splash Test. Male BALB/cJ mice were used for this behavioral study because of their high sensitivity to acute and chronic anxiolytic and antidepressant treatment. Unlike fluoxetine (18 mg/kg, i.p., 24 hours before testing), ketamine induced a trend toward an increase in anxiolytic-like effect in the OF and EPM paradigms. Interestingly, ketamine induced a strong antidepressant-like activity in the NSF and FST. The increase in swimming duration was responsible for this antidepressant-like activity. Changes in neurotransmitters release is currently under investigations using intracerebral *in vivo* microdialysis in mice to depict the mechanism underlying these behavioral effects at 24hr after ketamine injection. Then, we studied the behavioral and neurogenic effects of an acute ketamine dose in a mouse model of an anxiety/depressive-like state induced by chronic CORT administration. Behavioral tests were performed at 7 and 14 days after administration of ketamine (10 mg/kg, i.p.). At 7 days after treatment, but not 14 days, ketamine reduced the immobility duration in the TST and the latency to feed in the NSF paradigm in CORT-treated mice. Overall, our results are in favor of an antidepressant-like response of ketamine lasting for 7 days after its acute administration in anxio-depressive mice.

Title: Mechanisms underlying differential effectiveness of memantine and ketamine in rapid antidepressant responses

Authors: *E. S. GIDEONS, E. T. KAVALALI, L. M. MONTEGGIA
Neurosci., UT-Southwestern Med. Ctr., Dallas, TX

Abstract: Ketamine is a N-methyl-D-aspartate receptor (NMDAR) antagonist that elicits rapid antidepressant responses in patients with treatment-resistant depression. However, ketamine can also produce psychotomimetic effects which limits its utility as an antidepressant raising the question whether the clinically tolerated NMDAR antagonist memantine possesses antidepressant properties. Despite its similar potency to ketamine as an NMDAR antagonist, clinical data suggest that memantine does not exert rapid antidepressant actions for reasons that are poorly understood. In this study we recapitulated the ketamine and memantine clinical findings in mice showing that ketamine but not memantine has antidepressant-like effects in behavioral models. Using electrophysiology, we show that ketamine and memantine effectively block NMDAR-mediated mEPSCs in the absence of Mg^{2+}. However, in physiological levels of extracellular Mg^{2+} we identified key functional differences between ketamine and memantine in their ability to block NMDA receptor function at rest. This differential effect of ketamine and memantine extends to intracellular signaling coupled to NMDAR at rest, in that memantine does not inhibit the phosphorylation of eukaryotic elongation factor-2 nor augment subsequent expression of brain-derived neurotrophic factor, critical determinants of ketamine mediated antidepressant efficacy. These results demonstrate significant differences between the efficacies of ketamine and memantine on NMDA receptor mediated neurotransmission that impacts

downstream intracellular signaling which we hypothesize is the trigger for rapid antidepressant responses. These data provide a novel framework on the necessary functional requirements on NMDA receptor mediated neurotransmission as a critical determinant necessary to elicit rapid antidepressant responses.

Title: The mood stabilizer lithium ameliorates oxidative stress associated with acute ketamine-induced antidepressant-like effects

Authors: *C.-T. CHIU, L. SCHEUING, H.-M. LIAO, D.-M. CHUANG
NIMH, NIH, Bethesda, MD

Abstract: Numerous clinical and preclinical studies have underscored ketamine's remarkable antidepressant effects. Nevertheless, given the inevitable relapse of depressive symptoms and the potential for abuse, ketamine is not a viable long-term clinical option. The mood stabilizer lithium is a glycogen synthase kinase-3 (GSK-3) inhibitor with strong anti-suicidal properties. Our previous study found that the antidepressant-like effects induced by a single injection of ketamine in a mouse stressed model were potentiated and prolonged by pre- and post-ketamine lithium treatment, respectively. In the present study, we further identified that these behavioral benefits of lithium treatment were associated with GSK-3 inhibition and stimulation of the mammalian target of rapamycin (mTOR)/brain-derived neurotrophic factor (BDNF) signaling pathways in the prefrontal cortex of mouse brain. In addition, we observed that acute injection with ketamine at a dose that produced an antidepressant-like effect (50 mg/kg, i.p.) also markedly increased lipid peroxidation (141.49 ± 7.29%, $P<0.01$), catalase activity (120.64 ± 5.79%, $P<0.01$), and levels of oxidized glutathione (130.90 ± 7.75%, $P<0.01$; compared with stressed control) in the same brain region 20 minutes after injection, indicating elevated oxidative stress. Similar results were also found in the hippocampus and striatum of stressed mice. To investigate whether lithium can protect against the oxidative stress induced by

ketamine, mice were pretreated with 1200 mg/l of lithium chloride in drinking water for three weeks before ketamine challenge. The serum concentration of lithium after three weeks of treatment with this dose was at the lower end (0.483 ± 0.052 mEq/l; n=8) of the therapeutic spectrum for human patients with bipolar disorder. Compared with control stressed mice, lithium pretreatment robustly suppressed ketamine-induced lipid peroxidation (89.35 ± 13.09%, $P<0.01$), catalase activity (85.16 ± 3.40%, $P<0.01$), and levels of oxidized glutathione (103.49 ± 7.73%, $P<0.01$) in the prefrontal cortex of stressed mice. These oxidative metabolism markers induced by ketamine in the hippocampus and striatum were also reduced by lithium pretreatment. Despite the extant evidence suggesting that lithium has antioxidant properties, our study is the first to demonstrate that the oxidative stress induced by ketamine can be completely blocked by lithium pretreatment, underscoring lithium's neuroprotective aspects. Taken together, the antioxidant effects of lithium provide an additional benefit and rationale for its adjunctive use with ketamine in the treatment of depression.

Title: Ketamine prevents alcohol-induced depressive-like behavior in rats

Authors: *O. O. KALEJAIYE, J. FORD, Y. TIZABI
Pharmacol., Howard Univ. Col. of Med., Washington, DC

Abstract: A strong positive association exists between heavy drinking (i.e., alcoholism) and depression, and epidemiological studies suggest that this depression can negatively influence successful cessation of alcohol use. Therefore, there is a fundamental need to develop efficient and fast acting antidepressants that can specifically treat depression associated with alcohol use. Ketamine, a glutamatergic NMDA receptor antagonist has shown promise as quick acting antidepressant. However, its efficacy in alcohol-induced depression is unknown. In this study we sought to provide some answers by subjecting 4 groups of adult male Wistar rats to 4 different treatments. One group was injected with saline as control and all 3 other groups were injected

with alcohol (1g/kg ip) for 7 days to induce depressive-like behavior as assessed by forced swim test (FST) and sucrose preference test (SPT). One group of alcohol-treated rats was injected with 2 mg/kg ketamine daily, half h before alcohol administration and another group of alcohol-treated rats was injected with a single dose of ketamine (2 mg/kg), 16 h after the last alcohol injection. In all cases behavioral tests were carried out approximately 18 h after the last alcohol administration. All animals were tested for general locomotor activity in an automated activity-monitoring cage, for 5 min, followed by FST and SPT. FST, conducted for 5 min, was videotaped and immobility score, reflective of helplessness was determined. Sucrose consumption was performed for 6 h, where the bottles were switched after 3 h to avoid side preference. A decrease in sucrose consumption is reflective of anhedonia (lack of pleasure). Results indicate a "depressogenic" effect of chronic alcohol treatment as evidenced by higher immobility in the FST and a decrease in sucrose consumption. Pretreatment with daily ketamine, or a single injection of ketamine after daily alcohol administration normalized changes induced by alcohol. Locomotor activity was not affected by any treatment. These preliminary results suggest the usefulness of ketamine in alcohol-related depression. Supported by: NIH/NIAAA R03AA022479

Title: Involvement of serotonergic system in the antidepressant-like effects of a metabotropic glutamate 2/3 receptor antagonist and ketamine

Authors: K. FUKUMOTO, M. IIJIMA, *S. CHAKI
Mol Function Pharmacol Labs, Taisho Pharmaceut. Co., Ltd., Saitama, Japan

