Title: A role for PSD-95 and its binding partners in models of Traumatic Brain Injury.

Authors: *M. V. PATEL[1], D. F. MEANEY[2], B. L. FIRESTEIN[1];
[1]Cell Biol. and Neurosci., Rutgers Univ., Piscataway, NJ; [2]Dept. of Biomed. Engin., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Traumatic brain injury (TBI) damages neuronal networks, resulting in disrupted brain function and cognitive deficits. Normal dendrite morphology and synapse formation are required for proper neuronal signaling and survival. The study of new molecular targets to repair deficits in dendritic arbors and spines post-trauma will yield promising future directions for drug development for the treatment of patients who have suffered a TBI. Postsynaptic density-95 (PSD-95) is of particular interest as it is required for proper neuronal development. Specifically, PSD-95 inhibits dendrite branching by regulating microtubule dynamics and sequestering end-binding protein 3 (EB3), and potentially Adenomatous polyposis coli (APC), from the +TIPs of microtubules. Overexpression of PSD-95 causes decreased dendrite branching and increased number of mature spines, while knockdown has the opposite effect. Previous studies of TBI have shown a delayed reduction in PSD-95 levels post-trauma, suggesting a role for inhibition of PSD-95 after TBI. Based on these facts, we propose that altering PSD-95 protein levels post-injury will rescue dendritic arborization and synaptogenesis after injury. In line with a role for PSD-95 post-injury, we find increased interaction of PSD-95 with its binding partners, APC and EB3, in an in vitro TBI model of mechanical stretch injury, while total protein levels of PSD-95 and EB3 are decreased. In parallel, we use controlled cortical impact (CCI) in mice as an in vivo model of TBI, which shows decreased dendrite number in the early phase (0-3 days) and decreased synapse number in the late phase (3-7 days) post-injury. We find that there is no change in the interaction of PSD-95 and its binding partners 24 h after injury, while total EB3 protein decreases significantly at 24 h post-injury. As EB3 is involved in the promotion of dendrite branching, decreased levels of EB3 at 24 h post-injury suggests a role for EB3 in decreasing the dendritic network during the early injury phase after TBI. We began our studies with a time point of 24 h post-injury and are now examining brains at earlier and later time

points to determine changes in interaction of PSD-95 and its binding partners and total levels of these proteins. To aid in recovery, we will downregulate PSD-95 in the early phase post-injury to rescue dendritogenesis followed by upregulation of PSD-95 during the late phase post-injury to rescue spine number. We predict that PSD-95 will rescue normal function by promoting neuronal survival, dendrite branching, and spine formation after TBI.

Title: The role of CPE and its interactor, $p150^{Glued}$, in regulation of neuronal cytoskeleton and migration

Authors: *C. LIANG[1,2], D. CARREL[1], H. KIM[1], B. L. FIRESTEIN[1];
[1]Dept. of Cell Bio and Neuroscience, Rutgers Univ., Piscataway, NJ; [2]Mol. Biosci. Grad. Program, Rutgers Univ., Piscataway, NJ

Abstract: Carboxypeptidase E (CPE) is a member of carboxypeptidase family that processes neuropeptides and peptide hormones and regulates processes in the endocrine and nervous systems. CPE knockout mice have neurobehavioral deficits, including deficits in learning and memory. It was previously reported that $p150^{Glued}$ and CPE exist in a complex in cultured cells; our current study confirms this interaction in mouse brain and identifies the region in $p150^{Glued}$ that is responsible for CPE binding. In addition, our studies in cell lines suggest that CPE overexpression redistributes endogenous $p150^{Glued}$ from the centrosome, disrupts microtubule organization, and mediates the post-translational modification (PTM) of microtubules. As $p150^{Glued}$ is the largest subunit of the Dynactin complex, which is indispensible for the functional motor activity of dynein, we hypothesized that CPE exerts its effect on the cytoskeleton by altering PTMs of microtubules, resulting in alterations in localization of motor protein complexes and/or other microtubule-binding proteins. Thus, we extended our studies to assess the role of CPE in dendrite branching in primary cultured neurons, and in cortical neuron

migration via *in utero* electroporation since dendritogenesis and neuronal migration rely heavily on motor protein complexes and the stability of cytoskeleton. Preliminary data show that knockdown of CPE protein results in disrupted migration and altered cellular morphology in neurons in the cortical plate and decreased dendrite branching in cultured hippocampal neurons. Together, our studies provide new evidence for the role of CPE and its interactor, $p150^{Glued}$, in regulating multiple processes involved in neuronal development.

Title: Mir125b mediated filopodial dynamics in developing dendrites

Authors: *R. IYER[1], T. KIM[2], M. E. KANDEL[2], G. POPESCU[3,2], M. U. GILLETTE[1,3,4]; [1]Cell and Developmental Biol., Univ. of Illinois At Urbana-Champaign, Urbana, IL; [2]Electrical & Computer Engin., [3]Beckman Inst., [4]Neurosci. Program, Univ. of Illinois at Urbana Champaign, Urbana, IL

Abstract: Neurons have complex dendritic arbors, which contribute to the intricate circuitry found in the nervous system. The interplay between the intrinsic cellular machinery of neurons and external stimuli is critical for the establishment of this arbor, allowing dendrites to find their intended axonal partners. This process, however, is not well understood. Recent studies have pointed to microRNAs (miRNA), small noncoding RNAs about 22 nucleotides long, as potential sites for integration of external stimuli to changes in local protein expression. This can lead to rapid and local changes in filopodial and dendritic structures, a key requirement to navigate the spatio-temporally variant signals dendrites receive. Here we investigate the brain-abundant miRNA, miR125b, to elucidate its role in the dynamics of filopodia and the corresponding changes in filopodial and dendritic structure during development. miR125b has been shown to be maximally expressed at the developmental period corresponding to filopodial outgrowth in dendrites. We inhibit its activity in cultured neurons as dendritic filopodia explore their

microenvironment. Using a combination of confocal microscopy and high resolution image analysis we study the effect of miR125b inhibition on filopodial structure and density, dendritic outgrowth, as well as the expression and localization of a confirmed target of miR125-b: the GluN2A subunit of the NMDA receptor. Using microfluidic devices, we deliver a cell permeant inhibitor of miR125b to isolated dendrites, and study local changes in filopodial structure and GluN2A incorporation. To understand the effect of miR125b in the dynamics of filopodia, we use an innovative imaging technique, Spatial Light Interference Microscopy (SLIM), an interferometry-based, label-free, live imaging system that has topographic accuracy comparable to atomic force microscopy (Wang et al, Opt Express, 2011). Using SLIM, we characterize the rate of filopodial extension and retraction, and stability in response to miR125b inhibition. These high-resolution analyses reveal fresh insights into the process by which neurons integrate multiple external signals to establish the correct connections. Such insights are critical to understanding the implicated role of miR125b in various neurological disorders, *e.g*., Fragile X Syndrome and Alzheimer's Disease.

Title: Effect of the flavonoids quercetin and rutin in the dendritic branching of rat cortical neurons *In vitro*

Authors: *J. J. SUTACHAN-RUBIO[1], A. F. DIAZ ELJAIEK[2], H. G. GÓMEZ JIMÉNEZ[2], M. MUÑOZ[2], M. P. LOZANO[2], S. L. ALBARRACIN CORDERO[2];

Abstract: Recent studies have shown that activity-dependent pathways play an important role in the formation, growth and branching of dendrites. Additionally, it has been found that a

reduction in the complexity of the dendritic tree is a common feature share by neurodegenerative diseases, and different psychiatry and addiction disorders. For this reason, molecules that can impact in the signaling pathways that regulate the maintenance and complexity of dendrites may have therapeutic potential in the treatment of these diseases. Flavonoids are secondary metabolites from plants that have been shown to activate several signaling pathways that regulate the development and function of the nervous system. Although the prospective of flavonoids, there are not studies evaluating the potential of these molecules in regulating dendritogenesis. In the present work, we evaluated if the flavonoid quercetin and its glycosylated form rutin could regulate the dendritic branching of rat cortical neurons in vitro. The obtained results showed that rutin but no quercetin at low concentrations (0.1μM) increases the complexity of the dendritic tree. At higher concentrations (10 μM) neither rutin nor quercetin affects the complexity of the dendritic branching, however rutin stimulates dendritic growth. Additionally, the rutin-dependent effect on dendritic complexity was inhibited by the use of the LY294002 y PD98059 inhibitors, suggesting that rutin achieves its stimulatory effect by regulating the PI_3 and MAP kinase pathways. The obtained results suggest that glycosylated flavonoids have the potential to regulate not only the dendritic length but also the branching throughout the activation of several signaling pathways.

Title: Wnt5a is essential for dendrite maintenance and cognitive functions in adult brain

Authors: ***C.-M. CHEN**[1], L. OREFICE[2], S.-L. CHIU[3], T. LEGATES[1], S. HATTAR[1], R. HUGANIR[3], H. ZHAO[1], B. XU[2], R. KURUVILLA[1];

Abstract: The stability of neuronal connectivity is critical for brain functions, and morphological perturbations are a hallmark of neurodegenerative disorders. However, how neuronal morphology is maintained in the adult brain is not well understood. Here, we identify Wnt5a, a secreted morphogen, as an essential factor in maintaining dendritic architecture in the

adult hippocampus and for related cognitive functions in mice. Hippocampal neurons express Wnt5a, and the expression begins postnatally. Wnt5a deletion in hippocampal neurons does not compromise hippocampal development, but causes pronounced regression of dendrite arbors and spine densities in CA1 pyramidal neurons in adult life. Wnt5a loss results in attenuated CaMKII and Rac1 signaling and reduced expression of the GluN1 glutamate receptor subunit in the mature hippocampus, as well as defects in synaptic plasticity and spatial learning and memory, all of which precede the structural abnormalities. These findings identify a maintenance factor and provide insight into neuroprotective mechanisms in the adult brain.

Title: LRRC7 regulates neurite morphogenesis through mGluR5

Authors: *C. CHONG[1], C. NG[1], H. MAK[1], Q. LI[2], G. MCALONAN[3], S. CHAN[1]; [1]Paediatrics and Adolescent Med., [2]Psychiatry, The Univ. of Hong Kong, Hong Kong, Hong Kong; [3]Forensic & Neurodevelopmental Sci., King's Col. London, London, United Kingdom

Abstract: *LRRC7 (Leucine-rich repeat containing 7)* encodes for Densin-180, a scaffold protein in the postsynaptic density. *LRRC7* has been reported as a risk allele for childhood emotional dysregulation and autism spectrum disorder. Knockout mice were reported to have defects related to metal illnesses and abnormal dendritic spine development. To further define the role of LRRC7 in behavioural control, we made use of our transgenic mice line carrying a hypomorphic allele of *Lrrc7*. Mutant mice exhibited features of childhood emotional dysregulation, including excessive following and fighting at juvenile stage. Behavioural tests in young adults confirmed increased anxiety, abnormal social behavior and defective spatial working memory in mutants.

To reveal the molecular defects, we examined the dendritic complexity of hippocampal neurons in adult brain and in primary neurons from embryos. Mutant mice showed reduced dendritic complexity in both cases. Using primary neurons, we demonstrated that there was a reduced surface localization of mGlu5 receptor. Furthermore, augmentation of mGlu5 with CDPPB rescued the defects of neurite growth. To test for therapeutic potential of augmenting mGlu5 signaling in developmental emotional dysregulation, we tried acute injection of CDPPB and found that the treatment could alleviate the anxiety-like behavior and excessive social interaction of mutant mice. Our data suggested that *Lrrc7* mutant mice provide a valuable model for developmental emotional dysregulation and identify a novel role of LRRC7 as a scaffold for the regulation of mGlu5 trafficking and activity. Our data also highlight a novel role of mGlu5 signaling in early neuron morphogenesis.

Title: Using small peptides to study protein interactions and dendrite branching

Authors: *H. MENON[1], J. ROSHAL[1], H. M. CHAPMAN[2], T. L. WANG[2], M. R. SPALLER[2], B. L. FIRESTEIN[1];

Abstract: Appropriate dendritic patterning is essential for proper development of neuronal circuitry. Interestingly, a number of neuropsychiatric diseases, such as autism, schizophrenia and Alzheimer's disease, display abnormal dendritic branching. We previously reported that the protein cypin (cytosolic PSD-95 interactor) plays a key role in dendritic arborization. The interaction between cypin and PSD-95, via cypin binding to the first two PDZ domains of PSD-95, is essential for the promotion of stable dendrites. Cypin is a positive regulator of dendrite branching while PSD-95 inhibits dendrite branching. To test the importance of binding partners

to the PDZ domains of PSD-95 in the regulation of dendritogenesis, we characterized a set of small peptides that specifically bind to the PDZ domains of PSD-95. Our co-immunoprecipitation studies showed competition between cypin and a subset of the compounds for binding to PSD-95. Interestingly, a slightly different subset of compounds altered dendritic branching in cultured rat hippocampal neurons. This suggests that the observed branching phenotype is due to interaction of PSD-95 with a protein/s different than cypin. We are currently testing candidate proteins that interact with PSD-95 to determine whether they play a role role in dendritogenesis. Our studies will allow us to understand how the dendritic tree is shaped and elucidate potential therapies for disorders that show aberrant dendrite patterning and numbers.

Title: Elucidating the mechanism by which the GTPase Rem2 negatively regulates dendritic complexity

Authors: *K. M. KENNY, L. ROYER, A. R. MOORE, S. PARADIS;
Biol., Brandeis Univ., Waltham, MA

Abstract: Neurons in the mammalian CNS have a distinctive dendritic arbor, which is typically extensively branched, and this arbor influences the specific function of the neuron in part by ensuring that the proper synaptic connections are made within neural circuits. In addition, the nervous system has the amazing capacity to transform sensory experience from the environment into changes in neuronal activity that, in turn, cause long-lasting alterations in synaptic connections and dendritic arborization, Surprisingly little is known about the molecular mechanisms by which changes in neuronal activity are translated into changes in neuronal architecture.
We have identified Rem2, a member of the Rad/Rem/Rem2/Gem/Kir (RGK) family of small Ras-like GTPases, as an activity dependent negative regulator of dendritic complexity. Neurons

in which the Rem2 gene has been knocked down exhibit a dramatically increased dendritic arbor. Additionally, when Rem2 is overexpressed in neurons, they are unable to increase their dendritic arbor in response to increased neuronal activity. Taken together, these data indicate that Rem2 functions to restrict the dendritic arbor in response to experience.
We have placed Rem2 in a signal cascade downstream of Ca(2+)/Calmodulin-dependent kinase II (CaMKII) and upstream of CaMKIV to regulate dendritic complexity. We found that Rem2 is a direct substrate for CaMKII phosphorylation at serine 241 and 308; phosphorylation at these sites regulates Rem2 nuclear abundance. When we constitutively localize Rem2 to the nucleus, we observe significant decrease in dendritic complexity compared to control neurons, indicating that the function of nuclear Rem2 is to restrict dendritic arborization. Thus, we hypothesize that nuclear Rem2 regulates gene expression, possibly by mediating the activity of CaMKIV and its downstream target, the CREB transcription factor. As a first step towards investigating this hypothesis, we took an unbiased approach using mRNA sequencing to identify Rem2 dependent changes in gene expression. We are currently working to validate the hits from the mRNA sequencing to determine whether they could be novel regulators of dendritic complexity.

Title: Autism-associated mutation of syntaxin binding protein 5 disrupts dendrite arborization

Authors: *W. SHEN, Y.-C. LIN;
Hussman Inst. For Autism, Baltimore, MD

Abstract: Autism is a neurological condition that characterizes marked qualitative differences in communication and social interaction. As many as 1/3 of individuals with autism spectrum condition also have epilepsy. Consistent with the extremely heterogeneous presentation of autism, genetic studies have implicated numerous genes that may contribute to the autism phenotype. Deletion and mutations of syntaxin binding protein 5 (STXBP5, also known as tomosyn) are identified in association with autism and epilepsy. STXBP5/tomosyn is a syntaxin binding protein that contains a WD40 domain at the N-terminus and a SNARE motif at the C-terminus. STXBP5/tomosyn has a presynaptic role that negatively regulates neurotransmitter

release by forming syntaxin-SNAP25-tomosyn complex. STXBP5/tomosyn has also been shown to regulate neurite outgrowth in immature neurons. WD40 as scaffolding domains, have a variety of functions such as signal transduction and vesicle trafficking. Interestingly, two autism-associated variants of *STXBP5* exhibit missense mutations at the WD40 domain. Here, we hypothesize that the autism-associated STXBP5/tomosyn mutants affect dendrite arborization by regulating vesicle trafficking. To test this hypothesis, we first determined the subcellular localization of wildtype (WT) and mutant STXBP5/tomosyn in cultured hippocampal neurons. We transfected cultured neurons with GFP-tagged WT-tomosyn as well as two autism-associated tomosyn mutants. We found that WT- and mutant tomosyn all localize to axons, dendrites and dendritic spines. Overexpression of WT-tomosyn increased dendritic arbor complexity by increasing total dendrite length and branch tip number, compared to control neurons. The autism-associated tomosyn mutant failed to induce the dendrite complexity when compared to the WT-tomosyn. In conclusion, STXBP5/tomosyn plays a role in regulating dendrite arborization. Mutations of *STXBP5* found in individuals with autism may alter dendrite arborization and potentially disrupt normal developmental processes in the brain.

Title: Pannexin 1 regulation of neurite development: molecular mechanisms

Authors: *L. SWAYNE, A. K. J. BOYCE, L. E. WICKI-STORDEUR, J. C. SANCHEZ-ARIAS;
Med. Sci., Univ. of Victoria, Victoria, BC, Canada

Abstract: Peak expression of the Pannexin 1 (Panx1) ion and metabolite channel in neurons coincides with critical periods in dendritic spine development. Foundational in vitro studies in our lab have established that Panx1 regulates neurite outgrowth. To begin to unravel the specific molecular mechanisms involved, we examined Panx1 protein interactions that we discovered using an unbiased proteomic approach. We focused primarily on Collapsin Response Mediator Protein 2 (Crmp2), a cytoskeleton-regulating protein. We confirmed an association between Panx1 and Crmp2 in vitro and in vivo and mapped the interaction site to the distal C-terminus of Panx1. To probe the role of this interaction in neurite outgrowth, we next used a cell-permeable peptide of the interaction site (CT3) in our experimental models (in vitro: neurite outgrowth in cultured neural cells assayed by Incucyte live cell kinetic imaging, in vivo: dendritic spines of layer 5 cortical neurons by Diolistic labeling in early postnatal mouse brain). Treatment with CT3 enhanced neurite outgrowth both in vitro and in vivo. We further probed the precise mechanisms with supportive imaging and biochemical studies focusing on cytoskeletal dynamics. In summary, here we present several novel findings that expand our understanding of the molecular players underlying the cellular role of Panx1 in neurite development in the brain.

Title: Dscam promotes self-avoidance in neurodevelopment by masking diverse cell adhesion molecules

Authors: *A. M. GARRETT[1], A. L. D. TADENEV[1], A. KHALIL[2], P. G. FUERST[3], R. W. BURGESS[1];

[1]The Jackson Lab., Bar Harbor, ME; [2]CompuMAINE Lab., Univ. of Maine, Orono, ME; [3]Dept. of Biol. Sci., Univ. of Idaho, Moscow, ID

Abstract: During development, neurons balance attractive and repulsive signals to properly position cell bodies and neurites, and to form synapses with appropriate partners. The Dscams (from Down syndrome cell adhesion molecule) are Ig-superfamily members important for self-avoidance. *Drosophila Dscam1* promotes self-avoidance by generating up to 19,008 strongly homophilic isoforms, providing a code by which neurites can recognize and actively repel those from the same cell while still interacting with neighboring cells. Mammalian Dscams - *Dscam* and *Dscaml1* - serve a similar function without extensive isoform diversity. In the retina, mutant neurons of a given subtype form tight dendritic fascicles and lose their non-random mosaic spacing as their cell bodies pull into clumps. These clumps are homotypic, indicating that a shared cell-type identity promotes this interaction. Reasoning that this self-avoidance was likely to involve intracellular signaling common to both DSCAM and DSCAML1, we chose to focus on the C-terminal PDZ-interacting domain: The sequences encoding the final ten amino acids of both DSCAM and DSCAML1 were replaced by epitope tag sequences to eliminate the canonical PDZ-interacting domains. These mutations completely recapitulated the null phenotypes in some cell types, but left others relatively unaffected, leading us to hypothesize that Dscams mask cell-type-specific repertoires of CAMs in different cell types to prevent excessive adhesion, and that the PDZ-interacting domain is required to mask only some of these classes of CAMs. To test this, we focused on retinal ganglion cells labeled in *Cdh3-GFP* transgenic mice, a population that depends on DSCAM for self-avoidance and expresses a known repertoire of CAMs including *Cdh3* and *Cdh6*. We reasoned that if excessive adhesion provided by these Cadherins was normally masked by DSCAM, but was mediating unbalanced adhesion in our *Dscam* mutants, then Cadherin/ *Dscam* double-mutants would partially rescue the fasciculation phenotype. We quantified fasciculation via a novel image analysis approach in these double-mutants, and found that indeed there is reduced fasciculation compared to *Dscam* null mice. We found a similar reduction in fasciculation of melanopsin-positive ipRGCs in mice mutant for both *Dscam* and the *Pcdhg* cluster, indicating that DSCAM can mask diverse adhesion systems. We are currently testing other candidate adhesion systems in other cell types to ask if making double mutants with Dscam and PDZ-interacting CAMs can rescue fasciculation in cell types that require the PDZ interaction.

Title: A pannexin 1 blocker modulates the development of dendritic spines in the postnatal cerebral cortex

Authors: *J. C. SÁNCHEZ-ARIAS[1], L. E. WICKI-STORDEUR[1], L. A. SWAYNE[1,2];
[1]Div. of Med. Sci., Univ. of Victoria, Victoria, BC, Canada; [2]Island Med. Program and Cell. and Physiological Sci., Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Probenecid is an approved drug used for the treatment of gout, and has also recently become recognized as a blocker of Pannexin 1 (Panx1) ion and metabolite permeable channels. We recently demonstrated that Panx1 is essential for neural precursor cell (NPC) maintenance (Wicki-Stordeur, Sanchez-Arias et al., J Neurosci, 2016) and also that Panx1 negatively regulates neurite outgrowth in NPCs (Wicki-Stordeur and Swayne, Cell Commun Signal, 2013). NPCs and Neuro2a cells treated with Probenecid exhibited a dramatic increase in neurite extension. Panx1 has been localized to cell bodies as well as the post-synaptic membrane. In the cortex, Panx1 is relatively highly expressed in the early postnatal period and then drops off rapidly (highest at postnatal day 0 (P0) and dropping off after P10). This expression profile is closely associated with critical periods in the formation of dendritic spines and synapses. Taken together, these data led us to hypothesize that Panx1 plays a role in the development of dendritic spines, a process that occurs during the early postnatal period. To begin to investigate the role of Panx1 in the development of dendritic spines in vivo, we treated young male and female wildtype mice (C57BL/6J) with either Probenecid or Normal Saline (control) for discrete periods of time, with one group (n=20) receiving chronic treatment (every third day from P7 to P13); and a second

group (n=20) receiving exclusively an acute treatment at P13. Animals were sacrificed 24 hours after the last injection (P14), and we performed diolistic labelling (DiI) of the apical dendrites of Layer 5 Primary Somatosensory Cortex pyramidal neurons. Chronic Probenecid treatment resulted in a significant increase in length and number of spines (spine density) in both male and female treatment groups when compared to the control treatment groups. On the other hand, acute probenecid treatment resulted only in a significant total increase in spine density in the treatment groups (with no differences in length). Our results suggest Panx1 could play an important role in the development of dendritic spines in the cerebral cortex. These findings taken together with our recent work further establish Panx1 as an important modulator of developmental plasticity.

Title: Regulation of neuronal morphogenesis by 14-3-3epsilon (Ywhae) via the microtubule binding protein, doublecortin

Authors: *B. T. CORNELL, W. TOMOKA, V. ZHUKAREV, K. TOYO-OKA;
Neurosci., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: 17p13.3 Microduplication Syndrome is a newly identified genetic disorder and is characterized by various sized gene duplications in the 17p13.3 chromosome locus resulting in autism spectrum disorder (ASD), epilepsy and mental retardation. Importantly, a minimum duplication region strongly associated with the ASD phenotype has been classified and this 72kb region exclusively contains the gene encoding the protein 14-3-3ε, strongly implicating the overexpression of 14-3-3ε in ASD. In this work, through the use of *in vivo* and *in vitro* techniques, we have found that 14-3-3ε binds the microtubule binding protein Doublecortin in a phosphorylation specific manner and prevents its degradation resulting in an increase in Doublecortin protein levels. We also found that 14-3-3ε overexpression severely disrupts neurite formation by preventing the invasion of microtubules into primitive neurites, and this is rescued by the knockdown of Doublecortin in 14-3-3ε overexpressing neurons. Furthermore, using 14-3-3ε flox mice we found that the spatiotemporal deficiency of 14-3-3ε results in an increase in

neurite formation. Our findings provide the first evidence of cellular pathology in 17p13.3 Microduplication Syndrome.

Title: Femtogram-level analysis of mass-change dynamics in filopodia on the tips and shafts of developing dendrites in response to semaphorin3A

Authors: *A. JAIN[1], T. KIM[2], G. POPESCU[2], M. U. GILLETTE[1];
[1]Dept. of Cell and Develop. Biol., [2]Electrical & Computer Engin., Univ. of Illinois at Urbana-Champaign, Urbana, IL

Abstract: The intricate wiring of the nervous system relies on filopodial navigation to form complex interconnections between neurons through their axons, dendrites, and the cell soma itself. Until recently, cellular investigations into filopodial dynamics had focused primarily on axonal growth cone filopodia. Spurred by technological advances, scientists have now begun to explore the structural and functional landscape of dendritic filopodia. Here we investigate the role of Sema3A in guiding dendritic morphogenesis, spinogenesis, and synaptogenesis. We show that it acts not only at the level of the dendrites, promoting neurite survival and growth, but also at the level of the filopodia. Since there has been some evidence indicating a difference in filopodia borne along dendrite tips *vs.* those borne along dendrite shafts, we treat the two populations as distinct and tease apart their different responses. Structural analyses of numbers, lengths, and locations are complemented by studies of dynamic functional aspects, such as

growth and shrinkage rates detected as mass changes in individual filopodia. This is made possible through Spatial Light Interference Microscopy (SLIM), an innovative quantitative phase imaging method for high-resolution, label-free imaging of live cells through interferometry (Wang *et al.*, *Opt. Express*, 2011). SLIM permits measurement of the dry mass of live neurons at femtogram levels (Mir *et al.*, *Sci. Rep*., 2014). This convergence of filopodial investigations and the technology for engineering micro-environments, when coupled with high resolution imaging and analysis, enabled new insights on local signals, including Sema3A, that initiate and establish neuron-neuron interactions at the filopodial level. A greater comprehension of such processes that shape the development of neuronal networks is helping unravel the mechanistic bases of developmental disorders and diseases.

Title: Effects of an early postnatal intoxication event on medium spiny neuron morphology throughout mouse development

Authors: *J. INGERSOLL, E. B. D. CLABOUGH;
Biol., Hampden-Sydney Col., Farmville, VA

Abstract: Prenatal alcohol exposure can result in the emergence of a broad spectrum of anatomical or neurological abnormalities termed Fetal Alcohol Spectrum Disorders (FASD). The effects of ethanol exposure during development depend on the timing of exposure, as ethanol interrupts the specific brain development processes that are ongoing at the time of exposure. The severity of dysfunction varies with the dosage level of ethanol and, importantly, whether the dosage is chronic or acute. We investigated the effects of a single postnatal intoxication event on neuronal development in mice. We characterize the immediate effects of the ethanol exposure on the branching of the neurons in the striatum, but also examined the long term effects throughout development. Animals were exposed to brief, high levels of ethanol during the early postnatal period (during the most robust period of synaptogenesis). Mice were administered 2 doses of

ethanol (2.5 g/kg) on postnatal day 5 (P5) two hours apart. Brains were removed and processed for Golgi-Cox staining in order to capture the cellular morphological response to the insult after one day or after five months. These data find immediate alterations in the branching morphology of MSNs as a consequence of neonatal exposure to ethanol. The results enhance not just our understanding about the impact of toxins on neurons, but also highlights the dynamic nature of dendritic branching in the neuron. In addition, basic research on striatal MSNs is of interest to many fields, as the striatum is involved not only with the execution of complex motor skills, but also regulates aspects of long-term learning and addictive behavior.

Title: Comparison of Matrigel® and Poly-D-Lysine as plating matrix for mouse embryonic neuronal cell cultures and their effect on cell growth

Authors: *E. SEKERDAG, Y. CETIN TAS, G. NUR SAHIN, S. KARAHUSEYINOGLU, I. SOLAROGLU, Y. GURSOY-OZDEMIR;
Neurosci., Koç Univ., Istanbul, Turkey

Abstract: Aim: Extracellular matrix is important in the field of 2D and 3D cell culture techniques. Depending on the chosen culture matrix, cells can grow and differentiate in different manners, as fits most properly in the goal of the cell culture experiment. Our aim is to investigate and compare the cell growth manners of primary cortical neuron cells plated in poly-D-lysine (PDL) and matrigel culture matrices in order to obtain the most suitable culture condition for further studies.
Methods: Glass coverslips were coated by incubating the coverslips in 1 mL of 100 µg/mL of PDL solution or Matrigel® (BD) solution (dilution according to the manufacturer's protocol) overnight at 4 °C. PDL coated coverslips were directly used (without drying) for cell plating after washing twice with sterile distilled water. Coverslips incubated in matrigel solution were incubated for 1 hour at 37 °C, and cells were directly plated after removal of the matrigel solution. Primary cortical neuron cells were prepared from E17 mouse pups according to a modified protocol as described elsewhere [1]. At DIV3-14's, cultured neurons plated in both PDL and matrigel groups were fixed in 4% paraformaldehyde or 2.5% glutaraldehyde solution for immunofluorescence and SEM analysis, respectively. Immunofluorescent (IF) stainings,

Western blot and PCR analysis were performed and analyzed for antibodies against GFAP, Neu-N, Caspase-3 and NG2.
Results & Conclusion: According to preliminary data, neuronal cell cultures had a higher dimensional network in matrigel coated matrix compared to PDL coated matrix. Moreover, the axons were more tight, thick and linear compared to neuronal axons on PDL coated matrix. Axonal bundling and maturation which developed between groups of neurons, confirmed by both live-unstained cultures and cytoskeletal and neuron-specific IF stainings documented by 3D images, supported that this structure would posses a more 3D effect in vitro, hence may mimic a more physiological condition compared to conventional neuronal cultures and PDL-coated matrix enhanced neuronal cultures.

Title: Histone deacetylase 1 regulates neuronal structure and function via bdnf signaling in developing xenopus tectum *In vivo*

Authors: *W. SHEN[1], H. RUAN[2], Y. TAO[3], J. GAO[2], X. QI[2], X. GUO[2];
[1]Col. of Life and Envrn. Sci., Hangzhou Normal Univ., Zhejiang, China; [2]Hangzhou Normal Univ., HANGZHOU, China; [3]Nanjing Med. Univ. Affiliated Jiangsu Cancer Hosp., Nanjing, China

Abstract: Histone deacetylases (HDAC) are predominantly localized to the cell nuclei and play pivotal roles in brain formation and neurological diseases as a gene transcription repressor. Several studies have shown that application of broad-spectrum HDAC inhibitors can improve the deficits in learning and memory. Histone deacetylase 1 (HDAC1) is thought to play pivotal roles in neurogenesis and neurodegeneration. However, the role of HDAC1 in neuronal growth and structural plasticity in the developing brain in vivo remains unclear. In the present study, we examined the role of HDAC1 in excitatory and inhibitory synaptic transmission and experience-

dependent structural plasticity by knockdown or overexpression of HDAC1 in Xenopus optic tectal neurons in vivo. We made molecular tools of HDAC1-GFP for overexpression and HDAC1 morpholino (HDAC1-MO) for knockdown. Here, we show that HDAC1 knockdown dramatically decreases AMPAR-mediated synaptic currents and increases GABAAR-mediated currents, whereas HDAC1 overexpression significantly decreases the frequency of GABAAR-mediated synaptic currents. We find that HDAC1 activity is also critical for dendritic arbor growth and visual experience-dependent structural plasticity. We show that overexpression or knockdown of HDAC1 activity decreases dendritic arbor growth and visual experience-dependent structural plasticity. Interestingly, knockdown of HDAC1 but not of HDAC2/HDAC3 decreases the expression of BDNF. Epigenetic modification of histone has been shown to participate in synaptic plasticity and learning memory. We report that HDAC1 knockdown significantly increases the activity of histone acetylation (H4K5), which is partially rescued by acute BDNF treatment in the HDAC1-MO tadpoles. In particular, the deficits in dendritic growth and visually guided avoidance behavior in HDAC1-knockdown tadpoles are also rescued by acute treatment with recombinant BDNF. Our data establish an essential roles for HDAC1 and BDNF signaling in the regulation of dendritic growth, structural plasticity and function in intact animals in vivo.

Title: Expression of a null mutation gap junction protein during development results in neuronal arbor loss.

Authors: I. V. KATRITCH, D. DE GUZMAN, *E. R. MACAGNO, M. W. BAKER;
Div. Biol. Sci., Univ. of California San Diego Div. of Biol. Sci., La Jolla, CA

Abstract: The unique morphologies and patterns of connections made by neurons during development arises in part by an extended period of growth in which cell-cell interactions help to sculpt the arbor into its final shape, size, and participation with different synaptic networks. Here we examine the role of the gap junctions (GJs) in forming the neural arbor of a sensory neuron in

the medicinal leech *Hirudo Verbana*. Using a dominant-negative point mutation transgene (Inx1-PL; Yazdani et al., 2013 Dev. Neurobiol.73), we selectively knocked down innexin 1-based GJ formation in single dorsal Touch neurons (T_D) using intracellular nuclear transgene injection in leeches from mid-embryonic development onwards. Cells co-expressing EGFP were imaged 10 to 20 days later, and digitally reconstructed in 3D.
Initial observations of cells 20 days later, at the juvenile stage, knockdown cells, when compared to intracellular dye-injections and neurons expressing the wild-type innexin 1 transgene, developed a much sparser neural arbor, with a ~92% decrease in branch points, ~51% shorter total neurite path length, and a ~90% decrease in varicosities. On the other hand, both Inx1-PL cells and control cells, when imaged after only 10 days, had an extensive arbor, with a ~50% increase in branch points and ~43% increase in total neurite path length as compared to the control cells from the 20 day time point. This pattern of exuberant growth followed by a later retraction of branches without GJ formation suggests that electrical synapses are necessary for arbor stabilization during a critical period in the neurons development (Todd et al., 2010 J. Neurosci. 30).
Ongoing experiments will test whether the arbor is stabilized by electrical activity by overexpressing a voltage-gated potassium channel in the T_D as a means of reducing electrical activity in the cell. Additionally, if GJs and their cellular distribution help sculpt neuronal arbors, we will test if we can alter the T_D's arbor by ectopically expressing different leech innexin genes in the cell and thereby promote the formation of new synaptic connections and observe the effects on the development of the cell's arbor.

Title: Retinotectal circuit arbor remodeling through DSCAM knockdown *In vivo*

Authors: R. A. SANTOS, G. SHORT, *S. COHEN-CORY;
Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Wiring functional neural circuits during embryonic development requires coordinated organization between developing axon and dendritic arbors. The spatial pattern of dendritic branching is critical to the neuron's input connectivity so that incoming information from afferent axons is efficiently integrated. Although neurons can adopt an array of dendritic patterns to suit their input connectivity, dendrites of an individual neuron commonly self-avoid. Presynaptic axon arbors also exhibit patterned branching and self-avoidance as they innervate their targets. Down Syndrome Cell Adhesion Molecules (DSCAMs) have been shown to play key roles in dendrite and axon self-avoidance in Drosophila and other species. How DSCAM influences axon to dendrite interconnectivity in developing vertebrate neural circuits remains unknown. In this study, we utilized *Xenopus laevis* as a model to examine developmental effects of DSCAM *in vivo* and provide a unique temporal and spatial understanding of how visual circuits are dynamically shaped. In *Xenopus*, DSCAM immunoreactivity was localized to retinal ganglion cells (RGCs), midbrain neurons and tectal neuropil, at the time that retinotectal connections are made. To define cell-autonomous, cellular actions of DSCAM during pre- and postsynaptic neuron differentiation, we used single-cell loss-of-function approaches and analyzed changes in RGC axon targeting and branching and in tectal neuron dendrite elaboration through dynamic two-photon *in vivo* microscopy imaging. Single-cell electroporation of morpholino antisense oligonucleotides (MOs) to DSCAM together with Alexa-fluor 488 dextran in stage 43 *Xenopus* retina showed that RGC axons path find normally to the neuropil, but that their arbors exhibit abnormal branching patterns when compared to axons from control MO transfected RGCs. Conversely, single-cell DSCAM MO knockdown in tectal neurons did not impair dendrite self-avoidance. Rather, tectal neurons exhibited exuberant dendritic arbor growth within 24 hours of single-cell DSCAM MO transfection, an effect that became more robust over a three-day period of imaging. Together, our observations implicate DSCAM in the control of both pre- and postsynaptic neuronal cytoarchitecture and connectivity in the retinotectal circuit, whereby it primarily acts as a neuronal brake to limit and guide postsynaptic neuron dendrite growth. How these cell-autonomous changes in structural connectivity, as mediated by DSCAM, influence normal visual circuit function is an important question that is currently being investigated.