Abstract: Metabotropic glutamate 2/3 (mGlu2/3) receptor antagonists and an N-methyl-D-aspartate (NMDA) receptor antagonist, ketamine have been reported to exert antidepressant-like effects via α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptor stimulation and the subsequent stimulation of tropomyosin-related kinase B and the mammalian target of rapamycin signaling pathway, which may lead to an increase in the synthesis of synaptic proteins in animal models. Thus, AMPA receptor stimulation may trigger similar

neuronal mechanisms of antidepressant-like effects of mGlu2/3 receptor antagonists and ketamine. AMPA receptor stimulation has also been shown to mediate an increase in extracellular level of serotonin (5-HT) in the medial prefrontal cortex by an mGlu2/3 receptor antagonist and an NMDA receptor antagonist in rats. However, involvement of serotonergic system in the antidepressant-like effects of mGlu2/3 receptor antagonists and ketamine is not well understood. Therefore, we investigated involvement of serotonergic system in the antidepressant-like effects of an mGlu2/3 receptor antagonist, 2S-2-amino-2-(1S,2S-2-carboxycyclopropyl-1-yl)-3-(xanth-9-yl)propanoic acid (LY341495) and ketamine using animal models of depression such as a forced swimming test (FST) and a novelty-suppressed feeding test (NSFT) of male C57BL/6J mice. The administration of LY341495 or ketamine exerted antidepressant-like effects in the FST and NSFT, which were attenuated by an AMPA receptor antagonist, 2,3-dioxo-6-nitro-1,2,3,4-tetrahydrobenzo[f]-quinoxaline-7-sulfonamide (NBQX). The antidepressant-like effects of LY341495 and ketamine were blocked by pretreatment with a tryptophan hydroxylase inhibitor, para-chlorophenylalanine in the FST and NSFT. Moreover, the effects of LY341495 and ketamine were blocked by a 5-HT1A receptor antagonist, N-{2-[4-(2-methoxyphenyl)-1-piperazinyl]ethyl}-N-(2-pyridynyl) cyclohexane-carboxamide (WAY100635), but not by a 5-HT2A/2C receptor antagonist, ritanserin in the NSFT. These effects of LY341495 and ketamine were mimicked by an AMPA receptor potentiator, 2,3-dihydro-1,4-benzodioxin-7-yl-(1-piperidyl)methanone (CX546) in the NSFT. These results suggest that AMPA receptor-dependent activation of serotonergic system may be involved in the antidepressant-like effects of an mGlu2/3 receptor antagonist and ketamine.

Title: Involvement of the ventral hippocampus in the antidepressant-like effect of ketamine: Behavioral and optogenetic studies

Authors: *F. R. CARRENO, M. DEGUZMAN, A. SHAH, D. J. LODGE, A. FRAZER
Univ. Texas Hlth. Sci. Ctr-San Antonio, San Antonio, TX

Abstract: A single sub-anesthetic dose of ketamine exerts fast-acting and sustained antidepressant effects. However, the mechanisms and brain regions contributing to this effect are still unclear. We examined the role of the ventral hippocampus (vHipp) in the antidepressant response to ketamine as well as the contribution of the neurotrophin receptor TrkB, which is known to be phosphorylated by ketamine administration. Inactivation of the vHipp by lidocaine prevented the sustained (7 days), but not acute (30 min), antidepressant-like effect of ketamine in the forced swim test (FST). Given the role of BDNF in the antidepressant response to ketamine, we examined whether a transient increase in TrkB phosphorylation in the vHipp contributed to the sustained antidepressant response to ketamine. Similar to the effects of intra-vHipp lidocaine, blockade of TrkB receptor phosphorylation (by the tyrosine kinase inhibitor, K252a) in the vHipp at the time of ketamine administration attenuated its antidepressant-like effects measured 1 week following administration. Thus, it appears that ketamine induces plastic changes in vHipp afferents that underlie a sustained antidepressant response. A significant limbic projection of the vHipp is to the mPFC. To elucidate the consequence of augmented vHipp-mPFC activity, we utilized an optogenetic approach. AAV2-hsyn-ChR2-EYFP (or control) was injected into the vHipp and bilateral fiber optic cannulas implanted into the mPFC. ChR2 was activated by laser light and the behavioral effect in the FST recorded. Consistent with our ketamine data, optogenetic stimulation of vHipp-mPFC pathway significantly increased climbing in the FST; however, a decrease in immobility was not observed due to a significant decrease in swimming behavior. To test if the decrease in swimming was due to a feedback pathway from the mPFC to the dorsal raphe nucleus (DRN), we examined optogenetic stimulation following administration of the GABA-A receptor antagonist, bicuculline, into the DRN. Pretreatment with bicuculine abolished the decrease in swimming observed when the mPFC was stimulated and now a significant decrease in immobility was revealed. In conclusion, these data demonstrate a role for vHipp-mPFC plasticity in the antidepressant-like effects of ketamine.

Title: Enantioselective effect of ketamine metabolites on serine racemase expression and function in 1321N1 and PC-12 cells

Authors: N. S. SINGH[1], R. K. PAUL[1], M. KHADEER[1], *L. TOLL[2], I. W. WAINER[1]
[1]Lab. of Clin. Investigation, Natl. Inst. on Aging, Natl. Inst. of Hlth., Baltimore, MD; [2]Torrey Pines Inst. For Mol. Studies, Port Saint Lucie, FL

Abstract: (R,S)-Ketamine (Ket) is used in the treatment of bipolar depression (BD) and its clinical effects have been associated with attenuation of NMDA activity and neurogenesis via induction of the mammalian target of rapamycin (mTOR). Ket is rapidly and extensively metabolized into a variety of N-demethylated and hydroxylated compounds. We have recently demonstrated that in the Wistar rat, (R,S)-norketamine and (2S,6S)-hydroxynorketamine stimulated the activating phosphorylation of mTOR and its downstream targets and in PC-12 cells increased the expression of the monomeric form of serine racemase (mSR) via the mTOR pathway while decreasing mSR function as determined by intracellular levels of D-serine (Paul, et al., 2014, Anesthesiology, In press). In this study we have examined the effect of the individual enantiomers of four of the major Ket metabolites on mSR expression and intracellular D-serine levels in PC-12 cells, Table 1. All of the test compounds decreased intracellular D-serine concentrations by ~25% and increased the expression of m-SR. This apparent contradiction will be discussed during the presentation. In all cases the compounds with a 2S-configuration were more active than the corresponding 2R-isomers and the presence of a hydroxyl moiety at carbon 6 in cyclohexanone ring increased potency. These results are consistent with the reported enantiospecific therapeutic differences between (S)-Ket and (R)-Ket and support the hypothesis that ketamine metabolites contribute to the clinical effect of Ket via an indirect mechanism.

Table 1 - The effect of ketamine metabolites on the function and expression of serine racemase (SR) in PC-12 cells where IC_{50} values were determined from the concentration-dependent decrease in intracellular concentrations of D-serine and the arrows represent an increase in the monomeric SR expression relative to untreated control. The relative enantioselectivity factor (α) was determined from the ratio of IC_{50} values derived from the compounds with an R configuration at carbon 2 divided by the IC_{50} values derived from the corresponding compound with an S configuration at carbon 2.

Compound	Isomer	PC-12		Selectivity Factor (α)
		Intracellular D-Ser Concentration – IC_{50}	m-SR expression	
 Nodeketamine	R	224 ± 30 nM	↑	1.94
	S	115 ± 27 nM	↑	
 Dehydroxynorketamine	R	85 ± 30 nM	↑	2.13
	S	40 ± 15 nM	↑	
 Hydroxynorketamine	(2R,6R)	0.65 ± 0.53 nM	↑	4.64
	(2S,6S)	0.14 ± 0.09 nM	↑	
	(2R,6S)	3.76 ± 0.93 nM	↑	1.39
	(2S,6R)	2.69 ± 0.63 nM	↑

Title: Determining the involvement of lactate in mediating antidepressant responses

Authors: ***M. ELSAYED**[1,2], J.-M. PETIT[1,2], V. ELIGERT[1,2], P. J. MAGISTRETTI[1,2,3]
[1]UNIL, Lausanne, Switzerland; [2]Brain Mind Inst., EPFL, Lausanne, Switzerland; [3]BESE division, KAUST, Thuwal, Saudi Arabia

Abstract: Studies from our laboratory have shown that intracortical injection of Lactate, but not other metabolic products, stimulates the expression of plasticity related-genes in mice.

Furthermore, we have also shown that antidepressants can upregulate the expression of growth factors and promote Lactate release from astrocytes *in vitro* (Allaman et al, 2011). Given that patients with depression show decreases in astrocyte densities and in neuroplasticity, we ask whether Lactate, a glial metabolic product is involved in mediating antidepressant responses. Initial experiments were carried out to determine if antidepressants increase brain lactate levels *in vivo*. We used specific lactate biosensors implanted in freely-moving adult mice. With this technique, we determined the influence of different classes of antidepressants on brain lactate levels. Our preliminary findings indicate that unlike conventional antidepressants whose effects were examined after a chronic injection, the rapid acting antidepressant ketamine resulted in an increase in extracellular lactate levels within hours of injection. Moreover, this effect is specific to ketamine's action within the brain, as there was no influence on lactate levels in the blood. Future experiments would need to characterize the involvement of Lactate in ketamine mediated antidepressant effects. Furthermore, given that these biosensors are limited to recordings of changes in concentration following manipulation, additional related assays such as microdialysis or magnetic resonance spectroscopy would be needed to be carried out to confirm the specificity of the effects of the different classes of antidepressants on brain lactate levels.