Authors: *L. CHEN[1], Y. HUANG[3], J. HU[2], J. DUAN[2], Y. QU[2];
[1]Jinan Univ., Guangdong, China; [2]Jinan Univ., Guangzhou, China; [3]Hongkong Univ., HongKong, China

Abstract: The seven-pass cadherin *Celsr2* is one of the core PCP proteins, whose ortholog Flamingo regulates dendrite development in Drosophila. *Celsr2* is expressed both in neural precursors and posmitotic cells, and the expression of *Celsr2* persists in the adult brain. Here, we studied neuronal dendritic development and neural function in *Celsr2* mutant mice. Defective neurite growth is observed in primary neuronal culture, and live cell imaging shows *Celsr2* affects neurite appearance. Increased spine formation is found in *Celsr2* mutant mice by in vivo two-photon imaging. Celsr2 mutant mice display cognitive deficits in several behavior tests.

Title: Adult hippocampal neurogenesis and its regulation by components of FGF signaling

Authors: *M. GRONSKA[1], M. SCHACHNER[2], J. HEBERT[1];
[1]Albert Einstein Col. of Med., Bronx, NY; [2]Rutgers Univ., Piscataway, NJ

Abstract: Adult neurogenesis is a process of high interest due to the ability of newborn cells to integrate into the existing adult hippocampal circuits. Identification of the molecular pathways that determine different steps in the generation and maturation of newborn neurons would facilitate using adult neural stem cells (ANSC) to treat multiple brain disorders. We previously showed that loss of Fibroblast Growth Factor Receptors (FGFRs) 1-3 in ANSCs decreases cell

proliferation and dendritic elaboration. However, the identities of downstream components of the FGFRs in adult neurogenesis are unknown. In addition, FGFRs' interaction with non-canonical upstream ligands such as L1CAM, a cell adhesion molecule, previously shown in cell culture to interact with FGFRs to promote neurite extension is unknown. We are determining how cell proliferation and dendritic elaboration in the adult dentate gyrus (DG) are affected in FGFR conditional mutant mice that lack binding sites for the downstream mediators phospholipase-C gamma (PLCγ) or Fgf receptor substrate (FRS), and in L1CAM conditional mutant mice. In addition, we will test the consequences of the mutations on learning and memory in hippocampus-related tasks. Our data suggest that FRS- and PLCγ-mediated FGFR signaling is required for cell proliferation and dendrite elaboration. We are also testing whether L1CAM acts in a cell-type autonomous or non-autonomous manner to promote dendritogenesis in the DG. Determining which intra- and extracellular pathways deferentially affect hippocampal learning and memory will not only provide a better understanding of adult neurogenesis but will also provide targets for reversing deficiencies in this process, which leads to age-related memory decline.

Title: Properties of optimally tapered dendrites

Authors: ***A. D. BIRD**[1,2], H. CUNTZ[1,2];
[1]FIAS, Frankfurt, Germany; [2]Ernst Strungmann Inst. for Neurosci., Frankfurt, Germany

Abstract: Somatic integration of synaptic inputs relies on the propagation of currents arising from sources across the dendritic tree. Whilst active processes strongly contribute to current flow in most neurons, understanding the passive backbone to transmission allows a better intuitive grasp of dendritic function; the results of Rall in highlighting the properties of cylindrical dendrites are of foundational importance in compartmental modelling and computational neuroscience. Dendrites are, however, not generally cylindrical; they tend to taper in a way that

contributes to the normalisation of input currents towards the soma and which has a number of other potentially important computational effects.
We have recently derived an asymptotic approximation to the voltage in dendrites with an arbitrary taper profile using the insight that voltage attenuation is substantially faster than radius change in realistic morphologies. This result allows faster computation and greater insight than standard approaches using large numbers of cylinders or frusta to numerically compute voltage profiles. In addition, it provides easy generalisations of the standard results of cable theory involving transients and branches. In particular, our result allows the optimal dendritic taper profile for the propagation of synaptic currents towards the soma to be determined analytically. The optimal form has been shown to match results from non-parametric numerical optimization which predicted a quadratic form for the diameter taper.
We have further shown analytically the effects of optimal taper on a number of other important dendritic phenomena, including a more general robustness in response to morphological changes and increased sensitivity to distributed inhibitory input.

Title: Dendrite remodeling in the developing olfactory circuits

Authors: ***K. TOGASHI**, S. TAKEUCHI, H. KOIZUMI, K. EMOTO;
Dept. of Biol. Sciences, Grad. Sch. of Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: In the central nervous system, neuronal circuits are dynamically remodeled during the perinatal ages to establish functional circuits. In the mammalian olfactory bulb, mitral cells initially extend redundant dendrites radially from each cell body. After birth, excessive dendrites are eliminated and individual mitral cells form multiple "tufted-dendrites" called as primary dendrites radially, and extend several lateral dendrites tangentially. According to the maturation, each mitral cell eliminates the primary dendrites except only one. However, how mitral cells determine the primary and the lateral dendrites and whether all mitral cells develop uniformly remain elusive. To tackle these issues, we have established a technique to label developing mouse mitral cells at single cell resolution using adeno-associated virus (AAV). Quantitative analyses revealed that nearly 50 % of the mitral cells at embryonic day 18.5 (E18.5) already had primary dendrites and more than 80 % of the mitral cells at postnatal day 0 (P0) had primary

dendrites, indicating that tuft formation is independent on the exposure to odorants by respiration after birth. Based on these observations, we will discuss how mitral cells take their functional dendrites in the developing olfactory circuits.

Title: Dendritic Eph specifies pheromone-sensing circuit by organizing dendrite segregation in *Drosophila*

Authors: *T. CHIHARA[1,2,3], M. ANZO[2], S. SEKINE[2], S. MAKIHARA[2], K. CHAO[2], M. MIURA[2,3];
[1]Dept. of Biol. Science, Grad. Sch. of Sci., Hiroshima Univ., Higashi-Hiroshima, Japan; [2]Dept. of Genetics, Grad. school of Pharmaceut. Sci., The Univ. of Tokyo, Tokyo, Japan; [3]AMED-CREST, Tokyo, Japan

Abstract: The proper function of the neural network results from the precise connections among an enormous numbers of neurons. In order to organize a complex nervous system, the accurate targeting of both axon and dendrite from pre- and post-synaptic neurons is required. Previously, various molecular mechanisms for axon targeting have been revealed, however the dendrite-targeting mechanism and the way dendrites form a boundary to segregate each other are largely unknown due to the dendrites' diversity and complex morphology. As the model system, we utilized Drosophila olfactory projection neurons (PNs), which stereotypically target their dendrites to one of 50 glomeruli in the antennal lobe (AL), the first olfactory center in the brain. The previous study from our laboratory suggested that Eph/Ephrin signaling, well known axon

guidance molecule, is involved in dendrite targeting. Indeed, high Eph expression was observed specifically in the sex-related glomeruli in the developing AL. In addition, from genetic mosaic analysis, we have found that the widely conserved Eph receptor tyrosine kinase family member and its ligand, Ephrin, are essential for PN dendrites to segregate one another in some sex-related glomeruli. Our genetic data suggest that Eph/Ephrin signaling prevents the dendrites that target to one of the sex-related glomeruli (DA1) from getting entangled with dendrites targeting to adjacent glomeruli. In this study, we present that Eph/Ephrin signaling is required not only for axon guidance, but also for dendrite targeting. Furthermore, in PN dendrites, Eph/Ephrin signaling is designed to work for segregation.

Abstract: Vast majority of studies in cell biology are from the cultured cells. Although cultured cells have the same cellular environment, but it cannot provide the physiological or pathological conditions, which are required for cell growth, differentiation and proliferation. As a particular type of cell, neuron is consisted by soma, axons and dendrites, which are responsible for signal input and output. In vivo study put a neuron into an intact neuronal circuit; it is ideal for the study of the structure and function of neurons. Based on the development of fluorescent protein, it allows us to minitor the structure and function of neuron by in vivo labeling methods. As a model organism, Drosophila powerful genetics provides an opportunity for studying of cell biology. Drosophila larvae, which have a transparent epidermis, provide an opportunity to get high-resolution images by confocal microscopy. Here, we use fluorescent protein -labeled Golgi markers observed the structure of dendritic Golgi outposts in da neurons, further revealed the molecular mechanism of this structure; moreover, studied the funtion of dendritic golgi outposts. In cell biological level, this study provides a powerful tool to study biogenesis of Golgi complex;

meanwhile, Golgi outposts, as part of secretory pathway of the cell, gain an insight to understand dendritic formation, developmental regulation and plasticity.

Abstract: Bacterial infection has been implicated in preterm birth, which is a risk factor for the clinical features present in autism spectrum disorders (ASDs), such as poor sociability, impaired communication and perseverative behavior. A commonly found bacterial species in the placenta of preterm births is the gram negative bacteria *Ureaplasma* (UP). The bacterial load of UP correlates with a higher incidence of chorioamnionitis and preterm labor. This suggests that preterm birth with UP infection may be contributing factors for ASD, and possibly the heterogeneity of ASD phenotypes given the widespread presence of UP in the urogenital tract of humans. Indeed, a significantly higher risk for poor neurological and developmental outcomes in UP-infected versus -uninfected preterm births has been reported, however, a causal relationship demonstrating if and how UP infection may cause potential ASD phenotypes, has not been shown. In addition, a significant finding that may provide insight into the pathogenesis of UP-related neurological defects was demonstrated in an antenatal mouse model of chorioamnionitis in which histochemical markers of GABAergic inhibitory interneurons were reduced in the absence of cell death. These data suggest an alteration in excitation-inhibition (E/I) balance within key neural networks of the brain, a theory that has been proposed to explain the behavioral and cognitive aspects of ASDs. Therefore, we generated an early neonatal mouse

model of UP infection to test whether mice exposed to UP infection at birth display neurobehavioral deficits in adulthood. We found that male mice infected with UP at birth showed altered anxiety and reduced social approach behavior whereas female mice infected at birth displayed normal behavior in all measurements. Interestingly, the brains of male but not female UP-infected neonatal pups showed increased levels of ammonia; however, male mice exposed to UP using the identical infection paradigm did not display abnormal levels of ammonia in brain during adulthood despite the observed behavioral deficits. Taken together, these data suggest that Ureaplasma infection may lead to altered ammonia levels in brain during a critical early developmental window which may result in sexually-dimorphic neurobehavioral outcomes.

Title: Early life exposure to the organophosphorus pesticide chlorpyrifos produces behavioral phenotypes relevant to neurodevelopmental disorders

Authors: *E. L. BERG[1], J. K. RIVERA[1], M. CAREAGA[1], D. A. BRUUN[2], P. J. LEIN[2], J. L. SILVERMAN[1];

Abstract: Organophosphorus pesticides (OPs) are among the most widely used pesticides in the world. OPs have been implicated in the etiology of neurodevelopmental disorders including developmental delay and autism spectrum disorder (ASD) (Shelton et al., 2014; Shelton et al., 2012). Exposure to chlorpyrifos (CPF), one of the most widely used OPs, has been linked to mental and motor delays as well as increased rates of attentional issues, specifically attention deficit/hyperactivity disorder (ADHD), in children (Rauh et al., 2006). The present study examined sophisticated social and cognitive behaviors in a novel rat model of CPF exposure. Newborn Sprague-Dawley rats were administered either peanut oil vehicle, 1.0 mg/kg CPF, or

3.0 mg/kg CPF via daily s.c. injections from postnatal day (PND) 1 to PND 4. Isolation-induced ultrasonic vocalizations (USVs) were collected from pups on PND 5, 8, and 11. Sociability and repetitive self-grooming were assessed at the juvenile age using the ASD-relevant behavioral assays of three-chambered social approach and dyadic reciprocal social interaction. Locomotion was evaluated via an open field exploration assay and cognitive testing was carried out using pairwise visual discrimination and reversal learning in an operant touchscreen chamber. Pups exposed to 1.0 mg/kg CPF emitted fewer USVs than did pups treated with vehicle or 3.0 mg/kg CPF, and this effect was markedly higher in females. CPF did not affect the sociability phase of three-chambered approach; however, performance in the social novelty portion suggests that CPF disrupts recognition of previously acquired social cues. Relative to vehicle controls, CPF altered juvenile reciprocal social interactions on several key social parameters in a sexually dimorphic manner. CPF-treated females but not males displayed decreased rough and tumble playing while CPF-treated males exhibited increased chasing and anogenital sniffing, behaviors which were unaffected by CPF exposure in females. Moreover, self-grooming was elevated in both sexes at different doses. Similar exploratory behavior in a novel open arena was observed across treatment groups, eliminating hypo- and/or hyperactivity as confounding behaviors. Performance in the touchscreen learning task did not differ between CPF-treated rats and vehicle controls. Several pieces of evidence point to deficits in sex-dependent and/or species typical sociability in juvenile rodents. Impairments were noted in a range of behavioral assays which, taken together with existing literature, suggests that developmental OP exposures disrupt neurological development and neural correlates that underlie complex behaviors.

Title: Sex differences in autism-like repetitive behavior in response to postnatal opiate exposure in mice

Authors: A. REYNOLDS[1], K. KESAVAN[2], *D. M. CORDERO[3], D. SHIN[1], A. MAZARATI[1]; [1]Pediatrics- Neurol., [2]Pediatrics- Neonatology, [3]Pediatrics-Neonatology, UCLA, Los Angeles, CA

Abstract: Background:
Optimal management of pain is of vital importance in the neonatal intensive care unit (NICU), as a growing body of evidence has shown the detrimental impacts of untreated neonatal pain during a critical period in neurologic development. Opiates remain the gold standard for treatment of pain in the NICU; however there are serious concerns with long term neonatal opioid exposure, in particular, to the developing brain. Behavioral effects of opiate exposure in animals include (a) altered sensitivity to pain, (b) affective liability, (c) stereotyped behaviors, and (d) reduced socialization (refs) which are consistent with some of the symptoms of autism. With continued high rates of opiate use in the NICU, as well as maternal opiate use during pregnancy, it is critical that we understand the effects of opiates on development of autism-like behavior. Moreover, it is important to study these effects in male and female models given that both autism and opioid analgesia have known sex-differences.
Objective: This study aims to examine the relationship between neonatal opioid exposure and the development of autism-like behavior in male and female mice.
Methods: We exposed neonatal mice to either 2mg/kg of morphine twice a day or saline solution subcutaneously during postnatal day (P) 7-14. At P60, all pups (N=44: 7 morphine-exposed males, 10 morphine-exposed females, 16 naïve males, and 11 naïve females) were assessed for autism-like repetitive behavior using the marble burying test. A 2x2 ANOVA and post-hoc t-tests were conducted to examine independent and interactive effects of morphine and sex on behavior.
Results: We found a significant sex*postnatal opioid exposure interaction ($p<0.01$), wherein males showed increased repetitive behavior in response to morphine exposure (11 vs. 16 marbles buried in naïve vs. exposed males; $p=0.057$), and females displayed significantly decreased repetitive behavior in response to morphine exposure (15 vs. 9 marbles buried in naïve vs. exposed females; $p<0.05$).
Conclusion: Postnatal opioid exposure induces opposite effects on repetitive behavior in male and female mice. Specifically, opioid exposure increases autism-like repetitive behavior in males and decreases the behavior in females. This may be related to reports of increased repetitive behaviors in males with autism relative to females with autism.

Abstract: The etiology of autism spectrum disorders (ASD) is complex, involving interactions between genetic and environmental risk factors. Genetic evidence showed a convergence of multiple genes with functions in chromatin regulation and neuronal synapses, but how multiple genetic and environmental hits may impact the epigenetic regulation of synaptic genes is unknown. To investigate the cumulative impacts of large chromosomal copy number variants (CNV) on the brain methylome, whole genome bisulfite sequencing (WGBS) was performed on 41 post-mortem human cortical samples including chromosome 15q11-13 duplication (Dup15q), Prader-Willi (PWS), Angelman (AS), Down syndrome (DS), idiopathic ASD without detectable CNVs, and neurotypical controls. Significant global DNA hypomethylation was observed compared to controls specifically in brain samples from Dup15q, but not AS, PWS, DS, or idiopathic ASD. Based on a previously observed interaction between Dup15q and PCB 95, a Dup15q neuronal cell culture model (SH15M) and the parental SH-SY5Y (SH) cell line were cultured with or without PCB 95 and analyzed by WGBS. Similar to Dup15q brain, a significant global hypomethylation was observed in SH-15M compared to SH. Genes mapped to PMDs gained in SH-15M compared to SH were significantly enriched for ion channels at the post-synaptic membrane and these genes and functional categories overlapped with those independently altered with PCB 95 exposure, demonstrating a compounding effect of genetic duplication and chemical exposure. Most hypomethylated genes exhibited increased transcript levels in SH-15M, SH+PCB, and SH-15M+PCB compared to SH in short term cultures,

however, most transcript levels were reduced or heterogeneously dysregulated in long-term cultures, similar to the dysregulation in transcript levels in Dup15q brain samples. Mechanistically, overexpression of maternal UBE3A in Dup15q decreased RING1B which reduced ubiquitinated H2A levels, including monoubiquitin of acetylated H2A.Z, resulting in loss of this poised promoter chromatin mark and hypomethylation. These results demonstrate the compounding effects of cumulative genetic and environmental events on the neuronal methylome, leading to a convergence in transcriptional dysregulation of chromatin and synaptic gene pathways relevant to ASDs.

Title: Effects of A1 vs A2 beta casein containing diet on glutathione levels: Linking the Gut and the brain via redox -based epigenetic changes

Authors: *M. S. TRIVEDI[1], R. DETH[2], Y. ZHANG[3];
[1]Neuro-Pharmacology, [2]Nova Southeastern Univ., Fort Lauderdale, FL; [3]Northeastern Univ., Boston, MA

Abstract: Background Glutathione (GSH) is produced in every cell in the body, where it acts as an antioxidant to neutralize free radicals and prevent oxidative cellular damage. Alterations in GSH levels are reported in neurological, inflammatory diseases as well as immune dysfunction. Several studies in animals and humans involving supplementation with whey protein or whey protein isolates from milk have documented increases in plasma and tissue glutathione concentrations along with reductions in oxidative stress, while the effects of casein on GSH are as yet not clear. One of the major components of the casein family is beta-casein and evolutionarily there are two major type of beta-casein: A1 and A2. The presence of histidine at position 67 allows a protein fragment of seven amino acids, known as beta-casomorphin-7 (BCM-7), to be produced on enzymatic digestion only from A1 but not from A2 beta-casein. BCM7 is an opioid peptide and can act on mu-opioid receptor similar to morphine. We have previously reported that BCM-7 can reduce cysteine uptake in cultured human neuronal and gastrointestinal epithelial cells by activating opioid receptors, inducing oxidative stress by

decreasing the levels of GSH.Objective The current work was undertaken to investigate the effects of A1 vs A2 type of beta-casein containing diet on antioxidant GSH levels and inflammatory status in pre-clinical and clinical trials.Methods A pre-clinical study was performed using mouse and rabbit animal models fed on A1 and A2 beta-casein containing diet. The clinical study was performed in collaboration with researchers in China (NCT02406469https://clinicaltrials.gov/ct2/show/NCT02406469). We collected liver, brain and gut tissues in our preclinical study, whereas serum GSH was measured in our clinical study. In both cases HPLC coupled to an electrochemical gradient detector was used to evaluate GSH levels.Results In our preclinical study we observed significant decrease in GSH levels (indicating oxidative stress) in liver, gut and brain samples from animals (both mice and rabbit, $p<0.05$, N=12) fed on an A1 beta-casein containing diet as compared to animals fed on A2 beta-casein containing diet. Concurrently, we also observed elevated TNFalpha levels and NFkB levels in gut tissues of mice and rabbit on an A1 beta-casein containing diet as compared to animals fed on A2 beta-casein containing diet, indicating elevated inflammatory status ($p<0.05$, N=12). Similarly, in our clinical trial, human participants consuming A1 beta-casein containing milk had decreased GSH serum ($p<0.05$, N=45)

Title: Effects of maternal serotonin transporter genotype and stress on microbiota throughout pregnancy

Authors: *B. M. KILLE[1], D. J. DAVIS[2], P. M. HECHT[4], A. C. ERICSSON[2], D. Q. BEVERSDORF[3];
[2]Dept. of Vet. Pathobiology, Col. of Vet. Med., [3]Psychological Sci., [1]Univ. of Missouri, Columbia, MO; [4]USC, Los Angeles, CA

Abstract: Maternal stress during pregnancy (prenatal stress) has been shown to have potentially long lasting negative effects on offspring, including an increased risk for neurodevelopmental disorders such as autism spectrum disorder (ASD). A common deletion in the promoter region of the serotonin transporter gene (SLC6A4) has been associated with increased anxiety and increased stress reactivity. Previous work from our lab has established an interaction between this genetic polymorphism in mothers and prenatal stress in the risk for autism diagnosis in the

child. Further, data suggest there is a critical window of time during pregnancy (late second and early third trimester) in which mothers who are exposed to acute stressors and carry the short SLC6A4 allele are more likely to have a child diagnosed with autism. This phenomenon has also been demonstrated in heterozygous SERT knockout (Slc6a4+/-) mice, which display serotonin activity alterations similar to those found in humans carrying the short allele. Pups from Slc6a4+/- dams that have been subjected to stress display decreased social interactions and increased anxiety compared to offspring of wild type. Stress and stress reactivity can also interact to impact the gut microbiome. While wild type mice experience changes in microbiota as a result of an inflammatory stressor, we have found evidence that Slc6a4+/- mice have some protection against these effects. Vaginal and gut microbiota are also altered by pregnancy. In order to explore the interaction between stress, microbiome and pregnancy, the current study compared pregnant wild type and Slc6a4+/- mice divided into either a control condition or stress condition, in which they received two hours of restraint stress daily beginning embryonic day 12. At embryonic day 13.5, 15.5 and 18.5, dams were sacrificed for fetal tissue/placental collection and any fecal matter present was collected. Using next-generation sequencing of the bacterial 16s rRNA marker gene, we explored differences between microbial communities in order to help shed light on the complex interplay between stress, genetics and the microbiome at various stages of pregnancy.

Title: The bacterial peptidoglycan sensing molecule Pglyrp2 modulates brain development and behavior

Authors: *R. DIAZ HEIJTZ, H. FORSSBERG, T. ARENTSEN;
Karolinska Institutet, Stockholm, Sweden

Abstract: Recent studies have revealed that the gut microbiota modulates brain development and behavior, but the underlying mechanisms are still poorly understood. Here, we show that bacterial peptidoglycan (PGN) derived from the commensal gut microbiota can be translocated into the brain and sensed by specific pattern-recognition receptors (PRRs) of the innate immune system. Using expression-profiling techniques, we demonstrate that two families of PRRs that specifically detect PGN (i.e., PGN-recognition proteins and NOD-like receptors) are highly expressed in the developing brain during specific windows of postnatal development, and their expression is sensitive to manipulations of the gut microbiota. To begin addressing the potential influence of PGN-sensing molecules on brain development and behavior, we explored the role of PGN-recognition protein 2 (Pglyrp2) in the process. Using transgenic mice, we first investigated the effect of deleting Pglyrp2 on the expression of brain-derived neurotrophic factor (*Bdnf*) in the developing brain. *Bdnf* mRNA expression levels were significantly reduced in the striatum of three-day-old Pglyrp2 KO male mice compared to wild-type controls. We then subjected juvenile Pglyrp2 KO mice to a battery of tests for exploratory activity, anxiety and social behavior. In the open field, light-dark box and elevated plus maze tests, no significant behavioral changes were observed in Pglyrp2 KO mice. In the three-chamber social approach test, however, juvenile Pglyrp2 KO male mice spent significantly more time in the chamber containing the stimulus mouse than in the chamber containing the novel object, compared to control mice. Moreover, they also spent significantly more time sniffing and interacting with the stimulus mouse than the wild-type males did, indicating high sociability. Although juvenile Pglyrp2 KO female mice spent significantly more time in the chamber containing the stimulus mouse, they spent a similar amount of time as the wild-type females around the stimulus mouse. These results indicate that Pglyrp2 modulates the development of social behavior in mice. Moreover, these findings suggest that the central activation of PRRs by bacterial products could be one of the signaling pathways mediating the communication between the microbiota and the developing brain.

Title: Early life clinical dose penicillin exposure induces longterm effects on gut microbiota, brain inflammation and behavior which are partially restored by beneficial microbe administration

Authors: S. LECLERCQ[1], F. MIAN[1], A. STANISZ[1], L. BINDELS[2], O. KOREN[3], P. FORSYTHE[1], *J. BIENENSTOCK[1];
[1]McMaster Brain-Body Inst., Hamilton, ON, Canada; [2]Louvain Drug Res. Institute, Metabolism and Nutr. Res. Group, Univ. catholique de Louvain, Brussels, Belgium; [3]Fac. of Medicine, Bar-Ilan Univ., Safed, Israel

Abstract: Antibiotics (AB) are the most frequently dispensed drugs in pediatric patients and there is currently increasing concern that AB exposure early in life may have long-term consequences for health. Epidemiological studies have revealed that early life AB exposure increases the risk of developing allergies, inflammatory bowel diseases and obesity. The effects of AB on brain and behavior have been demonstrated by others, using very high doses of cocktails of mainly broad-spectrum antibiotics administered to adolescent or adult rodents. In this study, we have investigated the long-term effects on gut, microbiota, brain and behavior of a clinically relevant dose of oral penicillin given early in life, to both male and female Balb/c mice. Pregnant dams received penicillin V in drinking water 1 week before delivery and until weaning. Penicillin is absorbed by the gastro-intestinal tract, crosses the placenta and is found in the breast milk. The pups therefore received penicillin *in utero* and during the first 3 weeks of life while nursing. At weaning, pups were separated from their mothers and received regular drinking water. At 6-weeks old, the offspring were subjected to a battery of behavioral tests and gut (ileum, colon) and brain (hippocampus, frontal cortex) tissues were collected after the last test. We found that early life AB exposure had lasting effects on gut microbiota composition, modified the tight junctions of the blood-brain barrier, induced inflammation in the frontal cortex but not in the gut, and was associated with changes in brain neurochemistry (Corticotropin releasing hormone receptor 2, Brain derived neutrophic factor, Arginine vasopressin receptor 1b). Also, AB-treated mice exhibited decreased anxiety-like behavior, reduced social behavior and preference for social novelty as well as an unexpected aggressive behavior. Supplementation with *Lactobacillus rhamnosus* JB-1^{TM} during AB treatment restored certain biological and behavioral parameters. This study revealed that clinical pediatric low dose penicillin given early in life to mice had longterm effects on behavior, brain inflammation and microbiota, and may raise concerns about the behavioral consequences of AB therapy.

Title: Autism-relevant sociability deficits, repetitive behaviors, and neuroanatomical findings in the antigen-driven mouse model of maternal autoantibody related autism

Authors: ***K. L. JONES**[1], J. ELLEGOOD[3], E. EDMISTON[1], M. PRIDE[2], M. YANG[2], J. SILVERMAN[2], J. LERCH[3], J. CRAWLEY[2], J. VAN DE WATER[1];
[1]Div. of Rheumatology/Allergy and Clinical Immunology, [2]Dept. of Psychiatry and Behavioral Sci., Univ. of California Davis, Davis, CA; [3]Mouse Imaging Ctr., Hosp. For Sick Children, Toronto, ON, Canada

Abstract: Maternal autoantibodies reactive to proteins in fetal brain have been described by numerous researchers in a subset of mothers of children with autism spectrum disorder (ASD), but not in mothers of typically developing children. Our lab identified 7 protein antigens for maternal autoantibody related (MAR) ASD and recently mapped the antigenic epitope sequences recognized by these ASD-specific maternal autoantibodies. While previous passive transfer animal models yielded promising results, they did not reflect a constant exposure to the salient autoantibodies throughout gestation, as would be the case in the clinical setting. Therefore, we aimed to generate the first biologically relevant animal model of MAR ASD to directly assess

the pathologic significance of prenatal exposure to epitope-specific autoantibodies in generating ASD-relevant behaviors in offspring. In order to generate epitope-specific autoantibodies that mimic those found in the mothers of children with ASD, female C57BL/6J mice randomly assigned to MAR-ASD treatment received a series of immunizations containing peptide epitope sequences of the four primary target proteins of MAR ASD (lactate dehydrogenase A and B, collapsin response mediator protein 1, and stress-induced phosphoprotein 1). Control females were injected with saline only. Females were then paired with male breeders to produce the experimental offspring of interest. Subsequent male and female offspring were tested in a sequence of autism-relevant behaviors and developmental milestones from an early postnatal period through adulthood. Following behavioral testing, neuroanatomical differences in offspring were assessed via structural MRI at approximately 6 months of age. Our results indicate offspring prenatally exposed to autism-specific antibodies display robust deficits in social interactions and increased repetitive self-grooming behaviors as juveniles and adults during dyadic social interactions. Furthermore, the head sizes of MAR-ASD offspring were significantly larger than controls during early postnatal and adult time points, suggesting an altered neuroanatomical trajectory relative to control offspring. Increases in several cortical regions and white matter tracts were also observed in MAR-ASD adult brains relative to controls, with observed differences primarily driven by MAR-ASD females. By generating the MAR ASD-specific epitope antibodies in female mice prior to breeding, our antigen-driven mouse model demonstrates for the first time that these ASD-specific maternal autoantibodies are directly responsible for alterations in behaviors.

Title: Interactions between prenatal and early postnatal immune challenges in a mouse model of autism

Authors: E. L. MOKLER[1], A. J. ALEXANDER[1], S. M. LANDINO[1], B. C. FINGER[1], *Y. LI[2,1], V. Y. BOLSHAKOV[1], G. MISSIG[1], C. J. MCDOUGLE[3], W. A. CARLEZON, Jr.[1]; [1]Dept. of Psychiatry, Harvard Med. School, McLean Hosp., Belmont, MA; [2]Mailman Resch Ctr., McLean Hosp., Belmont, MA; [3]Lurie Ctr. for Autism, Massachusetts Gen. Hosp.,, Lexington, MA

Abstract: The role of immunological responses in the etiology of autism spectrum disorder (ASD) has long been hypothesized. A "multiple hit" model whereby multiple exposures to early life immune insults may contribute to the development of ASD. We developed a repeated immune challenge mouse model where pregnant mice were injected with the viral mimic poly(I:C) (20 mg/kg) on gestational day 12.5 of pregnancy. A subset of the offspring was injected with lipopolysaccharide (LPS) (10 mg/kg) on postnatal day 9 to induce a second robust innate immune response. A battery of behavioral assays were performed to characterize the behavioral phenotype of this model in relation to the core symptoms of ASD: deficits in communication and social interaction, and increases in stereotyped behaviors. To assess communication-related behavior, ultrasonic vocalizations (USVs) were recorded from male pups during a maternal separation test on postnatal days 10-16 and from adult males at seven weeks evoked from the presence of urine from a female in estrus. In both LPS treated pups and adults there were altered number of evoked USVs suggesting a dysregulation of communication. To measure social behavior, a one-chamber social interaction test was performed at 8 weeks. In males, postnatal LPS decreased social preference. To evaluate for the presence of stereotypic or repetitive behavior, mice were tested on a Rotarod at 7 weeks and were placed in a Y-Maze at 10 weeks to observe spontaneous alternations. Anxiety-like behaviors were measured from both males and females at 10 weeks in the open field test. There was heightened anxiety-like behavior for both sexes that received postnatal LPS. In sum, postnatal LPS was sufficient to produce a robust ASD-like behavioral phenotype, producing alterations in communication, social preference, stereotypic, and anxiety-like behavior. However, following prenatal poly(I:C) treatment we did not observe a reliable ASD-related behavioral phenotype, and found that the combination of polyI:C plus LPS produced only modest differences from the behavioral phenotype seen with postnatal LPS alone. Our findings provide evidence that perinatal immune insults can produce behavioral changes in mice resembling those found in ASD and lend further support to a potential immunological involvement in ASD.

Title: Sleep and epileptiform activity in a perinatal immune activation mouse model of autism spectrum disorder (ASD)

Authors: *G. MISSIG[1], A. J. ALEXANDER[1], E. L. MOKLER[1], A. J. WELLS[1], B. C. FINGER[1], C. J. MCDOUGLE[2], W. A. CARLEZON, Jr.[1];

Abstract: Increasing evidence suggests a role for inflammatory processes in autism spectrum disorders (ASDs). Some individuals with ASDs show elevated inflammatory markers and neuroimmune responses, as well as epidemiological association with familial autoimmune disorders. These findings raise the possibility that there is a subtype of ASD that is immunological in origin. Previous research in mice has shown that immune insults during critical developmental periods can result in a phenotype that reproduces some of the core features of ASD. We have recently developed a “multiple hit” immune model, whereby mice are exposed to repeated perinatal immune insults. In this model, pregnant mice are injected with the viral mimic poly(I:C) (20 mg/kg) on gestational day 12.5 in accordance to an established model of maternal immune activation. A subset of these offspring receives a second injection of LPS (lipopolysaccharide) (10 mg/kg) to induce a robust innate immune response on postnatal day 9. We have previously found that this model leads to a pronounced ASD-like behavioral phenotype with mice displaying deficits in social and communication behavior, increased repetitive behavior, as well as inducing a state of ongoing immune activation that persists into adulthood. Here, we examine this multiple hit immune activation model on two physiological measures that are commonly dysregulated in individuals with ASD, sleep and electroencephalography (EEG) epileptiform activity. Using a remote telemetry system, a transmitter was implanted at postnatal week 6 and measurements of EEG, electromyography (EMG), activity, and temperature were made for multiple weeks. During this period levels of activity, sleep, and circadian rhythm were analyzed. Prenatal LPS resulted in several alterations, including overall greater level of activity, consistent with the hyperactivity and sleep disturbances frequently observed in ASD. Considering that epilepsy is found in a higher percentage of individuals with ASD than in the general population and there is evidence for increased in epileptiform activity even in the

absence of epilepsy, we examined EEG recordings from perinatal immune activated mice for the presence of epileptiform activity. Analysis revealed that a subset of the mice that received postnatal LPS displayed heightened levels of epileptiform activity, which included the presence of spike-wave discharges during sleep. In sum, perinatal immune activation resulted in alterations in sleep and epileptiform activity resembling aspects of ASD, further supporting a potential immunological involvement in ASD.

Abstract: Many children and adolescents with Autism Spectrum Disorder (ASD) have significant gastrointestinal (GI) symptoms, but the etiology is currently unknown. Some individuals with ASD show altered reactivity to stress, as well as altered immune markers, particularly stress-responsive cytokines including TNF-α and IL-6. To assess potential relationships between GI symptoms and stress response, we examined whether GI symptoms were associated with increases in stress-associated endocrine and cytokine biomarkers in ASD. We hypothesized that positive relationships would exist between GI symptomatology and cortisol, TNF-α, IL-6. Furthermore, we conducted exploratory analyses to examine the effects of

the presence or absence of key co-occurring medical and psychological conditions on these relationships in ASD. A sample of 120 individuals aged 6-18 with ASD participated in the study. Participants provided pre- and post-stress salivary cortisol samples to measure the endocrine stress response, and a pre-stress blood sample to measure levels of interleukin 6 (IL-6) and tumor necrosis factor alpha (TNF-α). To assess the response to stress, cold pressor and vibrotactile stimulation were applied to the hands in independent trials. Upper and lower GI tract symptomatology were assessed using the QPGS Rome III. Exploratory analyses were conducted between measures of intelligence, key co-occurring conditions in ASD, and IL-6, TNF-α, and pre- and post-stress cortisol to examine potential relationships. Lower GI tract symptoms were significantly associated with post-stress cortisol concentration. This relationship between cortisol response to stress and GI functioning was greater for children who had a history of regression or loss of skills that were previously acquired. Exploratory analyses also revealed significant correlations between cortisol change score, IQ, and inappropriate speech. In contrast, lower GI tract symptoms were not associated with levels of TNF-α or IL-6. Significant correlations were found, however, between TNF-α and IL-6 and irritability, socialization, and IQ. These findings suggest that individuals with ASD and lower GI tract symptoms may have an increased response to stress, but this effect is not associated with concomitant changes in stress-associated cytokines. This relationship with stress may be relevant for future individualization of treatment of lower GI tract symptoms in ASD. The relationship between endocrine stress reactivity and lower GI tract symptoms in children with loss of skills, as well as the relationships between cortisol, IL-6, and intelligence in ASD, warrant further investigation.