Title: SSRI induced endogenous BDNF expression in Dentate Gyrus precisely regulates adult neurogenesis and anti-depressant effect

Authors: *Z. MA[1], L. F. PARADA[2]
[1]Developmental Biol., UT Southwestern Med. Ctr., Dallas, TX; [2]Developmental Biol., UT Southwestern Med. Ctr. at Dallas, Dallas, TX

Abstract: Hippocampal neurogenesis has been shown to play an important role in the behavioral repsonse to anti-depressant drugs (ADs) such as selective serotonin reuptake inhibitors (SSRIs). Despite rapid neurochemical action, SSRIs usually take several weeks to exert their clinical efficacy, suggesting a potential time lapse between the activation of neurotrophic factors and their actions on hippocampal neurogeneis. Our previous studies have demonstrated that chronic

SSRI treatment specifically causes trkB activation leading to enhanced progenitor cell proliferation and neurogenesis in Dentate Gyrus (DG). Specific ablation of TrkB in these progenitors blocks proliferation, neurogenesis and behavioral response to SSRIs. However, it is still not clear that how different cell types in DG respond to SSRI treatment and increase adult neurogenesis through BDNF transcriptional activation. Here, by using in-situ hybridization and BDNFlox-lacZ mice, in which lacZ gene is controlled by endogenous BDNF promoters, we found both granule cells and neural stem/progenitor cells increase BDNF expression with the exposure to chronic SSRI treatment, and induced BDNF proteins are mainly derived from differentiated DG granule neurons. Although the specific ablation of trkB in neural progenitor cells by Nestin-creER^{t2} can totally abolish the behavioral response to anti-depressive treatment, mice lacking BDNF in the same cell types initially respond normally to chronic ADs one week after the last dose, and then display the behavioral insensitivity in depression- and anxiety-like paradigms after two weeks. In contrast, mice with BDNF specifically knocking-out in DG neurons dramatically decrease BDNF level in DG and do not show any anti-depressant response to ADs. Moreover, it seems that the status of adult neurogenesis in DG is well correlated with the achievement of behavioral response to ADs in these BDNF/trkB conditional knock-out lines. More detailed analyses of neurogenesis are still going-on. Thus, our current data suggests that endogenous BDNF is an important mediator for hippocampal neurogenic niche to precisely regulate chronic anti-depressant response in mice.

Title: Exploring antidepressant-induced affective blunting in rats: Assessment of chronic fluoxetine administration on operant responding

Authors: *K. MATAZEL[1], R. J. RICE[1], A. L. PEHRSON[2], A. J. PRUS[1]
[1]Northern Michigan Univ., Marquette, MI; [2]Lundbeck Reseach USA, Inc., Paramus, NJ

Abstract: The most frequently prescribed pharmacological agents used for treating depression are those that prevent the reuptake of serotonin. In addition to the commonly known adverse effects of these compounds (e.g., sexual dysfunction, insomnia, serotonin syndrome), patients

chronically treated with serotonin reuptake inhibitors may develop a flattened affective state (sometimes referred to as “affective blunting”) characterized by a lack of facial emotional expression, little intonation or vocal variation, and decreased communicative gesturing that differ from depressive symptomology. The purpose of this study was to determine if antidepressant drugs may elicit an affective blunting state in rats by assessing the effects of repeated administration of the selective serotonin reuptake inhibitor fluoxetine on lever pressing for positive reinforcement. After response rates stabilized, a food deprivation curve was conducted over a 24 hour period before and after 21 days of fluoxetine administration (16 g/L in home cage water bottles). Fluoxetine administration did not produce a change in response rates compared to baseline. Further studies are needed to evaluate different types of positive reinforcers (e.g., sucrose pellets) and to assess avoidance of aversive stimuli (e.g., bright light) after chronic fluoxetine administration, in order to determine if affective blunting can be modeled in rats.

Title: Serotonin transport occupancy by S-citalopram and R/S-citalopram in the nonhuman primate brain: A [11C]MADAM PET study

Authors: *S. J. FINNEMA[1], C. HALLDIN[1], B. BANG-ANDERSEN[2], C. BUNDGAARD[2], L. FARDE[1]
[1]Dept. of Clin. Neurosci., Karolinska Institutet, Stockholm, Sweden; [2]Neurosci. Drug Discovery Denmark, H. Lundbeck A/S, Valby, Denmark

Abstract: *Rationale* Positron emission tomography (PET) can be used to assess changes in endogenous neurotransmitter concentrations in the living brain. Very recently, some novel serotonin (5-HT) receptor radioligands have been reported to be sensitive to drug-induced changes in 5-HT concentrations. High doses of selective 5-HT reuptake inhibitors (SSRIs) have been shown to decrease cortical radioligand binding in the monkey brain, consistent with increased 5-HT concentrations (Milak et al, 2011; Ridler et al, 2011; Nord et al, 2013). However,

in two recent studies on healthy subjects, a single, lower and clinical relevant SSRI dose increased cortical radioligand binding suggesting a potential decrease in 5-HT concentration in projection areas when initiating SSRI-treatment (Selvaraj et al, 2012; Nord et al, 2013). *Objectives* The cross-species differential SSRI effect may be explained by SSRI-induced 5-HT transporter (SERT) occupancy in the monkey brain being higher than clinical relevant. We here determined SERT occupancy after single doses of *S*-citalopram or *R*/*S*-citalopram in the monkey brain. *Methods* Ten PET measurements with [^{11}C]MADAM were performed in two female cynomolgus monkeys prior and post *S*-citalopram or *R*/*S*-citalopram administration. Relationships between dose, plasma concentration and SERT occupancy were interpreted by one-site saturation analysis. The binding affinity was expressed as the dose (ID_{50}) or plasma concentration (K_i) at which 50% SERT occupancy was achieved. *Results* SERT occupancy increased in a dose- and plasma concentration-dependent manner. The estimated ID_{50} and K_i values were 0.038 mg/kg (95%CI = 0.013-0.062) and 18 nmol/L (95%CI = 6.0-30) for *S*-citalopram and 0.046 mg/kg (95%CI = 0.013-0.078) and 7.9 nmol/L (95%CI = 2.2-14) for *R*/*S*-citalopram, respectively. *Conclusions* The obtained K_i values are comparable to values reported for human subjects (Lundberg et al, 2007). It can be concluded that the SSRI doses in previously reported 5-HT release studies in monkeys almost saturated SERT (Milak et al, 2011; Ridler et al, 2011; Nord et al, 2013). The PET-measured cross-species differential effect of SSRI on cortical 5-HT concentration is thus likely related to the SSRI dose, and appears consistent with known SSRI dose-effects on regional differences in microdialysis studies (Invernizzi et al, 1992). Future monkey studies using SSRI doses inducing clinically relevant SERT occupancy are called for to provide further understanding of SSRIs delayed onset of therapeutic effect.

Title: Tricyclic antidepressant amitriptyline acts on astrocytes leading to the increase in the FGF2 expression: A role of early growth response 1 signaling

Authors: N. KAJITANI[1,2], *K. HISAOKA[2], M. OKADA-TSUCHIOKA[1], M. HOSOI[1], C. SHIBASAKI[1,3], N. MORIOKA[2], Y. NAKATA[2], M. TAKEBAYASHI[1,3]
[1]Inst. Clin. Res, Natl. Hosp Org Kure Med. Ctr., Kure, Japan; [2]Dept. Pharmacol. Hiroshima Univ., Hiroshima, Japan; [3]Dept Psychiatry. Natl. Hosp Org Kure Med. Ctr., Kure, Japan

Abstract: [Background] Recently, fibroblast growth factor 2 (FGF2) has been proposed to play an important role in the therapeutic action of antidepressants. We have previously reported that a tricyclic antidepressant amitriptyline increases the FGF2 production and its release in rat primary cultured astrocytes, which is a primary source of FGF2 in the brain. However, the intracellular signaling of the amitriptyline-induced FGF2 production in astrocytes remains unclear. In this study, we focused on early growth response 1 (EGR1), which is one of the transcription factor known to regulate the FGF2 gene expression, and we examined whether the EGR1 is involved in the amitriptyline-induced FGF2 expression in astrocytes. [Method] We prepared astrocytes from the cortex of 1-day-old neonatal Wistar rat. We measured the expression levels of EGR1 and FGF2 mRNA using real time PCR and protein levels using immunoblotting. [Results] Treatment with amitriptyline significantly increased the EGR1 production in rat primary cultured astrocytes. We used the siRNA for EGR1 to examine the role of EGR1 in the amitriptyline-induced FGF2 expression in astrocytes. Down-regulation of EGR1 using siRNA blocked the amitriptyline-induced FGF2 mRNA expression. MEK1/2 inhibitor PD98059 significantly inhibited both EGR1 and FGF2 mRNAs induced by amitriptyline. Actually, amitriptyline increased the phosphorylation of ERK1/2 in astrocytes, suggesting that amitriptyline activates the ERK/EGR1 signaling cascade, resulting in FGF2 production. Furthermore, we attempted to identify the mechanism through which amitriptyline activates ERK/EGR1/FGF2 signaling cascade in astrocytes. Epidermal growth factor receptor (EGFR) inhibitor AG1478 and FGF receptor (FGFR) inhibitor SU5402, but not platelet-derived growth factor inhibitor AG1296 inhibited the amitriptyline-induced intracellular signaling cascade. In addition, heparin and matrix metalloproteinase (MMP) inhibitors GM6001 and prinomastat inhibited the effects of amitriptyline. [Conclusion] These results suggest that the amitriptyline-induced FGF2 expression is involved in the ERK-dependent EGR1 production. EGFR and/or FGFR mediate this intracellular signaling. Amitriptyline-induced EGFR and FGFR signaling might occur, at least in part, by the MMP-dependent shedding of heparin-sensitive EGFR and/or FGFR ligands, thus resulting in FGF2 induction in astrocytes. These findings indicate a novel mechanism of action of amitriptyline through astrocytes and further suggest that targeting this mechanism could lead to the development of a new class of antidepressants.