Title: Gene X environment interactions in the development of an autistic-phenotype in mice.

Authors: *D. S. COELHO[1], K. JIMENEZ[1], L. REDUS[1], L. MYATT[1], J. C. O'CONNOR[1,2]; [1]Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At San A, San Antonio, TX; [2]Audie L. Murphy VA Hosp., San Antonio, TX

Abstract: The etiology of autism spectrum disorder (ASD) is not well understood. Prenatal exposure to certain environmental factors or genetic mutations increase the risk for developing ASD. However, whether exposure to environmental risk factors by genetically susceptible individuals increases the severity of the disorder remains unknown. Therefore, we tested the hypothesis that mice with a targeted deletion of the contactin associated protein-like 2 (CNTNAP2) gene would exhibit a more severe ASD-like behavioral phenotype following maternal immune activation during gestation. CNTNAP2 mutation has been associated with the development of autism in humans and a mild ASD-like phenotype, characterized by deficits in communication, sociability and stereotypic behavior, in mice. Additionally, maternal immune challenge with the viral mimetic polyinosinic:polycytidylic acid (poly I:C) during gestation results in a neurodevelopmental and behavioral phenotype resembling ASD (i.e. impaired communication, disrupted social behavior and repetitive, stereotypic behaviors). Pregnant dams were administered poly I:C (20mg/kg) or saline intraperitoneally on gestational day 12.5. At various ages, the behavior of offspring was measured in the following tests; ultrasonic vocalization, juvenile play behavior, grooming, marble burying, Y-maze, 3-chamber social interaction and pre-pulse inhibition. Consistent with previous reports, CNTNAP2 gene deletion independently caused an increase in ASD-like behaviors, but in contrast with much of the literature, maternal immune challenge with poly I:C failed to induced a robust ASD-like phenotype in WT mice. In CNTNAP2 deficient mice, maternal immune challenge with poly I:C did precipitate several ASD-like behaviors in affected offspring, including increased marbles buried and decreased social interaction in the juvenile play test. Additionally, social interaction was significantly more impaired in male mice versus female mice born from poly I:C challenged dams. Consistent with previous reports, our data indicate that deletion of the CNTNAP2 gene in mice results in an ASD-like phenotype, and males appear more vulnerable to some, but not all, of the behavioral consequences of maternal immune challenge with poly I:C. In our hands, poly I:C had little behavioral impact on WT mice as they developed, and the severity of the CNTNAP2 phenotype was more profound than previous reports. The latter could have obscured our ability to measure gene x environment interactions in the development of an autistic-like phenotype in mice.

Title: Maternal inflammation impacts fetal neurodevelopment via placental serotonergic dysfunction

Authors: *N. GOEDEN[1], J. VELASQUEZ[1], K. A. ARNOLD[1], Y. CHAN[1], B. T. LUND[1], G. M. ANDERSON[2], A. BONNIN[1];
[1]USC, Los Angeles, CA; [2]Yale Univ. Sch. of Med., New Haven, CT

Abstract: Maternal inflammation during pregnancy affects placental function and is associated with increased risk of neurodevelopmental disorders in the offspring. The molecular mechanisms linking placental dysfunction to abnormal fetal neurodevelopment remain unclear. During typical development, serotonin (5-HT) synthesized in the placenta from maternal L-tryptophan (TRP) reaches the fetal brain. There, 5-HT modulates critical neurodevelopmental processes. We investigated the effects of maternal inflammation in mice triggered in mid-pregnancy by the immunostimulant polyriboinosinic-polyribocytidylic acid [poly(I:C)] on TRP metabolism in the placenta, and its impact on fetal neurodevelopment, postnatal formation of the serotonergic system, and several adult behaviors typically associated with serotonergic dysfunction. We show that a moderate maternal immune challenge rapidly upregulates placental TRP conversion to 5-HT through successively transient increases in substrate availability and TRP hydroxylase (TPH) enzymatic activity, leading to accumulation of exogenous 5-HT and blunting of endogenous 5-HT axonal outgrowth specifically within the fetal forebrain. The pharmacological inhibition of TPH activity blocked these effects. Postnatally, these effects lead to the disruption of several adult behaviors that are commonly associated with neurodevelopmental disorders like autism and schizophrenia. These results establish altered placental TRP conversion to 5-HT as a new mechanism by which maternal inflammation disrupts 5-HT-dependent neurogenic processes during fetal neurodevelopment. The findings presented here lay the framework for more detailed studies of infectious agents on placentally-derived modulators of neurodevelopment, particularly in view of recent infectious disease outbreaks (such as H1N1 influenza or Zika virus), suggesting that pregnant women and their fetuses are high-risk groups for severe and long-lasting complications

Title: Synergy between partial loss of GABRB3 and gestational immune events in a mouse model of autism

Authors: ***H.-R. LEE**, T. WEERAKKODY, G. C. NASTARIN, Y.-W. WU, J. HUGUENARD, J. B. DING, T. D. PALMER;
Stanford Univ., Stanford, CA

Abstract: Autism spectrum disorders (ASDs) involve persistent deficits in social communication and social interaction, along with characteristic repetitive patterns of behavior. The symptoms of ASD are present at an early age and ASD often occurs in families, suggesting a genetic basis. Intensive efforts to identify a common genetic mechanism suggest that a very small fraction of ASD diagnoses can be attributed to single gene mutations. Complex combinations of common allelic variants may account for up to half of ASD cases, with the remaining cases due to other factors. It is also suspected that genetic predisposition acts in combination with environmental influences. Maternal immune events during pregnancy are among the most pronounced non-genetic risks and interactions between single gene risk factors and gestational immune events are beginning to illustrate how a mild genetic risk may combine with a mild environmental risk to cause autism. Single nucleotide polymorphisms and disruptive mutations in the GABAA receptor beta-3 subunit gene (GABRB3) are among the high-confidence recurrent mutation in ASD. Here we show that GABRB3 heterozygosity in mice shows striking synergy with the activation of a maternal immune response during pregnancy. Offspring exhibit pronounced ASD and intellectual disability-like behaviors, including absence of social interaction, increased repetitive behavior, and impaired cognitive function. Global physiological aberrations are also noted in medial prefrontal cortex (mPFC). Both excitatory and inhibitory synaptic transmission of layer 2/3 neurons was markedly attenuated in conjunction with reduced dendritic spine density. Mice also exhibit a reduction in NMDAR function within mPFC layer 2/3 neurons. In multichannel extracellular recording, both synaptic sinks and sources are globally diminished in the mPFC layer 2/3. These results strongly suggest that partial loss of GABRB3 potently

interacts with gestational immune events to elevate the severity of ASD-like symptoms and extensively alter synaptic structure and neurotransmission.

Title: Rapidly reversible altered functional connectivity and autism-like behaviors in a model of maternal inflammation-induced mild brain overgrowth

Authors: J. E. LE BELLE[1], N. G. HARRIS[2], A. J. SILVA[3], *H. KORNBLUM[4];
[1]Intellectual and Developmental Disabilty Res. Ctr., [2]Neurosurg., [3]Neurobio., UCLA, Los Angeles, CA; [4]UCLA Med. Ctr., Los Angeles, CA

Abstract: Autism spectrum disorders (ASD) affect up to 1 in 68 children and are associated with a broad array of genetic alterations, making an understanding of ASD a daunting task. Additionally, while autism is clearly heritable, there is also a strong environmental component to ASD pathogenesis. Despite this complexity, there are common themes that have emerged from studying children with ASD and animal models. One such theme is that autism is associated with altered neuronal connectivity. Another is that many mutations merge onto common molecular pathways, including the PI3K/AKT/mTOR pathway. Within this pathway, there are autism-associated mutations in PTEN. Mutations in PTEN and other negative regulators of the pathway are also associated with brain overgrowth, suggesting a potential role for enhanced neural stem proliferation in the development of autism. Additionally, a significant consensus is emerging that maternal inflammation is a common environmental exposure that could interact with genetic risk factors to cause autism. We found that mild maternal inflammation at midgestation in the mouse leads to activation of PI3K/NOX/AKT/mTOR signaling in the brain, enhanced neural stem cell proliferation, enlarged brains, and behaviors consistent with an “autistic” phenotype in the offspring (Le Belle et al., 2014). The effect on brain size was even more profound in PTEN heterozygotes due to a more complete oxidative inactivation of PTEN function. Our new data

demonstrate that MIR-exposed offspring in our model have altered functional brain connectivity (fMRI) in mice with the largest behavioral changes. Furthermore, the long-term activation of the PI3K/AKT/mTOR signaling pathway observed in our model following MIR exposure led us to test the effects of an mTOR inhibitor, Rapamycin. We found that Rapamycin produces dramatic rescue of the autism-associated behaviors and functional brain connectivity in adult mice within 2 hours, despite the persistence of their enlarged brain size. This exciting result indicates that inhibition of the abnormal signaling pathway activation in adult mice can rapidly reverse neuronal dysfunction without needing to alter aberrant structural changes.

Title: The association between blood levels of inflammatory markers and autism in Jordan

Authors: *L. ALZGHOUL[1], A. H. I. YANIS[2], S. S. N. MAHMOUD[2], Y. Z. S. QWAIDER[2], M. ELDAHABI[3], S. ALBDOUR[3];
[1]Dept. of Physiol. and Biochem., The Univ. of Jordan, Amman, Jordan; [3]Dept. of Physiol. and Biochem., [2]The Univ. of Jordan- Sch. of Med., Amman, Jordan

Abstract: Almost one percent of the world's population has been diagnosed with Autism Spectrum Disorder (ASD) with a male predominance. Although the various studies aiming to understand the pathophysiology of ASD, there is still many to reveal especially in middle and low-income countries, such as Jordan, which might help in early detection and hence better prognosis. Recently, several studies have demonstrated a link between abnormal immune activation and ASD. For instance, Epidemiological studies have established a correlation between ASD and family history of autoimmune disease, and allergic disorders such as celiac disease. In addition, several studies found higher immune system markers in autistics compare to controls. Cytokines are molecules that function as signaling chemicals by the body's immune system. They participate in many complex physiological functions, including inflammation and immunity. Also, they have an important role in proper brain and nervous system development, which is dependent on the correct balance of cytokine levels and other regulatory molecules.

While several researches have demonstrated an increase pro-inflammatory cytokines levels with decreased anti-inflamatory cytokines levels in autistics compare to controls, these finding might be variable between different regions and ethnicities. For example, a study based in Saudi Arabia did found a lower incidence of Il-6 hyperactivity among autistic patients compared to a control group, and another study did not found any correlation between degree of autism severity and the level of cytokines. Hence, the goal of this study was to test several pro interleukins levels and blood markers of gluten sensitivity in autistic patients in Jordan compared to controls. To test that, blood samples were collected from autistics, their unaffected siblings, and healthy unrelated controls. Later on, the plasma levels of IL-6, IL-8, IL-9, and IL-10 was measured by ELISA and compared between groups. For Gluten sensitivity, serum levels of IgA and IgG against gliadin and anti tissue transglutaminase was also measured by ELISA among the three groups. Furthermore, the association between immunological markers with age and symptoms was also investigated. Our preliminary data revealed increase pro-inflammatory cytokines, mainly IL-6 in autistic group compare to controls. Furthermore, while autistics did not have higher incidences of positive IG levels for anti tissue transglutaminase, they have a higher IG levels against gliadin compare to the control group.

Title: Increased microglial priming in autism spectrum disorder, an immunocytochemical study in postmortem human temporal cortex

Authors: *A. S. LEE[1,3,4], M. A. MOORE[1], Z. T. SACCOMANO[3], E. C. AZMITIA[3], P. M. WHITAKER-AZMITIA[1,2];
[1]Psychology, [2]Psychiatry, Stony Brook Univ., Stony Brook, NY; [3]Biol., New York Univ., New York, NY; [4]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany

Abstract: Microglia can shift into different complex morphologies depending on the microenvironment of the central nervous system (CNS). The distinct morphologies correlate with specific functions and indicate the pathophysiological state of the CNS. Previous postmortem

studies of autism spectrum disorder (ASD) showed regions of neuroinflammation in ASD resulting in changes in microglia number. These change in the microglia density can be accompanied by changes in microglia phenotype but the individual contribution of different microglia phenotypes to the pathophysiology of ASD remains unclear. Here, we used an unbiased semi-stereological approach to quantify six structurally and functionally distinct microglia phenotypes in postmortem human temporal cortex, which were immuno-stained with an antibody against Iba1. In addition to stereological measures, we used three different methods to quantify Iba1-immunoreactive microglia. We now report in human postmortem cortex measures on six distinct phenotypes including ramified, primed, reactive, amoeboid, rod and dystrophic. The total density of all microglia phenotypes did not differ between ASD donors (n=10, 14.6 yrs, range 2.8-29 yrs) and typically developing individual donors (controls, n=9, 14.9 yrs, 1.8-32 yrs). However, there was a significant decrease in ramified microglia in both gray matter and white matter of ASD, and a significant increase in primed microglia in gray matter of ASD compared to controls. This increase in primed microglia showed a positive correlation with donor age in both gray matter and white of ASD, but not in controls. Our results provide evidence of a shift in microglial phenotype that may indicate impaired synaptic plasticity, and a chronic vulnerability to exaggerated immune responses. We suggest the priming of microglia is most likely due to the disruption of maternal environment during pregnancy and developmental influences rather than genetic predispositions, but the exact mechanism is unclear. Further investigation in the underlying mechanism of the shift in microglia phenotype may be a step forward in understanding the significance of maternal environment and microglial pathology in ASD. Quantitative methods of measuring Iba1-immunoreactive microglia did not show significant difference between ASD and controls, which suggests the importance of using visual categorization or finer and/or more sensitive methods when neuroinflammation is subtle to delineate the complex morphology of microglia.

Title: Age dependent response to simulated brain injury in the functional connectome

Authors: *M. HART[1], E. BULLMORE[2], R. DOLAN[3], I. GOODYER[2], P. B. JONES[2], J. SUCKLING[2];
[1]Univ. of Cambridge, Cambridge, United Kingdom; [2]Dept. of Psychiatry, University of Cambridge, United Kingdom; [3]Wellcome Trust Ctr. for Neuroimaging, University College London, United Kingdom

Abstract: Introduction Brain robustness and recovery from injury is believed to be maximal in infancy, and then reduce during development. Despite corroboration of this theory in animal models, clinical evidence in humans is suggestive of a more complex relationship. We sought to model this process with a percolation theory analysis of the functional connectome to clarify the relationship between age and response to brain injury. **Methods** We recruited 100 healthy participants aged 14 to 24 years (50 female) and acquired multi-echo, BOLD sensitive, echo-planar imaging at 3 Tesla. Functional connectomes were formed using an anatomical template of 116 regions and Pearson correlations without thresholding. Brain injury was simulated through removal of nodes individually or sequentially (in either a random or targeted manner). Gender and age specific changes were analysed with a general linear model and permutation testing, corrected for the false discovery rate. **Results** Overall there was little significant change with age in resistance to sequential node removal (either targeted or random). However, the effects of removal of individual brain regions did changes with age, with approximately 10% of all nodes demonstrating either an increase or decrease in their vulnerability. Regions of increased vulnerability with age included deep nuclei and the cerebellum, while regions of decreased vulnerability were predominantly on the medial surfaces (for example the posterior cingulate cortex).**Conclusions** Age dependent response to brain injury during the adolescent to adult period involves a reorganisation of individual components rather than reflecting an overall feature of connectome or brain network organisation. This process suggests a parsimonious explanation for divergent clinical effects whereby the effects of injury vary with location and age. Further directions could include determining the effects of potential age-dependent plasticity on recovery and relating this to concurrent developmental processes such as synaptic refinement. Clarifying the mechanisms underlying how the brain responds to injury may allow us to better tailor neurosurgical approaches to lesion resections, for instance by avoiding vulnerable areas or those that have potential for recovery.

Title: Inhibition of rho-kinase II has antidepressant-like efficacy in adolescent mice

Authors: L. P. SHAPIRO[1], *S. L. GOURLEY[2];
[1]Pharmacol., [2]Pediatrics, Neurosci. Program, Emory Univ., Atlanta, GA

Abstract: Adolescence represents a critical period of neurodevelopment, defined by structural reorganization and synaptic maturation within the prefrontal cortex. Although these processes are critical for the transition to adulthood, structural instability may open a window of vulnerability to neuropsychiatric disorders including depression. Interventions that facilitate activity-dependent neural remodeling, as occurs during adolescence, may be advantageous. Here we evaluated the therapeutic-like potential of Rho-kinase (ROCK) inhibition, which can expedite activity-dependent dendritic spine plasticity. The brain-penetrant ROCK inhibitor fasudil had antidepressant-like effects in the forced swim test in adolescent mice and was comparable to ketamine and fluoxetine. Fasudil also decreased the latency to approach a palatable food in the novelty suppressed feeding task, a rapid antidepressant-like effect. Within the adolescent ventromedial prefrontal cortex (vmPFC), fasudil increased levels of the post-synaptic marker PSD-95, while pruning dendritic spines, resulting in adult-like spine densities. Fasudil stimulated several neurotrophin-related signaling factors in the vmPFC, including increasing the ratio of full-length:truncated tyrosine kinase receptor B (TrkB). Subsequent experiments utilizing viral vector-based and pharmacological manipulations indicated, however, that the antidepressant-like actions of fasudil are nonetheless attributable to the inhibition of the neuronal ROCK isoform, ROCKII.