Title: Transcriptomic evidence for immaturity in the frontal cortex of mice treated with antidepressants

Authors: *K. OHIRA, H. HAGIHARA, R. TAKEUCHI, T. MIYAKAWA
Div. Systems Med. Sci, ICMS, Fujita Hlth. Univ., Toyoake, Japan

Abstract: The selective serotonin reuptake inhibitor, fluoxetine (FLX), is widely used to treat depression and anxiety disorders. Previous studies have demonstrated that FLX treatment can reverse the established neuronal maturation of granule cells in the hippocampal dentate gyrus, and of inhibitory interneurons in the basolateral amygdala. FLX can also increase hippocampal adult neurogenesis, which is the most widely reported effect. Recently, using immunohistological methods, we found that chronic FLX treatment decreased the levels of parvalbumin, which could be used as a maturation marker of fast-spiking interneurons, and perineuronal nets (PNNs), which are formed mainly around mature fast-spiking interneurons, in the medial frontal cortex (mFC) of adult mice, suggesting that FLX induces pseudo-immature status of these types of neurons. In this study, to further characterize the effect of FLX on mFC, we compared genome-wide gene expressions of FLX-treated mFC with those of the corresponding region of normally developing brains in mice. We found that the mFC in adult mice treated with FLX resembled juvenile mFC in terms of genome-wide expression profile. The common gene alterations between FLX-treated mFC of adult mice and mFC of normally developing mice might be partly accounted for by maturational abnormalities in fast-spiking interneurons, astrocytes, and oligodendrocytes, although the contributions of other cell types to the transcriptomic immaturity of the mFC treated with FLX cannot be excluded. In addition, gene expression patterns in the FLX-treated mFC of adult mice were similar to those in the developing mFC of humans. Our results suggest that FLX treatment induces pseudo-immaturity of the mFC of adult mice with respect to gene expression patterns.

Title: Cognitive assessments prospectively differentiate future responders and non-responders to selective serotonin reuptake inhibitor treatment among medication-naïve patients with major depressive disorder

Authors: *M. M. HERZALLAH[1,2], M. B. TAHA[2], J. Y. NATSHEH[2,3], M. A. SEHWAIL[2], M. A. GLUCK[3]
[1]Rutgers, The State Univ., Newark, NJ; [2]Palestinian Neurosci. Initiative, Al-Quds Univ., Abu Dis, Jerusalem, Palestinian Territory; [3]Ctr. for Mol. and Behavioral Neurosci., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Short cognitive assessments of learning from positive feedback have the potential to prospectively differentiate future SSRI responders from non-responders in patients with Major Depressive Disorder (MDD). We evaluated a group of medication-naïve patients with MDD before and after 4-6 weeks of treatment with SSRI, as well as a matched group of controls tested across the same time interval. All subjects were administered a probabilistic category-learning task that allowed for the dissociation of learning from positive versus negative feedback. At the time of retesting, 65% of our sample responded to SSRI treatment, while 35% were non-responders. We compared the cognitive profiles of these two subpopulations at both baseline and retest against that of healthy subjects. While SSRI non-responders show balanced learning between positive and negative feedback at both baseline and again at retesting following SSRI administration, the SSRI-responders in their medication-naïve state show a strong bias for negative feedback, which was later altered by SSRI therapy to become more balanced during the subsequent post-treatment retesting. The findings in SSRI-responders replicate our earlier results (Herzallah et al., 2013a) using a within-subject design. These cognitive differences between responders and non-responders assessed prospectively prior to any SSRI treatment have the potential to inform the development and validation of a pre-treatment cognitive assessment to predict future clinical response to SSRIs. No such assessment currently exists and, if successfully developed and validated, would have the the potential to significantly impact clinical treatment as well as inform the search for new antidepressant medications that would provide symptomatic relief to those who do not benefit from SSRIs. The ability to differentiate, a priori, the SSRI-

responders from the non-responders prior to initiating antidepressant treatment, would also shed much-needed light on the complex and poorly understood underlying heterogeneity of MDD.

Title: Selective serotonin reuptake inhibitor treatment response: Identification of affected molecular pathways in responder and non-responder mouse model

Authors: D. PARK, C. DOURNES, *O. F. ALMEIDA, M. B. MÜLLER-SITZ, C. W. TURCK
Max Planck Inst. of Psychiatry, Muenchen, Germany

Abstract: Selective Serotonin Reuptake Inhibitors (SSRIs) are commonly used antidepressants for the treatment of psychiatric diseases including Major Depression Disorder (MDD) and various types of anxiety-related disorders. However, current SSRIs have a delayed onset of therapeutic efficacy of several weeks. In addition, a substantial number of patients do not show any improvement during or after antidepressant treatment. To analyze antidepressant treatment resistance, we used the forced swim test (FST) which differentiates responder and non-responder mice. Following one month of chronic Paroxetine treatment DBA mice were categorized into a Paroxetine-treated Long-time Floating (PLF) group, Paroxetine-treated Intermediate Floating (PIF) group, and a Paroxetine-treated Short-time Floating (PSF) group. To identify proteome signatures in PLF and PSF mice, we performed quantitative mass spectrometry of hippocampal membrane- and cytosol-fractions. Metabolite level differences were also investigated in the hippocampus and plasma of PLF and PSF mice. Integrated proteomic and metabolomic analyses revealed that pathways including energy metabolism, neurotransmitter degradation, and glutamatergic signaling are differentially affected in response to chronic Paroxetine treatment in PLF and PSF mice. Validation by Western blot analyses revealed that expression of N-Methyl-D-aspartate (NMDA) receptors 1 (NR1), NR2A and NR2B, post synaptic density-95 (PSD-95) and neuronal nitric oxide synthase (nNOS) is markedly lower in PSF compared to PLF mouse hippocampi and correlates with FST floating time. These data point towards a role of glutamatergic neurotransmission in SSRI treatment response.

Unit of Electron Microscopy., Kurume Univ. Sch. of Med., 67 Asahi-machi, Kurume, Fukuoka 830-0011, Japan

Abstract: Chronic fluoxetine increases the excitability of mature granule cells (GCs) in the dentate gyrus (DG) as well as the stimulation of neurogenesis. Perforant path axons (boutons) from the entorhinal cortex to DG form synapses on dendritic spines of GCs, known as perforant path synapse. Electrophysiological analysis using voltage sensitive dye detected the enhanced excitatory neurotransmission of perforant path synapse in the middle molecular layer (MML) of DG after chronic fluoxetine treatment. In this study, we investigated the effect of chronic fluoxetine (15 mg/kg/day, 14 days) on the morphology of perforant path synapse in the MML by focused ion beam (FIB)/scanning electron microscopy (SEM). 3D ultrastructural analyses of dendritic spine revealed the appearance of the extremely large-sized spine after chronic fluoxetine, which was confirmed with quantification of spine volume. The large-sized spine had a postsynaptic density with large volume. However, chronic fluoxetine did not affect spine density or volume distribution of the regular-sized spine. We next analyzed characteristics of perforant path bouton. The presynaptic bouton connected to the large-sized spine was large in volume and contained mitochondria and synaptic vesicles with large volume. In addition, the presynaptic bouton with large volume had a connection with multiple spines, and a tight correlation between volume of each presynaptic bouton and sum of spine volumes connected to

the bouton was found. These results demonstrate that chronic fluoxetine treatment affects structures of both the perforant path axon and the dendritic spine of GCs and induces the enlargement of perforant path synapse, which may be involved in the increased glutamatergic neurotransmission of perforant path synapse.

Title: Diving while taking an antidepressant: A case report of a diver with depression

Authors: D. A. DANCZYK[1], *J. V. PARDO[1], D. F. COLVARD[2]
[1]VAMC, Minneapolis, MN; [2]DivePsych, Raleigh, NC

Abstract: INTRODUCTION / BACKGROUND Very little research has been conducted on antidepressant use in the diver population. The prevalence of divers with depression requiring medications is estimated at 4.8%. The purpose of this article is to assist clinicians in the treatment of Major Depressive Disorder (MDD) for those with occupational or recreational diving habits. MATERIALS / METHODS This is a case presentation of a 37 year old male veteran with MDD, recurrent, who deep-sea dives as a hobby, and required cross-titration from mirtazapine to escitalopram due to weight gain. Data gathered from patient interview as well as treatment record. RESULTS Anecdotal evidence indicates diving is in itself a therapeutic treatment for mild depression. The patient in this case successfully cross-titrated to an SSRI, and did not have side effects while diving. SUMMARY / CONCLUSIONS Being treated with an antidepressant is no longer a strict contraindication to diving. No controlled studies have been conducted of divers at various pressure depths while on psychotropic medication. Despite this, a framework for determining fitness to dive can be used by the clinician. This includes close assessment of side effects before diving in determining the safety of a medication on a case-by-case basis.