Title: Adolescent exposure to methylmercury and d-amphetamine produce comparable reversal-learning impairments in mice

Authors: *R. A. SAUER, S. R. BOOMHOWER, K. R. JOHNSON, M. C. NEWLAND; Psychology, Auburn Univ., Auburn, AL

Abstract: Adolescence is a dynamic period of neuronal development in which the dopamine (DA) neurotransmitter system matures. These changes to the DA system may cause adolescents to be especially susceptible to neurotoxicants and drugs that act on DA. One such neurotoxicant, methylmercury (MeHg), inhibits the dopamine transporter (DAT) and promotes DA efflux in vitro. Gestational exposure to MeHg is associated with lasting deficits in behavioral flexibility and increased sensitivity to dopamine agonists, but the impact of adolescent MeHg exposure remains to be explored. Moreover, it is unclear whether the interactions of MeHg with DA are a mechanism by which MeHg produces these behavioral deficits. To assess the role of DA in MeHg's developmental neurotoxicity, we compared adolescent MeHg exposure to that of a drug that inhibits DAT and induces DA efflux, *d*-amphetamine (*d*-AMP). Adolescent male C57Bl/6n mice were randomly assigned to two MeHg-exposure groups (0 ppm and 3 ppm) and two *d*-AMP-exposure groups (saline and 1 mg/kg), producing four treatment groups (n = 10-12/group): Control, MeHg, *d*-AMP, and MeHg + *d*-AMP. MeHg exposure (via drinking water) spanned postnatal day 21 to 60 (the murine adolescent period), and once daily i.p. injections of *d*-AMP or saline spanned postnatal day 28 to 42. As adults, mice were trained on a spatial-discrimination-reversal task in which trials were response-initiated and the spatial location of a lever press (left or right) predicted reinforcement. Following two spatial discrimination reversals, a visual-discrimination task (extradimensional shift) was instated in which the presence of a stimulus light above a lever (lit or unlit) predicted reinforcement. Responding was modeled using a logistic function, which estimated the rate (slope) of a behavioral transition and trials required to complete half a transition (half-max). Adolescent exposure to MeHg alone, *d*-AMP alone, and MeHg + *d*-AMP increased estimates of half-max on the second reversal. MeHg exposure alone also increased half-max and decreased the rate of the transition following the extradimensional shift. Conjoint exposure to MeHg and *d*-AMP produced more perseverative errors and omissions following a reversal. The similar effects of MeHg and *d*-AMP exposure, alone and in combination, on reversal performance provide indirect evidence for the hypothesis that disruption of DA neurotransmission is a mechanism of MeHg-induced behavioral toxicity. Additionally, these data suggest that adolescence is a time during which the brain and behavior may be especially susceptible to MeHg exposure and its interaction with psychomotor stimulant drugs.

Title: Epigenetic and behavioral influences of adolescent methylmercury exposure in mice

Authors: *S. R. BOOMHOWER[1], S. V. BACH[2], J. J. DAY[2], M. C. NEWLAND[1]; [1]Psychology, Auburn Univ., Auburn, AL; [2]Neurobio., Univ. of Alabama at Birmingham, Birmingham, AL

Abstract: Environmental stressors during critical developmental periods can have long-lasting, epigenetic consequences on neural and behavioral development. Exposure to the environmental neurotoxicant, methylmercury (MeHg), produces neurobehavioral dysfunction that persists long after exposure ceases. In animal models, gestational MeHg exposure disrupts cortical development, impairs reversal learning, and distorts the impact of reinforcing events on behavior in adulthood. The enduring impact of MeHg exposure supports a hypothesis that epigenetic dysregulation is a key mechanism underlying MeHg's toxicity. Perinatal MeHg exposure has been linked to decreased gene expression and deacetylation of histone N-terminals, a classic epigenetic mark, in the prefrontal cortex of adult animals. The impact of MeHg exposure during other sensitive periods of development, such as adolescence, has not been examined. Male C57Bl/6n mice were randomly assigned to three MeHg exposure groups (n = 12 in each): 0, 0.3, and 3.0 ppm MeHg (via drinking water). Exposure lasted from postnatal day 21 to 60, the murine adolescent period. As adults, lever-pressing was maintained under a multiple fixed-ratio (FR) schedule of reinforcement for sweetened-condensed milk. The response-to-reinforcer ratio increased within a session: FR 1, 5, 15, 30, 60 and 120. Responding was analyzed using Mathematical Principles of Reinforcement, a theoretically-driven model of reinforcement-based learning whose parameters reveal information about motor function, reinforcer efficacy, and saturation rate—a measure of the effects of delayed reinforcement. To examine the genome-wide transcriptional impact of adolescent MeHg exposure, directional poly(A)$^+$ RNA sequencing was performed on prefrontal-cortex samples from a separate cohort of animals exposed to 0 ppm (n = 7) and 3 ppm MeHg (n = 7) during adolescence. Adolescent MeHg exposure decreased estimates of minimum response time thereby increasing maximum response rates. MeHg also increased saturation rate, indicating that temporally distal responses were less likely to be strengthened by

reinforcement. Further, adolescent MeHg exposure suppressed expression of fourteen genes, including a number of immediate early genes implicated in neural development, learning, and motor function (e.g., *Btg2*, *Arc*, and *Fos*). Adolescence represents a vulnerable developmental window for long-lasting behavioral and epigenetic effects of neurotoxicant exposure. Neuroepigenetic markers coupled with detailed, theory-driven behavioral analyses provide a deeper understanding of brain-behavior relations with MeHg exposure.

Title: Pubertal stress exerts sex-specific deficits on pre-pulse inhibition and forced swim test performance in adulthood

Authors: *C. DRZEWIECKI, J. WILLING, L. CORTES, J. JURASKA;
Univ. of Illinois at Urbana/Champaign, Champaign, IL

Abstract: Adolescence, the period between childhood and adulthood, is a peak time for the onset of various mental illnesses, including depression, anxiety, and schizophrenia. Additionally, numerous neuroanatomical changes occur across adolescence, particularly within the medial prefrontal cortex (mPFC), a region implicated in these disorders. Previous research from our laboratory has demonstrated that the onset of puberty in both male and female rats may affect neuronal and/or synaptic pruning within the mPFC, suggesting puberty is a critical time for development of this region. While research suggests that adolescent stress during adolescence may contribute to symptoms of mental illness, no research to date has examined the role of pubertal onset in sex-specific effects of stress. We exposed male and female rats to a combination of isolation and restraint stress during the onset of puberty or during the post-pubertal period of adolescence, with an additional unstressed control group. At young adulthood, all subjects were tested in an Elevated Plus Maze (EPM), Forced Swim Task (FST), Pre-pulse Inhibition (PPI), Open Field Task, and a Novel Object Recognition task. While we found no

effects of stress on Open Field or Novel Object Recognition performance, we did find sex-specific effects of pubertal stress on EPM, FST, and PPI. Females stressed during the window of pubertal onset displayed an increased latency to enter an open arm in the EPM, as well as increased time spent immobile during the FST. Males stressed during pubertal onset showed deficits on a PPI task. These results demonstrate sex-specific effects associated with pubertal, but not post-pubertal, stressors during adolescence, which may contribute to peak onset of mental illnesses during this time.

Title: Novelty preferences are associated with blood flow changes in addiction regions of the brain of female juvenile rats

Authors: ***A. N. ROCK**[1], M. ROHAN[2], S. B. LOWEN[2], K. J. NORMAN[3], S. L. ANDERSEN[3]; [1]McLean Hospital; Harvard Med. Sch., Belmont, MA; [2]McLean Imaging Center; Dept. of Psychiatry, [3]Lab. of Developmental Neuropharmacology; Dept. of Psychiatry, McLean Hospital; Harvard Med. Sch., Belmont; Boston, MA

Abstract: Adolescence is a critical neurodevelopmental period rife with novelty-seeking and impulsive behaviors that facilitate drug use and increase vulnerability to addiction. Concurrent with and related to these changes, the adolescent prefrontal cortex overexpresses dopamine D1 receptors (D1r) in glutamatergic neurons that project to the reward area of the nucleus accumbens. These D1rs are associated with an increased sensitivity to drug cues. We investigated whether the overexpression of D1rs within the female adolescent rat brain would increase either novelty-preferring behaviors and/or preferences to cocaine-associated environments. We also assessed whether conditioned odor cues would change blood flow in addiction-relevant brain areas. On postnatal day (P) P16, a lentiviral vector that overexpressed D1r was injected into the prelimbic prefrontal cortex of female rats, while a control group received only the green fluorescent protein-expressing vector. Rats were then behaviorally tested

for novelty preference on P19-P23. Afterwards, rats were administered two cocaine injections (10 mg/kg, i.p.) on P24-P27 paired with an odor stimulus to condition a place preference to the setting in which they received the drug. Employing the methods of Lowen et al (2015), the same cocaine conditioned odor stimulus was used in conjunction with whole-brain functional magnetic resonance imaging (fMRI) at 9.4T on P28 to determine blood flow responses to the drug cue. Contrary to our hypothesis, post-conditioning trials revealed a trend (P=0.08) in which the control group spent the majority of time in the drug-paired chamber, while the rats overexpressing D1r demonstrated no preference. Functional MRI responses to the conditioned odor in both the rats with increased preference to novel environments and those treated to overexpress D1rs indicated increased activation in the prefrontal cortex and the dorsal striatum, and a concurrent decrease of activity in the insula.The strong activation in the dorsal striatum observed in female adolescent rats suggests that blood flow increases in this region, which are associated with habit formation and cue reactivity rather than reward per se, might place adolescent females at elevated risk for addiction. The decrease in activation in the insula in these rats suggests a corresponding decrease in response inhibition. These two imaging observations in this two-day cocaine and odor stimuli conditioning experiment suggest increased vulnerability to psychostimulant addiction in adolescent females may be related to novelty preferences.

Title: Adolescent methylphenidate exposure alters nicotine self-administration and the accumbal firing response to nicotine

Authors: *C. C. DE PRETER[1], L. J. HERNANDEZ[1], S. L. KIRBY[1], R. B. CAMPBELL[2], E. BEAUMONT[2], C. A. BRADLEY[1], M. I. PALMATIER[1], R. W. BROWN[2];

Abstract: This study was designed to analyze the effects of adolescent exposure to methylphenidate (MPH; trade name: Ritalin) on nicotine self-administration, the motivation to obtain nicotine, and accumbal neuronal firing rate in female adolescent rats. MPH is the most

commonly prescribed medication for Attention Deficit-Hyperactivity Disorder (ADHD) which is diagnosed in 3-5% of adolescents in the United States. However, this disorder is often misdiagnosed, and MPH is often prescribed to individuals not diagnosed with ADHD. Adolescent female Sprague-dawley rats were ip administered 1 mg/kg MPH or saline using a "school day" regimen of five days on, two days off, beginning on postnatal day (P)28 and this regimen was maintained throughout testing. A 1 mg/kg dose of MPH has been shown to result in brain plasma levels equivalent to clinical dosing in humans. Indwelling catheters were implanted in the jugular vein at P35, and one week later on P42, animals began nicotine self-administration. MPH (1 mg/kg) was administered each day approximately 6 h before each self-administration session began, which allows for nearly full plasma clearance of MPH (half-life = 1 h) before self-administration commenced. Rats were reduced to 85% of their free-feeding body weight and sipper tubes were made available to the rats in this paradigm, and responses to licking the tube produced an infusion of nicotine solution (15μg/kg) over a range of fixed ratio (FR) reinforcement schedules followed by a progressive ratio (PR) schedule, a measure of motivation. The schedule of reinforcement during 60 min sessions was increased from an FR5 to FR15 over approximately a three-week period. Results revealed that MPH pre-exposed rats self-administered significantly higher amounts of nicotine as compared to animals treated with saline throughout the FR5 and FR10 schedules. Further, MPH enhanced the motivation to self-administer nicotine on the PR schedule compared to controls, demonstrating an enhanced motivation to obtain nicotine produced by MPH. Finally, animals that had been pre-exposed to MPH and self-administered nicotine demonstrated a lower rate of basal accumbal firing as compared to controls, but a burst firing in response to nicotine that was higher than rats pre-exposed to saline. In conclusion, MPH altered the behavioral and neural response to nicotine in the nucleus accumbens.

Title: Epigenetic alterations apparent in brain-expressed genes after severe childhood trauma

Authors: *A. ZIMMERMAN[1], F. E. MENNEN[2], E. L. BEARER[1];
[1]Univ. of New Mexico Hlth. Sci. Ctr., Albuquerque, NM; [2]Sch. of Social Work, USC, Los Angeles, CA

Abstract: Childhood maltreatment is a major risk factor for poor physical outcomes in adulthood including depression, anxiety and cognitive dysfunction. Therefore, it is necessary to develop biomarkers as indicators of maltreatment at an early age, before later-life clinical outcomes present themselves. For a preliminary study, we used children who were referred by Los Angeles County Child Protective Services to Children's Institute Inc. for recruitment into a trauma therapy program. Children, exposed to documented trauma at some point before entry into therapy, were followed for 6 to 8 months. Between their intake and one-month follow-up after therapy, only a portion of these children continued to experience traumatic events. At entry into therapy and one-month post therapy, three centimeters of hair were taken to measure average cortisol as a representative marker of long-term stress. Using an Illumina Infinium MethylationEPIC BeadChip we measured genome wide DNA methylation from saliva for over 850,000 methylation sites for six children to observe differences in children recently exposed to severe trauma, compared to children with no recent report of severe trauma. While average cortisol was not significantly correlated with caregiver-reported trauma, we found significant alterations in DNA methylation were apparent after traumatic experiences, such as domestic or sexual violence, especially in cases with no reported traumatic event in the previous month. These significant changes were primarily in genes involved in immune response and regulation of DNA methylation, while a few methylation sites were altered for genes over-expressed in the brain. While global methylation levels from one time point to another were not drastically changed, a subset of promoter regions and gene bodies were significantly altered indicating that significant methylation changes can occur in a period of only a few months. It also appears that the duration and intensity of the trauma may play a role in the amount of change seen in methylation levels. After seeing significant methylation changes in individuals with a similar trauma history, we hope to validate this finding in children from a different fifteen-year study to determine long-term effects that severe childhood maltreatment has on DNA methylation from early childhood into adulthood.

Title: Developmental changes in the influence of COMT genotype on the flexible processing of self-generated information and trait anxiety

Authors: *E. J. KILFORD[1], I. DUMONTHEIL[2], S.-J. BLAKEMORE[3];
[1]UCL Inst. of Cognitive Neurosci., London, United Kingdom; [2]Dept. of Psychological Sci., Birkbeck, Univ. of London, London, United Kingdom; [3]Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: The catechol-O-methyltransferase enzyme (COMT) is a major determinant of prefrontal dopamine levels. The Val[158]Met polymorphism of the *COMT* gene has previously been associated with reciprocal variation in executive function and affective reactivity, hypothesised to represent a trade-off between cognitive efficiency and affective resilience. In adults, the Met allele, which results in lower enzymatic activity and higher dopamine availability, has been associated with superior executive function and working memory, whereas the Val allele has been associated with advantages in affective processing and lower levels of anxiety disorders and related traits. Dopamine effects on prefrontal function follow an inverted U-shape curve, with both deficient and excessive levels resulting in poor cognitive performance. A recent study demonstrated that Met allele advantages on working memory emerge during adolescence, consistent with developmental changes in the dopaminergic system that are hypothesised to shift the relative position of each *COMT* genotype group on the dopamine curve. We investigated developmental changes in the influence of *COMT* genotype on both executive function, specifically the flexible processing of self-generated information, and trait anxiety. A cross-sectional sample of healthy adults and adolescents (N=307, aged 9 to 37 years) performed a behavioural task in which they processed alternating blocks of self-generated and stimulus-oriented information, and completed measures of self-reported trait anxiety. We hypothesised that associations between *COMT* genotype and cognition would be moderated by developmental

stage.
Age group x *COMT* genotype interactions were found for both task accuracy and trait anxiety. Met/Met adults were more accurate and had higher trait anxiety relative to adult Val carriers, whereas Met/Met adolescents were relatively less accurate and had lower trait anxiety than adolescent Val carriers. These results extend previous findings of developmental variation in the association between *COMT* genotype and prefrontal cognition to other aspects of executive function and to individual differences in trait anxiety, consistent with trade-off models of *COMT* genotype effects.

Title: Escalation of methamphetamine intake in adolescent rats compared to adults

Authors: *S. J. LUIKINGA[1,2], H. B. MADSEN[1,2], I. C. ZBUKVIC[1,2], A. J. LAWRENCE[1,2], J. KIM[1];

Abstract: Methamphetamine (Meth) abuse is a growing problem in Australia, with the rise in its purity as a main concern. Additionally, the age of Meth abusers has significantly dropped over the past few years with children as young as 10 years admitted to hospital on Meth. Therefore, we used the intravenous self-administration paradigm to compare Meth abuse-related behaviour in adolescent (postnatal day 35) and adult (postnatal day 70) rats. Rats were trained to lever press for Meth at a dose of 0.03 mg/kg/infusion. It was found that both adults and adolescents acquired in a similar manner however, after acquisition, adolescent rats escalated their intake when the dose was increased (0.1mg/kg/infusion, $p<0.05$). To test whether this escalation was due to pre-

exposure to Meth or due to a particular affinity for 0.1mg/kg/infusion, a new group of rats acquired at 0.1mg/kg/infusion, and then were tested on 0.3mg/kg/infusion. Interestingly, both age groups acquired in a similar manner and again an escalation of intake was seen in the adolescent group on the high dose ($p<0.05$). We also investigated the effects of meth vs saline on the number of interneurons in adolescent and adult rats using immunofluorescent staining of Parvalbumin (PV) and Somatostatin (SST). Preliminary data suggest that meth self-administration reduces the number of PV-positive interneurons in the infralimbic cortex in adolescents more dramatically compared with adult rats.

Title: The impact of adolescent alcohol exposure on fear memory acquisition, extinction, consolidation, and recall in adulthood

Authors: *R. J. NEWSOM, E. GLOVER, J. CHANDLER, J. GASS;
Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: Ethanol is the most commonly used drug among adolescents in the United States, and is frequently ingested in repeated binge-like episodes involving large amounts consumed over short periods of time. The lasting effects of these binge-like exposures are not well understood. In the present study, we examined the effects of adolescent intermittent ethanol (AIE) vapor exposure (postnatal days 28-44) on fear conditioning and extinction in adulthood. AIE-exposed and air-exposed controls received 3 daily sessions of fear conditioning in which an auditory tone was paired with a moderate (0.75 mA) foot shock. Following conditioning, all rats were given 5 daily extinction sessions in which the visual context was altered and the auditory tone was no longer followed by a foot shock. All rats had reached extinction criteria on the 5th day of extinction. Following extinction, rats were tested in multiple conditions to allow for examination

of context-induced freezing behavior, retention of extinction learning, and spontaneous recovery of conditioned freezing behavior. The results indicated that AIE-exposed rats acquired fear conditioning more quickly when compared to air-exposed controls. Additionally, AIE-exposed rats exhibited significantly less freezing in response to the fear context. However, when tested in a retention trial to assess their ability to retain the extinction memory of the tone AIE-exposed rats display significantly higher freezing rates in response to the tone. Furthermore, AIE-exposed rats demonstrated higher freezing rates during a spontaneous recovery test of conditioned freezing three weeks later. These data suggest that AIE exposure results in lasting neural alterations that increase susceptibility to fear memory acquisition and disrupt consolidation of contextual and extinction memories in adulthood. These behavioral alterations are possibly due to AIE-induced disruptions in multiple neural mechanisms related to memory formation and consolidation. We are currently examining the impact of AIE exposure on stress reactivity measures and exploring potential mechanisms to attenuate AIE-induced deficits in fear-related memories.