Abstract: Selective serotonin reuptake inhibitors (SSRIs) are the most common form of psychotherapy among pregnant women with mood disorders. Serotonin plays a key role in neuronal proliferation, migration, and synaptogenesis, raising concerns about possible effects on the fetal brain. Research on prenatal SSRI exposure and human neurodevelopment has yielded conflicting results and no study has examined this issue using neuroimaging. The aim of this retrospective cohort study was to determine whether brain volumes and white matter microstructure differed in neonates exposed to SSRIs during pregnancy. 27 SSRI-exposed neonates of women with mood disorders were matched to 54 unexposed neonates with no history

of maternal mood disorder. High-resolution structural magnetic resonance imaging (sMRI) and diffusion weighted imaging (DWI) scans were acquired with a 3T Siemens Allegra scanner. An automatic, atlas-moderated expectation maximization segmentation tool was used to classify global tissue volumes. Regional differences in gray matter volumes were examined using deformation morphometry. Quantitative tractography was performed using the UNC-Utah NA-MIC DTI framework adapted for our neonatal sample. No significant differences were found in global tissue volumes. SSRI-exposed neonates exhibited a cluster of decreased gray matter in the thalamus ($p = 0.0088$) compared to unexposed neonates. DTI analysis revealed significantly altered diffusion along major white matter tracts. Results suggest SSRI exposure has minimal effects on tissue volumes. In contrast, SSRI exposure may impact white matter microstructure. Additional research is needed to clarify whether SSRIs directly alter white matter development or whether this relationship is mediated by severity of depressive symptoms during pregnancy.

Title: Fluoxetine treatment ameliorates adult-onset depression induced by perinatal arsenic exposure via a neurogenic mechanism

Authors: *C. R. TYLER, B. SOLOMON, A. M. ALLAN
Neurosciences, Univ. of New Mexico, Albuquerque, NM

Abstract: The role of environmental factors in the etiology of major depressive disorder (MDD) is widely acknowledged, but the molecular mechanisms and responses to antidepressants are relatively unknown. Epidemiological studies have shown that arsenic exposure increases the risk for developing psychiatric disorders, including MDD. In this study, we used a 50 parts-per-billion (ppb) perinatal arsenic exposure paradigm, which produces deficits in adult hippocampal neurogenesis (AHN) at postnatal day (PD) 70, to assess the potentially beneficial effects of chronic fluoxetine (50 or 100 mg/L) treatment on environmentally induced depression. Arsenic exposure generated depressive-like symptoms in a mild learned helplessness (LH) task in the forced swim task after 10 minutes of exposure to 2,4,5-trimethylthiazoline (TMT, as a predator odor). Five weeks of fluoxetine treatment prevented depressive-like behaviors in both the LH and FST in arsenic-exposed animals at PD70. The stress response, measured via corticosterone (CORT) levels at baseline and after TMT exposure, was blunted in arsenic-exposed animals; chronic fluoxetine treatment attenuated this effect. Morphologically, fluoxetine reversed arsenic-induced deficits in the number of differentiated and surviving neural progenitor cells (NPCs). Enhanced neurogenesis after fluoxetine treatment is likely mediated via increased brain-derived neurotrophic factor (BDNF), c-AMP response element binding protein (CREB), the glucocorticoid receptor (GR), or histone deacetylase 2 (HDAC2) in dentate gyrus tissue from arsenic-exposed males. This study demonstrates that damage induced by perinatal arsenic exposure is reversible with chronic fluoxetine treatment resulting in restored resiliency to depression via a neurogenic mechanism.

Title: Association between the COMT Val158Met polymorphism and the clinical response to SSRI or SSRI with antipsychotics in obsessive-compulsive disorder

Authors: *H. UMEHARA[1], S. NUMATA[1], A. TAJIMA[2], M. KINOSHITA[1], S. NAKAAKI[3], I. IMOTO[2], S. SUMITANI[1], T. OHMORI[1]

[1]Dept. of Psychiatry, [2]Dept. of Human Genet., The Univ. of Tokushima Grad. Sch., Toskushima, Japan; [3]Lab. of Aging, Behavior and Cognition, Dept. of Neuropsychiatry, Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Object: Accumulating evidence indicates that abnormalities in serotonergic and dopaminergic systems are involved in the pathophysiology and/or treatment of obsessive-compulsive disorder (OCD). Catechol-O-methyltransferase (COMT) is an enzyme that participates in the metabolic inactivation of dopamine and norepinephrine, and the Met allele of the COMT Val158Met polymorphism (rs4680) is associated with lower enzymatic activity. The purpose of the present study was to investigate whether this functional variant of the COMT gene is associated with OCD and the clinical responses of OCD. Methods: We performed a case-control association study between rs4680 and OCD (n=1,115), and conducted a meta-analysis of genetic association studies (n=3,659). Ninety-one patients with OCD participated in our pharmacogenetic study. The patients were divided into three groups according to pharmacological response, as evaluated by the Yale Brown Obsessive-Compulsive Scale (Y-BOCS): group A, responders to a selective serotonin reuptake inhibitor (SSRI) (n=53); group B, responders to a SSRI with an atypical antipsychotic (n=22); and group C, non-responders to a SSRI with an atypical antipsychotic (n=16). Patients who showed a >35% decrease on the Y-BOCS after treatments were considered responders. The risks of OCD and pharmacological response were tested for their association with rs4680 genotypes by logistic regression, assuming an additive contribution of the Met allele. Results: Although we found no significant association between the Met allele and OCD risk within the Tokushima sample set (per-allele OR, 1.15; 95% CI, 0.90-1.48; P = 0.27), the meta-analysis of the genetic association studies, including our sample set, demonstrated a significant association between the Met allele and OCD (per-allele OR, 1.16; 95% CI, 1.05-1.48; P = 0.0054). On the other hand, no significant association between the Met allele and SSRI response (group A vs. group B plus C) was observed (per-allele OR, 1.40; 95% CI, 0.76-2.58; P = 0.28). Moreover, no significant association between the Met allele and the response to a SSRI with antipsychotics (group B vs. group C) was observed (per-allele OR, 0.37; 95% CI, 0.18-1.06; P = 0.06). Conclusion: Our results suggest that the COMT Val158Met polymorphism could be a risk factor for developing OCD. However, this polymorphism may not be associated with the therapeutic responses to a SSRI or to a SSRI with an atypical antipsychotic in OCD.

Title: Region-specific induction of FosB isoforms in mouse brain after stress or chronic fluoxetine exposure

Authors: M. A. THIBAULT[1], A. L. EAGLE[1], S. KASKA[1], E. J. NESTLER[2], M. S. MAZEI-ROBISON[1], V. VIALOU[3], *A. ROBISON[1]
[1]Neurosci., Michigan State Univ., East Lansing, MI; [2]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY; [3]Neurosci., Univ. Pierre et Marie Curie, Paris, France

Abstract: An estimated 1 in 10 U.S. adults report depression, but current pharmacological therapies are effective in only about 50% of patients. In order to uncover novel gene targets that may allow for therapeutic treatment of currently refractive individuals, we examine the gene targets of transcriptional changes that occur with chronic exposure to antidepressants, including the selective serotonin reuptake inhibitor fluoxetine. We have previously shown that induction of the transcription factor ΔFosB in the nucleus accumbens (NAc) of mice promotes resilience to the social defeat model of depression and is required for fluoxetine-mediated reversal of the social defeat phenotype (Vialou et al., 2010). Here, we show by immunohistochemistry that FosB isoforms are induced in more than 25 different brain regions by chronic fluoxetine, including many regions classically associated with depression and mood, i.e. hippocampus (HPC) and prefrontal cortex (PFC). Further, we demonstrate by Western blot that FosB isoforms are differentially expressed by brain region, both in the basal state and after fluoxetine-mediated induction. While HPC and PFC have low basal levels of FosB isoforms and show high levels of ΔFosB after fluoxetine, NAc has a higher basal expression of FosB, ΔFosB, and Δ2ΔFosB, and shows a proportionally greater induction of full-length FosB after fluoxetine. We also observe differential isoform expression in these brain regions after chronic social defeat stress, indicating that FosB isoform expression patterns may underlie susceptibility and resilience to stress. Because each FosB isoform has different gene targets that may very further by brain region, we hypothesize that determining the brain-region-specific gene expression changes mediated by FosB isoforms may uncover novel targets for therapeutic intervention in mood disorders that could improve treatment of currently refractive individuals. In line with this hypothesis, we are currently conducting experiments to determine whether ΔFosB expression in hippocampus controls mood or mediates the antidepressant effects of fluoxetine and are exploring ΔFosB gene targets in this and other brain regions.

Title: Cognitive aging in retired professional athletes

Authors: *A. HINDS, J. J. LEDDY, J. BAKER, T. SHARMA, B. S. WILLER
Univ. at Buffalo, Buffalo, NY

Abstract: Recent reports of early onset dementia, cognitive impairment, and violent behavior in individuals with a history of concussive injury has raised concern over the long-term risks for athletes participating in contact sport. Understanding the risk factors and symptom progression that may ultimately lead to a diagnosis of chronic traumatic encephalopathy (CTE) in former professional athletes is essential for early intervention and treatment of affected individuals (Antonius et al., 2014). Previous literature suggests that difficulty with executive function is a problem in athletes at risk for developing CTE (Stern et al., 2011). To evaluate risk for CTE, we compared cognitive performance in 18 retired professional athletes (aged 40-72) that had played a contact sport, with age-matched controls from non-contact sports. Contact athletes included professional hockey and football players who had played in the National Football league and National Hockey league. All participants completed a battery of neuropsychological tests that assess a range of cognitive functions, including memory, attention, language, information processing speed, and executive function. We also assessed self-report of executive functioning (the BRIEF questionnaire), lifestyle factors, mood, and behavioral characteristics such as impulsivity and risk-taking. Although we did not find any specific pattern of cognitive deficits amongst contact sport athletes, more than two-thirds of these individuals self-reported executive dysfunction on the BRIEF, scoring in the abnormal range on indices of behavioral regulation and metacognition (which includes working memory, task monitoring, planning and organizing). Interestingly, self-report of these deficits was not consistent with actual cognitive difficulty, as measured by performance on several tests requiring executive functioning (including the Wisconsin Card Sorting test). These results suggest that, while contact athletes may be at risk for long-term executive function difficulties, we do not find substantial evidence of a direct causal link between sport history and executive dysfunction.

Title: Functional differences in the brain following trauma: A quantitative meta-analysis of fMRI studies in post-traumatic stress disorder

Authors: ***E. A. STARK**[1], C. E. PARSONS[2], A. STEIN[2], H. MCMANNERS[2], A. EHLERS[3], M. L. KRINGELBACH[2]
[1]Univ. of Oxford, OXFORD, United Kingdom; [3]Exptl. Psychology, [2]Univ. of Oxford, Oxford, United Kingdom

Abstract: Neurobiological models of post-traumatic stress disorder (PTSD) propose that dysregulation of limbic-prefrontal activity underlies its aetiology. Much of the empirical data for these theories is derived from neuroimaging studies where the brain activity of adults with PTSD is compared to that of adults without PTSD. However, the typical comparison groups in functional magnetic resonance imaging (fMRI) studies are mixed: some trauma-exposed and some unexposed. We therefore performed a systematic review and voxel-based meta-analysis of task-based fMRI studies of PTSD, to explore differences in functional activity between adults with PTSD and either trauma-exposed or unexposed control participants. We aimed to disentangle the effects of trauma exposure on the brain from effects of trauma exposure leading to PTSD We searched the databases: Web of Science, PsycINFO, and Scopus for studies published between 1st January 2000 and 31st December 2013. Fifty studies were included in the final review. The analysis was threefold. First, we used activation likelihood estimation analysis to explore significant differences in regional brain activity between adults with PTSD and adults without PTSD. Second, we separated studies by the nature of the comparison group: whether they had been exposed to trauma or not. Third, we explored functional differences in the PTSD brain in response to stimuli unrelated to trauma, in comparison to that of both trauma-exposed and trauma-naïve controls. Our main results suggest that the experience of trauma, whether or not it leads to PTSD, may have an important, long-lasting effect upon functional brain activity.

Trauma-exposed individuals who do not develop PTSD do still appear to display functional differences in brain activity. Furthermore, our results suggest that the nature of the stimuli used in the study (trauma-related or unrelated) may also have an important impact upon resultant brain activity in PTSD relative to both control groups (trauma-exposed and trauma-naïve). We review findings in the context of extant neurobiological models. We propose important future directions for neuroimaging work in this area, and also explore the clinical relevance for trauma-exposed individuals who do not develop full-blown PTSD.

Title: Concurrent measurement of Neuropeptide Y (NPY) in cerebrospinal fluid (CSF), plasma, and saliva from combat veterans with and without posttraumatic stress disorder (PTSD)

Authors: *R. SAH[1], N. N. EKHATOR[2], L. JEFFERSON-WILSON[2], P. HORN[3], T. D. GERACIOTI[2]
[1]Psychiatry & Behavioral Neurosci., Univ. Cincinnati, CINCINNATI, OH; [2]Veterans Affairs Med. Ctr., Cincinnati, OH; [3]Mathematical Sci., Univ. of Cincinnati, Cincinnati, OH

Abstract: Neuropeptide Y (NPY), a 36-amino acid peptide transmitter, is recognized as a resilience-to-stress factor in humans. Previous work from our group found reduced cerebrospinal fluid (CSF) concentrations of NPY in veterans with combat-related PTSD in comparison with both healthy volunteers and combat veterans without PTSD. Studies on plasma NPY in combat PTSD subjects from other groups have observed both, reduced or increased levels that are dependent on trauma exposure or recovery, respectively. In the current study we performed serial measurement of NPY in CSF, plasma, and saliva samples collected from combat veterans with or without PTSD over a 6 hour time interval. The objective was, a) to extend previous single time

point studies to continuous sampling in order to examine repeated measures data, including afternoon CSF NPY levels, b) to compare simultaneously-obtained plasma and saliva pools with CSF to explore their potential as biomarkers of central NPY. Consistent with our previous findings with a single time point collection, we observed an enduring reduction in CSF NPY in veterans with PTSD as compared with the combat-no PTSD group. Two way ANOVA, using diagnosis and time as variables, revealed a statistically significant effect of diagnosis [$F_{(1,111)} = 7.80$; $p=0.006$] with no time or diagnosis x time interaction. No significant difference in plasma or saliva NPY concentrations between the combat-PTSD and combat-no PTSD cohorts was observed. Collectively, our data indicate that decreased CSF NPY concentrations in combat veterans with PTSD appear to be a feature of the disorder, and one that persists throughout the day (ruling out acute stress-related responses during lumbar puncture). Additionally, plasma and salivary pools did not reflect CNS NPY alterations in PTSD, at least under baseline conditions of the current study. Funded by VA merit grants (TDG, RS)

Abstract: Previous research has shown that posttraumatic stress disorder (PTSD) is associated with exaggerated amygdala activation to clear indicators of potential threat in the environment (i.e., fearful facial expressions; e.g., Rauch et al, 2000; Shin et al., 2005; Williams et al., 2005). However, many individuals with PTSD are hypervigilant when threat is not clearly present. In the current research, we sought to study amygdala responses to ambiguous social signals (i.e., surprised facial expressions, which can be interpreted positively or negatively [Kim et al., 2003]) in PTSD. Using functional magnetic resonance imaging (fMRI) and a well-validated set of surprised facial expressions (Ekman & Friesen, 1976), we studied Vietnam combat veterans with PTSD (n=12) and without PTSD (n=16). The two groups did not significantly differ in their categorization or valence ratings of the surprised faces, but the PTSD group demonstrated greater amygdala activation to the surprised expressions than the non-PTSD group. Thus, although there appeared to be no interpretation bias on the behavioral level, greater amygdala activation in the PTSD group could reflect greater evaluation of the ambiguous social stimuli.

Title: Neuropeptide Y and the association with deployment to a combat zone and symptoms of post traumatic stress disorder: A longitudinal prospective military cohort study

Authors: *E. GEUZE[1,2], A. REIJNEN[1,2], E. VERMETTEN[1,3,2,4]

Care, Utrecht, Netherlands; [3]Leiden Univ. Med. Ctr., Leiden, Netherlands; [4]Arq Psychotrauma Expert Group, Diemen, Netherlands

Abstract: Introduction: Neuropeptide Y (NPY) is a peptide neurotransmitter highly expressed in the limbic and brain stem areas and in the autonomic nervous system. NPY is suggested to represent a biological correlate of resilience, promoting stress regulation. Therefore, it is relevant to examine NPY in studies on the neurobiology of stress-related disorders, such as posttraumatic stress disorder (PTSD). Reduced NPY concentrations are found in PTSD patients compared to healthy controls. However, studies have also reported reduced baseline NPY levels to be associated with trauma exposure rather than PTSD. The aim of the current study is to assess the effect prolonged high-intensity stress on plasma NPY levels and the association with the development of PTSD symptoms. Method: This study is part of a prospective cohort study on deployment-related health problems in the Dutch armed forces. A total of 920 males volunteered to participate in the study prior to a 4-month deployment to Afghanistan. About one month prior to deployment and at 1 and 6 months post-deployment participants completed various questionnaires and blood samples were collected. In addition, follow-up assessments with questionnaires were performed at one and two years after return. The presence of PTSD symptoms was assessed with The Dutch Self-Rating Inventory for PTSD (SRIP). Results: Preliminary findings show a significant increase in plasma NPY levels shortly after deployment. Further analyses will be performed to test the hypothesis that NPY levels are lowered in participants with a high level of PTSD symptoms and to test if these NPY levels are low pre-trauma or if this is evoked by trauma. Discussion: Plasma NPY levels increase after deployment to a combat-zone. The (alterations in) NPY levels might be associated with the development of PTSD symptoms. More insight on NPY as a vulnerability and/or protective factor might provide treatment options for military personnel with a high level of PTSD symptoms, and might also provide potential preventive interventions strategies.