Title: Effects of chronic intermittent adolescent ethanol exposure on early and late modulation of Ox/Hcrt system

Authors: *M. SANCHEZ-ALAVEZ, W. NGUYEN, S. MORI, D. N. WILLS, B. CONTI, C. L. EHLERS;
Mol. Cell. Neurosci., Scripps Res. Inst., LA Jolla, CA

Abstract: Recently it has been shown that the orexin/hypocretin (Ox/Hcrt) system is involved in the mediation of sleep as well as the reward aspect of ethanol intake. However the effect of ethanol itself on the Ox/Hcrt system has been poorly explored. Here we investigated the effects of chronic intermittent ethanol (CIE) exposure on early (0h and 24h) and late modulation (4 weeks) of Ox/Hcrt system after CIE exposure in adolescent rats. 48 rats (P22) were divided in

two groups, the control group (n=24) and EtOH group (n=24) that was exposed to CIE for 5 weeks (P22-P56). Control and CIE groups were subdivided in three subgroups (n=8) and sacrificed at P57 (0h), P58 (24h) and P85 (4 weeks) after CIE exposure. Ox/Hcrt levels and the expression of prepro Ox/Hcrt mRNA and GABARα1 mRNA on lateral hypothalamus were investigated using an enzyme link immunoassay (EIA) and SQPCR respectively. In addition, Ox/Hcrt 1 and 2 receptors mRNA, GAD65 mRNA, GAD67 mRNA were evaluated in the anterior hypothalamus, which includes the median preoptic area (MnPO). Results show that CIE did not change Ox/Hcrt peptide levels on lateral hypothalamus although expression of prepro Ox/Hcrt mRNA increased on P57 (0h, $p<0.05$) returning to control expression levels on P58 and P85. GABARα1 mRNA was upregulated at P85 compared to control ($p<0.05$). No significant changes were observed in the expression of GAD65, GAD67 and Ox/Hcrt 1 and 2 receptors mRNA in the anterior hypothalamus. These data indicate that CIE during 5 weeks disrupt the early modulation of prepro Ox/Hcrt mRNA expression and late modulation of GABARα1 mRNA on lateral hypothalamus.

Title: Developmental effects of the AMPA receptor antagonist NBQX differ from adolescent-specific effects of ethanol on social interactions

Authors: *C. DANNENHOFFER, E. I. VARLINSKAYA, L. P. SPEAR;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Adolescent and adult rats respond differently to drugs of abuse, including ethanol. We have previously shown pronounced age differences in sensitivity to the social consequences of acute ethanol challenge. Adolescents, but not adults, display increases in social activity in a modified social interaction test following a low dose of ethanol, and are less sensitive than adults to the social inhibitory effects of higher doses of ethanol. Among the prominent neural effects of ethanol are its glutamate antagonistic-like effects, raising the possibility that age dependent effects of ethanol on social behavior may be related to developmental alterations in

glutamatergic function. Indeed, reminiscent of the developmental data with ethanol, adolescents show age-specific induction of social facilitation by the selective NMDA NR2B antagonist ifenprodil, and are less sensitive than adults to the social inhibitory effects of this NMDA antagonist. The purpose of the current experiment was to determine whether an ontogenetic pattern similar to those of ethanol and ifenprodil will be evident following antagonism of another type of glutamate receptor, namely AMPA receptors. The effects of a specific AMPA1 receptor antagonist, NBQX, were assessed in a social interaction test in adolescent and adult male and female Sprague Dawley rats. Animals were injected i.p. with a dose of NBQX (0.0, 1.0, 2.0, 4.0, 6.0 and 8.0 mg/kg) and placed alone into a two-compartment apparatus for a 30-min habituation period. A non-familiar social partner was then placed into the chamber for 10 min, and the session was videotaped for later scoring of the social behaviors. There were significant main effects of age and dose for all social measures (social investigation, contact behavior, play fighting, and the preference/avoidance coefficient), with adolescents generally showing more social behavior than adults. Unlike effects shown previously with ethanol and ifenprodil, no stimulatory effect of NBQX emerged at any dose in adolescents. Both adolescents and adults were sensitive to the social inhibitory effects of the two highest doses of NBQX, with few age differences in this social inhibition. Taken together, the data provide little evidence for notable differences between adolescents and adults in response to NBQX in a social interaction test, findings that vary considerably from the adolescent-specific effects of ethanol and the NR2B antagonist ifenprodil on social behavior. Results from this study further our understanding of the potential role of specific glutamate receptor systems during ontogeny in contributing to age-specific effects of ethanol on social behavior during adolescence.

Title: Adolescent intermittent binge ethanol alters ERK1/2 phosphorylation expression in the different brain regions of adult rat

Authors: *W. LIU, F. T. CREWS;
Bowles Ctr. for Alcohol Studies, Univ. of North Carolina-Chapel Hill, Chapel Hill, NC

Abstract: Adolescence is a vulnerable developmental period when many binge drink. We previously found that adolescent intermittent binge ethanol (AIE) decreased ERK1/2 phosphorylation (pERK1/2) immunoreactivity (pERK1/2+IR) in the frontal cortical regions of adult rat brain. AIE blunted acute ethanol-induced decrease in the prelimbic and infralimbic cortex. In the current study, we determined the effect of AIE on pERK1/2+IR in other brain regions of adult (P80) rats. Male Wistar rats were bred and reared in our vivarium. On the day following birth (P1), litters were culled to 10 pups. At weaning on P21, male offspring were weight matched and pair-housed. Two groups, water control and ethanol (AIE, 5 g/kg/day, i.g., P25-P54; 2 days ethanol, 2 days off) were further divided at P80 following 26 days without ethanol, into water or ethanol (4 g/kg, i.g.) challenge separately, and sacrificed 2 hours later. At P80, in non-ethanol treatment control, ethanol challenge decreased pERK1/2+IR about 50~90% in most brain regions, including agranular insular (AI), forceps minor of the corpus callosum (fmi), ectorhinal (Ect), perirhinal (PRh) and lateral entorhinal (LEnt) cortex; amgydala, the ventral part of lateral septal nucleus (LVS), granular cell layer (GCL), lateral habenular nucleus(LHb), rostral linear nucleus of the raphe (RLi), anterior (aVTA) and posterior (pVTA) ventral tegmental area, except the nucleus accumbens (NAc) and medial habenular nucleus (MHb) which were not changed. In AIE treated group, AIE decreased adult pERK1/2+IR baseline (of control) in AI (19%, $p<0.001$); Ect (15%, $p<0.001$), PRh (27%, $p<0.001$), LEnt (10%); LVS (41%, $p<0.01$); amgydala (Lateral: 13%, $p<0.001$; Basolateral: 17%, $p<0.01$; Central: 34%, $p<0.01$); RLi (57%, $p<0.01$); aVTA (24%, $p<0.001$) and pVTA (24%, $p<0.001$) except NAc shell and GCL which pERK1/2+IR were increased about 216% and 166% (of control), separately, and NAc Core, the habenular nucleus and fmi which were not changed. In contrast, AIE blunted acute ethanol-induced decrease in the fmi ($p<0.05$); and AIE had a trend to blunt acute ethanol-induced increase in NAc shell (p=0.068). In the some brain regions, baseline was near zero suggesting a long lastly effect to AIE. These findings indicate that adolescent intermittent binge ethanol has a long lastly impacts on the activation of extracellular signal-regulated kinase in nucleus accumbens shell and granular cell layer of hippocampus of adult rat brain. ERK1/2 pathways involved in AIE effect on brain functions will further be investigated. (Supported by the NADIA from NIAAA).

Title: Arrested development following adolescent alcohol intake? Investigation of risky behavior and NAcc phasic dopamine release during development

Authors: *L. KRUSE, A. SCHINDLER, K. REICHARD, J. J. CLARK;
Univ. of Washington, Seattle, WA

Abstract: Adolescence is characterized by increased sensation seeking and risk taking, often including initial experimentation with alcohol. Adolescent alcohol use is a major public health concern given that age of onset of alcohol use is one of the best predictors of development of alcohol use disorders in adults. Using a preclinical model of risky decision making, we have previously demonstrated that voluntary alcohol intake during adolescence, but not adulthood, promotes maladaptive, risky choice behavior in adulthood. These data indicate a unique vulnerability of adolescents to the long-term effects of alcohol on decision making. Using fast scan cyclic voltammetry (FSCV), we further demonstrated increased phasic dopamine release in the nucleus accumbens core (NAcc) in response to risky, but not safe, options in adults exposed to alcohol as adolescents. Consistent with this data, we recently showed that pedunculopontine tegmental nucleus (PPT), but not median forebrain bundle (MFB), stimulated dopamine release is greater in the NAcc of adults exposed to alcohol during adolescence compared to controls. We hypothesize that exposure to alcohol during this critical developmental period arrests normal brain development "locking in" an adolescent phenotype of risk taking behavior and increased phasic dopamine release that persists into adulthood. Here, we utilize *in vivo* FSCV, as well as probability discounting as a preclinical model of risky decision making, to begin to examine this hypothesis. Briefly, the probability discounting task involves a choice between a 'safe' lever that consistently delivers a low reward or a 'risky' lever that delivers a high reward at decreasing probabilities. Risky decisions are those where a large but uncertain reward is favored over a smaller certain reward of equal or expected value. Our results demonstrate that adolescent animals show a risk preference comparable to that of adult animals that voluntarily consumed alcohol during adolescence. In further support of our hypothesis, we show that PPT, but not MFB, stimulated phasic dopamine signaling in the NAcc peaks in late adolescence (PND50-55) and closely resembles PPT stimulated dopamine release in adult animals that were exposed to alcohol as adolescents. Present studies are utilizing *in vivo* FSCV in freely behaving animals to examine risky choice in late adolescence versus adulthood and associated phasic dopamine signaling to a risky decision. Together, our results provide novel insight into the long-term effects of adolescent alcohol exposure on maladaptive decision making and the underlying neurocircuitry.

Title: Voluntary ethanol consumption during adolescence enhances the sensitivity and response to nicotine within the mesolimbic dopamine system during adulthood

Authors: *Z. A. RODD, A. L. BRACKEN, G. A. DEEHAN, Jr, C. P. KNIGHT, R. A. WAIESS, W. J. MCBRIDE, R. L. BELL, S. R. HAUSER;
Indiana Univ, Sch. Med., Indianapolis, IN

Abstract: The age of onset of alcohol consumption in adolescents is associated with an increased risk of alcoholism during adulthood. The negative consequence of adolescent alcohol consumption is not specific to alcoholism, since there is a link to an increase risk of addiction to other drugs of abuse. Very little preclinical data has examined the effects of adolescent alcohol consumption on the response to other drugs of abuse during adulthood. Previous work from our laboratory has indicated that microinjection of nicotine directly into the posterior VTA stimulates dopamine (DA) release in the nucleus accumbens shell (AcbSh). The current study examined the effects of voluntary adolescent ethanol consumption on the ability of nicotine microinjected directly into the posterior VTA to stimulate (DA) release in AcbSh. Alcohol-preferring (P) male rats were allowed to consume EtOH (concurrent 15 and 30%) during post-natal day 30-60. After adolescent exposure, all rats were maintained without further treatment until at least post-natal day 90. Rats were implanted with ipsilateral guide cannulae aimed at the posterior VTA and the AcbSh. Microinjections were administered at a volume of 100 nl over a 5-sec period 3 times a minute (every 20 sec) during the first 10 min of the sample (30 microinjections total). This injection protocol mirrored self-administration for nicotine into the pVTA. Following microinjections, a minimum of 5 additional samples were collected. Rats were microinjected with aCSF, 1, 10 or 50 μM nicotine. Microinjection of 10 or 50 μM nicotine into the posterior

VTA of adolescent naïve P rats increased DA levels in the AcbSh (maximum response approximately 43 and 78%, respectively). The data indicated that lower concentrations of nicotine stimulated DA release in P rats that consumed ethanol during adolescence. In addition, the amount of DA released by 1, 10, or 50 μM nicotine microinjected into the posterior VTA was larger in the adolescent drinkers (48, 105, and 187%, respectively). The data indicate that adolescent ethanol consumptions results in a persistent alteration in the response to nicotine within the mesolimbic DA system. This cross sensitization produced by adolescent ethanol consumption could be the biological basis for the heightened rate of addiction to other drugs of abuse observed in adolescents who consume alcohol at an early age.

Title: Exposure to nicotine during adolescence increases the neurochemical response to nicotine within the mesolimbic dopamine system during adulthood.

Authors: *S. R. HAUSER[1], A. L. BRACKEN[2], C. P. KNIGHT[3], G. A. DEEHAN, Jr.[2], R. A. WAEISS[2], W. J. MCBRIDE[2], R. L. BELL[2], Z. A. RODD[2];

Abstract: There is a positive correlation between the onset of drug use during adolescence with drug dependency during adulthood. The biological basis for this alteration in risk for addiction is unknown. Therefore, determining the biological consequences of adolescent exposure to nicotine on adult responsiveness to nicotine is of particular importance. Previous work from our laboratory has indicated that nicotine treatment during adolescence increased the onset of nicotine-induced locomotor activity during adulthood. The current study examined the effects of adolescent nicotine exposure on the ability of nicotine microinjected directly into the posterior VTA to stimulate dopamine (DA) release in the nucleus accumbens shell (AcbSh). Wistar male rats were administered 0 or 0.5 mg/kg nicotine during post-natal day 30-55. After adolescent exposure, all rats were maintained without further treatment until at least post-natal day 90. Rats were implanted with ipsilateral guide cannulae aimed at the posterior VTA and the AcbSh. Microinjections were administered at a volume of 100 nl over a 5-sec period 3 times a minute (every 20 sec) during the first 10 min of the sample (30 microinjections total). This injection protocol mirrored self-administration for nicotine into the pVTA. Following microinjections, a minimum of 5 additional samples were collected. Rats were microinjected with aCSF, 100 or 200 μM nicotine. Microinjection of 100 or 200 μM nicotine into the posterior VTA of adolescent naïve Wistar rats increased DA levels in the AcbSh (maximum response approximately 55 and 62%, respectively). The neurochemical response to nicotine microinjected into the posterior VTA in Wistar rats treated with nicotine during adolescence was significantly greater (maximum response approximately 188 and 239%, respectively). In addition, the effects of nicotine microinjection into the posterior VTA were more prolonged in nicotine treated adolescent rats compared to controls (80 min compared to 40 min). The data indicate that adolescent exposure to nicotine results in a persistent alteration in the response to nicotine within the mesolimbic DA system. This increase responsiveness to, and effectiveness of, nicotine within this system may be part of the biological basis for the increase propensity for nicotine dependency during adulthood following nicotine use during adolescence.

Title: Adolescent alcohol exposure produces resistance to habit formation in adulthood

Authors: J. I. OBSORNE, J. M. BARKER, *L. CHANDLER;
Dept Neurosciences, Med. Univ. S Carolina, Charleston, SC

Abstract: Adolescence is a period of significant cortical development and refinement of neural circuits. Binge drinking patterns, which are common in adolescents, may result in aberrant remodeling of these circuits and potentially promote addiction in adulthood. Addiction is a chronic relapsing disorder characterized by inflexible drug seeking and may involve a transition from goal-directed behaviors, where drugs and alcohol are sought for their reinforcing properties, to automatic habitual behaviors. Here, we investigated how a model of binge-like alcohol exposure (intermittent ethanol exposure in adolescence; AIE) may result in dysregulation of behavioral flexibility in adulthood. To determine how adolescent alcohol exposure impacts habitual reward seeking in adulthood, male and female Long Evans rats were exposed to ethanol via vapor inhalation in the AIE paradigm. Subsequently, adult rats that had been exposed to AIE were trained to lever press for a 20% liquid sucrose reward on random interval (habit-promoting) and random ratio (action-promoting) schedules. Because habits are insensitive to changes in action-outcome contingencies, the expression of goal-directed or habitual reward seeking strategies can be assessed using contingency degradation paradigms. Contrary to our hypothesis that binge alcohol exposure during adolescence would facilitate habitual behavior in adulthood, we observed that at a time point where control adult rats exhibited habitual reward seeking on the interval (habit-promoting) lever, AIE-exposed adult rats exhibited goal-directed response strategies. Current studies are investigating c-fos induction after the expression of either goal-directed or habitual behavior in brain areas known to mediate behavioral flexibility.

Title: Sex and adolescent intermittent ethanol promote Pavlovian conditioned approach to cue, no contribution of GLT-1

Authors: A. C. MADAYAG[1], S. J. STRINGFIELD[1], K. J. REISSNER[2], B. C. RILEY[1], C. A. BOETTIGER[1], *D. L. ROBINSON[1];

Abstract: Ethanol binge drinking during adolescence has been associated with maladaptive behavior in adulthood such as disinhibition, addiction, and cognitive impairment. It is difficult to determine if people who binge drink during adolescence later exhibit behavioral deficits in adulthood due to preexisting traits, or as a consequence of adolescent ethanol consumption. Preclinical models provide the opportunity to manipulate ethanol exposure in otherwise homogeneous populations to identify ethanol's persistent neurobiological effects. We hypothesize that binge levels of adolescent intermittent ethanol (AIE) disrupt developing meso-cortico-limbic circuitry, which in turn alters reward-associated learning in adulthood. Previous studies show sex-specific differences in AIE-induced changes to basal and evoked glutamate levels in the nucleus accumbens in adulthood. Thus, we hypothesize that one mechanism by which AIE alters reward processing is via glutamate signaling in accumbens, particularly by changes in astrocytic glutamate transport. To test these hypotheses, we exposed rats to AIE then used Pavlovian conditioning in adulthood to assess reward-associated learning. Male and female rats received intermittent 5g/kg gavage ethanol or equivalent water volume from P25 to P54. Around P70, rats began Pavlovian conditioning (20 sessions, 15 trials/session). During a trial, an inactive lever extended and a cue light illuminated; this compound stimulus was the conditioned stimulus (CS). After 30 s, the CS ended and 0.1mL of 20% sucrose was delivered to the receptacle. Sign tracking (ST, CS approach behavior) has been suggested to indicate vulnerability to addictive and impulsive behavior. ST was indicated as lever presses, latency to lever press, and the probability to press the lever in a given trial; goal tracking (GT, approach to the receptacle) was indexed by reward receptacle entries, latency to enter the receptacle, and the probability to enter the receptacle in a given trial. Five days after the last session, fractionated nucleus accumbens tissue was analyzed for membrane expression of GLT-1, the astrocytic glutamate transporter. We observed main effects of both AIE and sex on adult lever presses, with female sex and AIE history both promoting lever pressing. Other ST indices were higher in females (main effects of sex), whereas metrics of GT were lower in AIE-exposed animals (main effects of AIE). However, these behavioral effects were not associated with GLT-1, as western blot analysis of GLT-1 yielded no differences among groups. Collectively, these findings show that females exhibit higher ST, whereas AIE shifted behavior from GT to ST in both sexes.