Title: Frontal cortex activity during emotional processing is altered in veterans with hazardous alcohol use and posttraumatic stress disorder

Authors: G. FORSTER[1], *D. M. OLSON[1], L. BAUGH[1], J. HANSEN[2], S. ENGEL[1], R. GAHER[2], J. SIMONS[2], V. MAGNOTTA[3]
[1]Basic Biomed. Sci., [2]Psychology Dept., Univ. of South Dakota, Vermillion, SD; [3]Carver Sch. of Med., Univ. of Iowa, Iowa City, IA

Abstract: Emotionally-significant stimuli activate frontal cortical regions such as the anterior cingulate cortex (ACC), thought to inhibit the activity of subcortical structures involved in the expression of fear and anxiety states. Many imaging studies suggest that posttraumatic stress disorder (PTSD) is associated with hypofunction of the ACC. For example, Vietnam veterans with PTSD fail to show rostral ACC activation during the emotional counting stroop task (ECST) in conditions when combat-related words are presented. However, other studies show increased activation of the ACC with combat-related imagery in veterans with PTSD. Differences between studies have been attributed to variation in the tasks used, the chronicity of PTSD (i.e. Vietnam verses post 9/11 veterans), differences in PTSD symptomology, and regional differences in emotional processing within the ACC. Another factor that could influence frontal cortex function is alcohol use. As many as 50-85% of individuals with PTSD have a comorbid alcohol use disorder, and hazardous alcohol use is associated with reduced ACC activation during evaluation of emotional facial expressions. Therefore the current study aimed to determine behavioral and neural reactivity in response to the ECST in post-9/11 veterans with and without hazardous alcohol use. Eighty-five male and female right-handed veterans of Operations Enduring Freedom and Iraqi Freedom (OEF/OIF) were assessed for combat intensity, PTSD, alcohol use and alcohol dependence, and completed the Wisconsin Card Sorting Task (WCST) as a measure of executive functioning. Participants underwent functional magnetic resonance imaging (fMRI) while performing the ECST adapted for OEF/OIF veterans. At the conclusion of the scanning, participants provided arousal ratings for words comprising the ECST. Veterans with PTSD exhibited increased reaction times to combat-related words in the ECST, and provided higher arousal and negative ratings for combat words compared to veterans without PTSD. However, there was no effect of PTSD on any measure on the WCST, suggesting that frontal-related behavioral alterations might be specific to emotional processing in veterans with PTSD. Interestingly, veterans with PTSD and hazardous alcohol use showed increased activity of the rostral ACC in combat word conditions of the ECST as compared to controls (veterans without PTSD or hazardous alcohol use); a pattern not observed in PTSD or hazardous alcohol groups alone. Overall, findings suggest that hazardous alcohol use might contribute to inconsistencies in rostral ACC reactivity between different imaging studies of PTSD populations.

Title: Antisaccade as an objective measure of inhibitory control in PTSD: an eye-tracking study

Authors: M. J. REINHARD[1], L. M. WONG[1], S. BANSAL[2], N. ALLEN[1], *B. L. SCHWARTZ[1]
[1]VA Med. Ctr., Washington, DC; [2]George Mason Univ., Washington, DC

Abstract: BACKGROUND: The antisaccade task is used to assess the competition between involuntary, stimulus-driven (bottom-up) and voluntary (top-down) eye movements and attention. Neuroimaging, animal studies, and single-cell recording have verified the central role of inhibitory brain mechanisms in antisaccade performance. Because inhibitory control difficulty is a salient feature of PTSD, we assessed whether antisaccade performance was impaired in this population, and whether performance related to a clinical neuropsychological measure of attention and inhibitory control METHOD: Veterans with (PTSD+; n=10) and without PTSD (PTSD-; n=10) were administered an eye movement task, with fixation on a center point and a target circle presented peripherally. They were asked to look toward the target (prosaccade) or in the direction opposite the target (antisaccade). Errors for both tasks were compared between groups, and correlated to PTSD symptom scores and the continuous performance test (CPT). RESULTS: There was no difference between groups on error rate for the prosaccade task ($t = -1.14$, $p = 0.27$), however the PTSD+ group made significantly more errors than the PTSD- group on the antisaccade task ($t = -2.30$, $p = 0.04$). In PTSD+, increased errors in the prosaccade task were associated with increased avoidance and numbing symptoms ($r = 0.63$, $p = 0.05$), and in the antisaccade task were associated with increased re-experiencing symptoms ($r = 0.74$, $p = 0.01$). Groups did not differ in performance on the CPT. In PTSD+, increased errors in the antisaccade task were associated with increased commission errors ($r = 0.88$, $p = 0.002$) and decreased d-prime ($r = -0.87$, $p = 0.002$) in the CPT. In PTSD-, these associations were not observed. CONCLUSIONS: This study demonstrates that antisaccade performance: (1) differs between PTSD+ and PTSD- veterans, (2) declines with increased PTSD symptoms, and (3) relates to inhibitory control impairment in a clinical neuropsychological test. Findings suggest that the

antisaccade task is a sensitive and potentially reliable neurobehavioral marker of inhibitory control disturbances in PTSD.

Title: More than meets the eyes: the impact of eye gaze and emotional expression on antisaccade performance in PTSD

Authors: ***L. M. WONG**[1], S. BANSAL[2], N. ALLEN[1], A. H. ADAMS[1], B. L. SCHWARTZ[1], M. J. REINHARD[1]
[1]VA Med. Ctr., Washington, DC; [2]George Mason Univ., Washington, DC

Abstract: BACKGROUND: Social avoidance and interpersonal difficulty are core symptoms of PTSD, and inhibitory control impairments are often observed in individuals with the disorder. In many social interactions, one must interpret human directional gaze cues and emotional expressions, and respond accordingly−looking in the same direction of someone's gaze is an automatic response. The antisaccade task has been used in many populations to assess inhibitory control, the ability to suppress an automatic response. We examined how directional gaze and affect impact inhibitory control in PTSD, and whether performance related to a clinical neuropsychological measure of executive function. METHOD: Participants were veterans with PTSD (PTSD+; n=11) or without PTSD (PTSD-; n=10). They viewed centrally presented neutral and fearful faces, the eye gaze of which was either to the left or right. In the Prosaccade and Antisaccade tasks, respectively, participants looked in the same or opposite direction of the eye gaze. Dependent variables were error rate and first accurate saccade latency. These variables were compared between groups, and correlated to the letter-number sequencing task. RESULTS: In a Group (PTSD+ and PTSD-) X Task (Prosaccade and Antisaccade) X Emotion (neutral and fear) ANOVA, there was no effect of Group on errors ($F = 0.05$, $p = 0.83$), though people in both groups do make more errors in the Antisaccade task ($F = 0.72$, $p = 0.03$). There was an effect of

Group on latency, such that PTSD+ was slower overall ($F = 6.22$, $p = 0.01$), which was driven by slowing in the Antisaccade ($t = -2.22$, $p = 0.04$) but not Prosaccade task ($t = -0.33$, $p = 0.74$). Inhibitory cost was calculated as the increase in first accurate saccade latency in the Antisaccade relative to Prosaccade task. Inhibitory cost did not differ between groups ($t = -0.94$, $p = 0.36$), but in PTSD+ was associated with impaired performance on a letter-number sequencing task ($r = -0.68$, $p = 0.04$). CONCLUSIONS: This study demonstrates that human directional gaze (1) can be used in a social version of the antisaccade task, (2) is sensitive to inhibitory control impairment in PTSD, and (3) can be used in a task that relates to other measures of executive function. These findings suggest that eye-tracking measures are an effective tool in examining how social and affective cues affect cognitive function in PTSD.

Title: Antagonism of melanocortin 4 receptors by intranasal HS014 attenuates single prolonged stress triggered changes in several brain regions

Authors: *L. I. SEROVA[1], M. LAUKOVA[2], L. G. ALALUF[1], E. L. SABBAN[1]
[1]Biochem. and Mol. Biol., New York Med. Col., Valhalla, NY; [2]Biochem. and Mol. Biol., New York medical Col., Valhalla, NY

Abstract: The melanocortin receptor four (MC4R) is expressed in many brain regions and is implicated in regulation of stress-related functions. We have previously shown that intranasal (IN) infusion of MC4R antagonist HS014, shortly before single prolonged stress (SPS) animal model of PTSD can attenuate development of several behavioral impairments. Male Sprague Dawley rats infused IN with 100 μg HS014 not only had reduced despair behavior in forced swim immediately following immobilization stress but also attenuated development of depressive- and anxiety-like behavior induced by traumatic stress of SPS. However, low dose HS014 (3.5 ng) effectively attenuated only anxiety-like behavior (Serova et al. 2013, Beh. Brain

Res,.250:139-147). Here we evaluated their effects on SPS-elicited changes in HPA axis and expression of genes of interest in mediobasal hypothalamus, hippocampus and locus coeruleus. Rats were given IN HS014 (3.5 ng or 100 µg) or vehicle 30 min prior to SPS stressors or left unstressed (controls). Acute responses were evaluated 30 min following SPS stressors. HS014 infusion led to smaller rise in plasma corticosterone (100 µg HS014) as well as absence of induction of corticotropin-releasing hormone (CRH) mRNA in mediolbasal hypothalamus (both doses) and of mRNA for norepinephrine biosynthetic enzymes (TH and DBH) in locus coeruleus (especially 3.5 ng HS014). Long-term responses were examined 7 days after SPS stressors, time requested for developing PTSD-related symptomology. In the mediobasal hypothalamus, SPS triggered induction of CRH mRNA which was attenuated with HS014 (both doses). However, HS014 was not effective to change the SPS-elicited elevation in mRNAs for the glucocorticoid receptor (GR) and FKBP5, a component of GR co-chaperone complex. In the ventral hippocampus, the SPS-elicited increase of GR protein levels was absent in animals given HS014 (both doses). The results demonstrated that antagonism of MC4R by intranasal infusion prior to traumatic stress attenuates development of molecular abnormalities in several brain regions implicated in mediating PTSD-associated impairments.

Title: Intranasal oxytocin affects amygdala reactivity towards emotional faces in recently traumatized individuals

Authors: *J. FRIJLING[1], M. VAN ZUIDEN[2], S. B. J. KOCH[2], L. NAWIJN[2], D. J. VELTMAN[3], M. OLFF[2,4]
[1]Dept of Psychiatry, Ctr. for Anxiety Disorders, [2]Psychiatry, Academic Med. Ctr., Amsterdam, Netherlands; [3]Psychiatry, VU Univ. Med. Ctr., Amsterdam, Netherlands; [4]Arq Psychotrauma Expert Group, Diemen, Netherlands

Abstract: Background: Few interventions are available that effectively prevent post-traumatic stress disorder (PTSD) development early post-trauma. PTSD is characterized by amygdala hyperresponsiveness, which also may be a pre-existing risk factor for PTSD development. Intranasal oxytocin (OT) may prevent PTSD early after trauma, since it targets amygdala reactivity. Here we used fMRI to study the effects of intranasal OT on amygdala reactivity in recently traumatized individuals at increased PTSD risk. Since effects of OT may differ between males and females, we additionally aimed to explore differential effects of sex. Methods: In a randomized double-blind placebo-controlled fMRI study we assessed amygdala responses towards emotional faces (fearful, happy, neutral) in 41 recently trauma-exposed individuals (M = 17). Participants were recruited from Emergency Departments after experiencing a traumatic event. Within 7 days post-trauma trauma-exposed individuals were assessed for increased PTSD risk using 2 questionnaires. Within 11 days post-trauma participants were scanned after either intranasal OT (40 IU) or placebo administration. Treatment effects were assessed for each emotion separately. Small volume corrected analyses were conducted for bilateral amygdala. Post hoc, we tested for differential effects of sex. Results: Compared to placebo, OT administration increased right amygdala (xyz 29 3 -21) reactivity during processing of fearful faces. Exploratory analyses showed that OT increased left amygdala (xyz -26 -9 -15) reactivity during processing of neutral faces in females, and also tended to decrease right amygdala (xyz 25 -11 -11) reactivity during processing of fearful faces in males. Conclusion: These results indicate that OT affects amygdala reactivity in recently traumatized individuals, however the effects depend on stimulus valence and sex. The exploratory analyses revealed a possible dual effect of OT in the right amygdala during fearful face processing in males. The influence of sex and other interindividual factors (e.g. acute PTSD symptom severity) on the effects of OT on the amygdala should be further investigated.

Title: Persistently elevated ghrelin underlies continued vulnerability to enhanced fear following stress exposure

Authors: *E. S. HARMATZ, K. GOOSENS
Brain and Cognitive Sci., MIT, Cambridge, MA

Abstract: In humans, prolonged stress exposure produces vulnerability to trauma-associated mental health disorders such as post-traumatic stress disorder (PTSD) for years after stressor exposure is terminated. We have recently shown that chronic stress produces vulnerability to enhanced fear in a rat model of PTSD by elevated signaling through ghrelin and growth hormone. Specifically, chronic stress persistently enhances circulating peripheral levels of acylated ghrelin and also levels of growth hormone in the basolateral amygdala. We hypothesized that the persistent elevation in circulating ghrelin might underlie the long-term vulnerability to PTSD that follows stress exposure. To address this issue, we first examined circulating ghrelin levels in rats seventy days following stressor termination. Rats were exposed to immobilization stress (STR) or handling (no stress, or NS) for two weeks and tail blood samples were collected seventy days following the final stress or handling session. We found that ghrelin levels were significantly elevated even at this remote time point. Because we have previously shown that antagonism of the ghrelin receptor during stress exposure prevents stress-related enhancement of fear, we conducted an experiment to determine whether stress-enhancement of fear would re-emerge if ghrelin receptor antagonism was terminated at the end of stress exposure. Rats were exposed to 14 days of either STR or NS and received injections of either vehicle (VEH) or the ghrelin receptor antagonist GHRP-6 [D-Lys3] (DLys) daily; all rats received vehicle injections for 14 days after the final stress or handling session. Tail blood samples were collected during the post-stress period to determine whether DLys administration affected endogenous circulating ghrelin levels. Auditory fear conditioning was administered on the fifteenth day following the final stress or handling session. This resulted in the following groups: NS-Veh/Veh, STR-DLys/Veh, STR-Veh/Veh. We found that rats in both the STR-DLys/Veh and STR-Veh/Veh groups displayed enhanced fear memory relative to rats in the NS-Veh/Veh group. Moreover, the administration of DLys during stress did not prevent stress-associated enhancement of circulating ghrelin. These studies are consistent with the idea that stress-related enhancement of ghrelin contributes to continued vulnerability to fear after stress exposure. **Keywords:** Stress, Amygdala, Learning, Restraint, PTSD, Rat

Title: N/OFQ system selective antagonism decreases binge-like alcohol drinking in mice

Authors: *G. BRUNORI[1,2], A. CIPPITELLI[1], A. OZAWA[1], J. SCHOCH[1], M. GORMAN[1], K. GAIOLINI[1], N. ZAVERI[3], R. CICCOCIOPPO[2], L. TOLL[1]
[1]Torrey Pines Inst. For Mol. Studies, Port Saint Lucie, FL; [2]Sch. of Pharmacy, Pharmacol. unit, Univ. of Camerino, Camerino, Italy; [3]Astraea Therapeut., Mountain View, CA

Abstract: Several lines of evidence suggest a role of the N/OFQ system in alcohol-related behaviors. The 'drinking in the dark' (DID) procedure is a well-established animal model of human binge-like alcohol drinking known to reliably generate high levels of voluntary alcohol consumption and pharmacologically relevant blood alcohol concentration in alcohol preferring mice strains (e.g. = C57BL/6J). Frequent binge drinking facilitates alcohol dependence. Thus, the DID model may represent a useful tool for studying the neurobiology underlying the transition to dependence. In the present study the contribution of N/OFQ receptor (NOP) signaling in the binge-like drinking behavior is investigated. During the 4-day DID procedure C57BL/6J mice received alcohol (20% v/v) in place of water, beginning 3 hours into the dark cycle. Mice had 2 hours access to alcohol solution during days 1 to 3, and 4 hours on day 4. On the fourth day, mice were given a subcutaneous injection of the NOP selective agonist AT 202 (0, 3, 10 mg/kg) or antagonist SB 612111 (0, 3, 10, 30, 60 mg/kg) 30 minutes before receiving alcohol. We have determined that binge-like alcohol drinking was significantly attenuated by pretreatment with SB 612111 (30, 60 mg/kg), while pretreatment with AT 202 did not alter the consumption. The finding that the NOP antagonist SB612111 can attenuate alcohol drinking indicates that NOP receptors are involved in excessive alcohol intake before the development of dependence. Current studies are aimed at evaluating the alterations of the N/OFQ system signaling using immunoreactivity mapping of the NOP receptor on NOPeGFP knock-in mice (generated on the C57BL/6J-mouse background).

Abstract: Stress exposure may facilitate the transition from casual alcohol use to excessive drinking associated with dependence. Our lab has previously found that daily forced swim stress (FSS) prior to ethanol drinking sessions results in enhanced ethanol consumption in mice with a history of chronic intermittent ethanol (CIE) vapor exposure but not air-exposed controls (CTL). Kappa opioid receptors (KORs), which are activated by stress and upregulated by chronic ethanol, pose one potential mechanism by which stress may interact with ethanol dependence. Other laboratories have shown that administration of the KOR agonist U50,488 can mimic behavioral effects of FSS. Accordingly, the present study was designed to determine whether U50,488 administration could substitute for the effects of repeated daily FSS on ethanol consumption in CIE and CTL C57BL/6J mice. Once stable baseline ethanol intake was established in a 1-bottle (15% ethanol) limited access (1 hr/day) procedure, mice received chronic intermittent exposure (16 hr/day x 4 days/week) to ethanol vapor (CIE group) or air (CTL group). The weekly cycles of inhalation exposure were alternated with 5-day drinking test cycles. Intake sessions were conducted in drinking chambers configured with lickometer circuitry. CIE and CTL groups were further subdivided into stress conditions: 1) no stress, 2) FSS (10 min; 4 hr prior), or 3) 5 mg/kg injection of U50,488 (in lieu of FSS exposure) 60 min prior to each ethanol drinking test session. Blood samples were collected after the last drinking