Title: Voluntary exercise prevents adolescent binge ethanol-induced loss of hippocampal neurogenesis by creating resiliency against innate immune activation

Authors: *R. P. VETRENO, C. LAWRIMORE, F. T. CREWS;
Sch. of Med., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: Adolescence is a developmental period of heightened neuroplasticity. Alcohol abuse and binge drinking are common during human adolescence. Using a rodent model of adolescent intermittent ethanol (AIE; 5.0 g/kg, i.g., 2-day on/2-day off from postnatal day [P] 25 to P55), we discovered a persistent loss of neurogenesis in the adult hippocampus that we tied to increased expression of innate immune signaling molecules. In the present study, we tested the hypothesis that voluntary wheel running (24 hr/day from P24 - P80) would prevent the AIE-induced reduction of adult hippocampal neurogenesis by blocking upregulation of innate immune signaling molecules. Voluntary exercise in the form of wheel running prevented the AIE-induced reductions of hippocampal neurogenesis (i.e., doublecortin-immunoreactive [DCX+IR] cells) and progenitor cell marker expression (Ki-67 and nestin) as well as the increase in cell death (cleaved caspase-3) in adulthood (P80). Expression of phosphorylated (activated) NF-κB p65, which is essential for NF-κB nuclear translocation and induction of proinflammatory cytokines, was upregulated in the post-mortem human alcoholic and adult AIE-treated hippocampus, an effect that was prevented by exposure to voluntary wheel running. Adolescent intermittent ethanol upregulated innate immune gene expression in the adult brain, which was prevented by voluntary wheel running exposure. Treatment with indomethacin (non-steroidal anti-inflammatory drug) prevented the AIE-induced loss of hippocampal neurogenesis, supporting a role for innate immune signaling molecules in the loss of neurogenesis following adolescent binge ethanol exposure. Together, these data reveal that exercise prevents the deleterious effects of AIE on adult hippocampal neurogenesis through an innate immune mechanism. (Supported by the NADIA of the NIAAA)

Title: The effects of the oxytocin agonist way 267464 on social behavior in adult male and female rats following adolescent intermittent ethanol exposure

Authors: *J. SAALFIELD, C. DANNENHOFFER, D. WERNER, E. VARLINSKAYA, L. SPEAR;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: We have previously demonstrated lasting, sex-specific adverse social consequences of early adolescent intermittent ethanol exposure (AIE), with male, but not female, rats exhibiting social anxiety-like alterations when tested as adults. Oxytocin (OXT) has long been implicated in social behavior, with diverse lines of evidence supporting the suggestion that OXT increases approach and decreases avoidance to social stimuli. The current study aimed to determine if administration of the selective non-peptide OXT receptor agonist WAY 267464 (WAY) restores social behavior disrupted by AIE in male rats. Same-sex group-housed (4 to a cage) male and female Sprague-Dawley rats were given 4 g/kg ethanol (25%) or water intragastrically (i.g.) every 48 hr for a total of 11 exposures during postnatal days (P) 25-45. On P70-72, animals were assessed in a modified social interaction test. Experimental animals were injected interperitoneally (i.p.) with one of the three doses of WAY (0.0, 2.5, or 5 g/kg), and were placed individually for a 30-min habituation period in a two-compartment testing apparatus with an aperture connecting the two sides. A social partner of the same age and sex was then introduced for a 10-min test period. During the test session, the behavior of the animals was recorded by a video camera for later scoring. Behaviors scored included two social behaviors that are sensitive to anxiogenic stimuli: social investigation and the coefficient of social preference/avoidance. Social investigation was defined as the sniffing of any part of the body of the partner. Social preference/avoidance was analyzed by separately measuring the number of crossovers demonstrated by the experimental subject towards as well as away from the social partner and assessed by means of a coefficient [coefficient (%)= (crossovers to the partner – crossovers away from the partner)/(total number of crosses) X 100]. Consistent with prior findings, the results revealed sex-dependent baseline effects of AIE on social anxiety, with males, but not females, demonstrating greater social anxiety-like alterations, indexed through decreases in social investigation and social preference. Importantly, this AIE-induced social anxiety was reversed by WAY267464. Experiments are also currently assessing neuropeptide and OXT receptor levels

within hypothalamic and limbic structures. Determining the efficacy of pharmacological agents such as WAY for reversing behavioral phenotypes produced by AIE will be of importance in future translational efforts designed to mitigate lasting consequences of adolescent binge-level ethanol exposures.

Title: The role of pubertal timing in the social and neural consequences of early adolescent intermittent ethanol exposure

Authors: *E. U. KIM, L. P. SPEAR;
Binghamton Univ., Binghamton, NY

Abstract: Alcohol use is typically initiated in adolescence with earlier use being a major predictor for the development of alcohol use disorders (AUDS). Studies have also reported that pubertal timing in early adolescence plays a role in the initiation and escalation of alcohol use. Our lab has previously shown that males exposed to adolescent intermittent ethanol exposure (AIE) prior to and throughout puberty (P25-45) were more socially anxious and sensitive to ethanol-induced social facilitation than males given comparable exposure later in adolescence (P45-65). Thus, early AIE could potentially elevate adult use for its anxiolytic effects or to enhance positive social experiences, changes which may be attributable to alterations in neural expression of oxytocin (OXT) and vasopressin (AVP). The goal of this study was to determine the role of pubertal timing in the development of social and neural vulnerabilities in adulthood after early AIE. Male and female Sprague-Dawley rats were intubated with 4g/kg of EtOH (25% v/v) or water (H20) every other day from P25-45. Non-intubated (NI) and non-handled (NH) groups were included to control for intubation effects and experimenter handling, respectively. EtOH, H2O, and NI rats were weighed and checked daily until P50 for indices of puberty (age of vaginal opening [VO] in females and partial or complete balano-preputial skinfold separation [BPS] in males). While no differences were seen in age of partial BPS, EtOH and H2O males completed BPS earlier than NI males. Females in the H2O group exhibited VO at a younger age

than NI females, an effect that was reversed in the EtOH group. On P70, animals were tested with social partners for changes in play fighting, social investigation, contact and preference. Brain were collected immediately after testing for determination of OXT and AVP 1a receptor mRNA (OXTR, AVP-1aR) expression in the central amygdala (ceA) and lateral septum (LS). Although no AIE-induced changes in behavior were evident, OXTR expression was increased in the ceA and LS for males and females following social testing relative to non-tested controls. AVP-1aR expression was greater in the socially than non-tested females in the ceA but lower for socially-tested males in the LS. A main effect of adolescent exposure was seen in AVP-1aR and OXTR expression in the LS for males and females, respectively, with greater expression in the NH relative to all other groups. Furthermore, individual differences in gene expression were correlated with sexual development and social test behaviors. These data suggest that the OXT/AVP system is influenced by pubertal development and associated with the expression of adult social behaviors.

Title: Binge-like alcohol exposure during adolescence disrupts dopaminergic neurotransmission in the adult prefrontal cortex.

Authors: *H. TRANTHAM-DAVIDSON[1], L. CHANDLER[2];
[1]Neurosci., [2]Med. Univ. of South Carolina, Charleston, SC

Abstract: The prefrontal cortex (PFC) is critically involved in cognitive function and inhibitory control. Adolescence represents a critical period of continued development of this region that parallels the maturation of its cognitive function. This extended period of developmental plasticity is thought to render the PFC, and its underlying circuitry, especially vulnerable to environmental insults that may result in deficits that persist well into adulthood. Alcohol drinking typically begins during adolescence when consumption of large quantities, in binge-like episodic patterns, is common. A primary function of dopamine (DA) in the PFC is to maximize

the efficient processing and transfer of information within the neurocircuitry that mediates decision-making. Dopamine innervation of the medial PFC peaks in early adolescence and then undergoes pruning and changes in DA receptor function during the transition to adulthood. These changes appear to play a critical role in the maturation of the executive function of the PFC. To determine adolescent alcohol-mediated changes in dopamine transmission, we performed whole cell patch clamp recordings in acute PFC slices from adult rats (PD90-PD110) that received five 14 hour cycles of intermittent vapor exposure to alcohol during adolescence (PD28-PD44). Recordings targeted PrL layer V pyramidal neurons labeled with a retrograde tracer to isolate specific prefrontal projections to subcortical structures (BLA, NAcc core and NAcc shell). These studies revealed that AIE exposure resulted in a loss of D1 receptor modulation of intrinsic excitability and synaptic transmission in mPFC projections to NAcc core, but had no effect on D2 or D4 receptor function in this pathway. Interestingly, treatment with the D2 agonist eticlopride during AIE exposure prevented the loss of D1 receptor function. In contrast, eticlopride treatment had no effect in the control air exposed rats. Taken together, these findings demonstrate that binge-like alcohol exposure during adolescence compromises D1 receptor function and co-administration of a D2 receptor agonist during AIE exposure can protect against these deficits and may prevent AIE induced deficits in the cognitive function of the PFC.

Title: Intrinsic connectivity of the hippocampal formation of pigeons: an *In vitro* tracing study

Authors: *N. ROOK[1], M. STACHO[1], A. SCHWARZ[1], V. P. BINGMAN[2], O. GUNTURKUN[1]; [1]Biopsychology, Ruhr-University Bochum, Bochum, Germany; [2]Dept. of Psychology, Bowling Green State Univ., Bowling Green, OH

Abstract: Pigeons have incredible navigational abilities and are able to return to their home loft when being displaced at distances over thousands of kilometers. Ablation experiments have shown that an intact hippocampus (HC) is important for this capability. Similar to mammals, birds with damage to the HC are severely impaired on a variety of spatial tasks including navigation or retention of spatial information. However, since avian and mammalian evolutionary lines have separated 300 million years ago, the organization of the avian and mammalian HC is vastly different. Information flow within the avian HC has been shown to be

rather bidirectional in contrast to the unidirectional trisynaptic pathway found in the mammalian HC. Given the similar role of the mammalian and avian HC in spatial navigation, the question arises of whether some characteristics of the avian and mammalian HC may be evolutionarily conserved.
We combined in vivo tracing with high resolution in vitro tracing in the HC of pigeons to address this issue. Using in vitro tracing, we were able to investigate the internal connectivity at a more specific level than previous studies, especially with respect to its topological organization.
We found that input to the HC is distributed to all hippocampal regions via dorsolateral subdivisions (DL; predominantly via its ventral part). Our data suggests that a dorsomedial and ventrolateral zone can be distinguished within the HC. The former might process the thalamic input in intrinsic reverbatory circuits and then transfer it to the ventrolateral zone from which the hippocampal output is generated. Moreover, we selectively targeted the medial (VM) and lateral (VL) ventral cell layers by performing in vitro injections and could show that connections arising from those two subdivisions are indeed intrinsic to the HC. This finding underpins the already proposed equivalence to the dentate gyrus of mammals. Additionally, our in vivo tracing data indicates that projections from the area corticoidea dorsolateralis (CDL) are possibly roughly topographic such that the more medial (proximal) part of CDL projects to more dorsal parts of the HC, whereas the distal part of CDL projects to more ventral parts of the HC.
Despite the large phylogenetic distance between birds and mammals, some features such as topographically organized intrinsic hippocampal connectivity are shared by those two taxa, and may be one explanation for the functional equivalence between the avian and mammalian HC in spatial navigation.

Title: Documenting brain diversity in field-caught lizards, from skull to cell: Initial development of a processing pipeline for top down, multi-scale structural analyses of a single brain by integrating specialized microcomputed tomography (diceCT), Nissl-based cytoarchitectonics, and immunohistochemistry

Authors: *D. F. HUGHES[1], P. M. GIGNAC[3], E. GREENBAUM[1], A. M. KHAN[2];

Abstract: Diffusible iodine-based contrast-enhanced computed tomography (diceCT) is an emerging tool that facilitates the non-destructive visualization of gross neuroanatomical features at levels of detail previously unattainable with traditional computed tomography approaches. In remote field conditions, we tested a protocol to prepare specimens for diceCT scans using immersion fixation and prolonged storage in fixative. We experimentally developed this protocol (field-fixation followed by diceCT) using novel field-collection procedures for a lizard model. Our field-preservation approach was found to be tractable with diceCT, allowing for the preservation and detailed visualization of bony anatomy as well as muscular, epithelial, glandular, and neural tissues (i.e., differentiating myelinated from unmyelinated structures)—all in the same individual specimen.

In this study, we integrated this validated field-based protocol for diceCT imaging within a processing pipeline that aims to examine the tissue structures of the head (bone and nervous tissues) in 3-D space and ground truth these models with more fine-scale histological analyses of cellular distribution. The process involves first imaging field-collected specimens in their native state (unstained) to reconstruct high-density tissue structures (e.g., skull), which are 3-D rendered using Avizo software. The same specimens are next stained with Lugol's iodine (I_2KI) and re-scanned to visualize soft-tissue structures such as the brain and cranial nerves. Images of stained specimens are then also 3-D rendered to produce models of soft-tissue structures within the head. Models of both the skull and brain are pseudo-colored according to region and integrated to inform the interrelationships between central and peripheral components of the nervous system and cranium. These datasets, in turn, can be analyzed to quantify and compare neuroanatomical structures among different body regions and species. Finally, brain tissue stained with Lugol's iodine can be de-stained and used for subsequent histological preparations to visualize cytoarchitectural features at the microscopic level. Our results—a pipeline for reciprocal illumination of field-fixed brains from the gross anatomical to the cellular levels—set up the potential for a comprehensive mapping of brain interconnectedness in three dimensions across spatial scales for poorly known, and in this case, unknown lizard species.

Title: Invariant microglial cell densities in mammalian brains

Authors: S. E. DOS SANTOS, L. BOTELHO, M. MEDEIROS, J. PORFIRIO, J. BRITO, *S. HERCULANO-HOUZEL;
UFRJ, Rio de Janeiro, Brazil

Abstract: Brain structure mass scales as a universal function of numbers of non-neuronal cells across mammalian species, while brain structure mass scales differently with numbers of neurons across brain structures and across primate and non-primate clades. The universality of the relationship for non-neuronal cells suggests that similar scaling rules apply to endothelial cells and individual glial cell subtypes.
Here we aim to determine if the universal scaling rule found for non-neuronal cells as a whole applies to microglial cells in particular. In that case, brain structure mass should scale universally with their numbers of microglial cells across species, and microglial cell densities should be found to remain invariant across brain structures and species, as found previously for non-neuronal cells as a whole.
Microglial cells are the resident macrophages of the brain whose actions contribute to the maturation and plasticity of neural circuits that ultimately shape behavior. Invariant microglial cell densities across brain structures and species would be consistent with their key role in the construction and modeling of brain structures.
We quantify the total number of microglial cells, their proportion to non-neuronal cells as a whole, and the ratio of microglial cells to neurons in species belonging to several mammalian clades. We used the isotropic fractionator and immunocitochemistry to anti-Iba1 and anti-NeuN antibodies to estimate numbers of microglial cells and neurons in several brain structures. We examined the brains of 28 species of mammals (10 marsupials, 5 artiodactyls, 8 primates and 5 afrotherians).
Microglial cells represent between 1% of all cells in the cerebellum and 12% in the cerebral cortex and rest of brain, at densities between 1,000 and 10,000 cells/mg. Each brain structure gains microglial cells as a similar power function of its number of neurons across species.

Importantly, all brain structures vary in mass across all species as a single power function of the number of microglial cells in the structure with a joint exponent of 0.946±0.027 ($p<0.0001$) indicating that brain structures of similar size are composed of similar numbers of microglial cells across different mammalian clades. Additionally, the ratio between microglial cells and neurons decreases universally with increasing neuronal density across structures and species. The present finding that numbers of microglial cells scale in a similar manner across the wide range of mammals studied indicates that the addition of these cells to the brain is governed by conserved developmental and evolutionary mechanisms.

Title: A new high resolution anatomical template for macaque MRI data analysis

Authors: *C. SPONHEIM[1], J. SEIDLITZ[4,2,1], F. Q. YE[3], D. A. LEOPOLD[3], L. G. UNGERLEIDER[1], A. MESSINGER[1];
[1]Lab. of Brain and Cognition, [2]Developmental Neurogenomics Unit, [3]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD; [4]Dept. of Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Although published paper atlases of the macaque brain provide accurate renderings of an individual animal, they lack the generalizability and ease of use of a multi-subject digital template based on Magnetic Resonance Imaging (MRI). The use of standardized templates (e.g., the ICBM-152 template; Mazziotta et al., 2001) is common in human neuroimaging, where it has greatly facilitated comparisons across studies. Such a template of the macaque brain could similarly benefit the non-human primate imaging community. Indeed, macaque templates generated using iterative co-registration approaches are currently available (McLaren et al., 2009; Frey et al., 2011). However, there have recently been substantial improvements in non-linear deformation-based registration methods. To make use of these approaches, we developed a new high-resolution digital template of the macaque monkey brain. The template, dubbed the NIMH Macaque Template-35 (or NMT-35 for short), reflects the morphology of 35 adult

macaques (*Macaca mulatta*) scanned at the NIMH at 4.7T. Using both AFNI (Cox, 1996) and the Advanced Normalization Tools (ANTs) package (Avants et al., 2011), the individual anatomical scans were first rigidly aligned to stereotaxic space (Saleem and Logothetis, 2006), then recursively deformed in a non-linear fashion to locally match the group average, and lastly averaged together. The result is a high contrast template that preserves and even enhances the cytoarchitectonic and morphological details common to the group. The template, paired with tissue segmentation maps and atlases of anatomical regions, provides possibilities for precise single-subject brain extraction (i.e. skull-stripping) and segmentation, as well as accurate characterizations of functional and structural MRI results. For example, functionally defined areas (i.e. face and object responsive patches) could be combined across subjects and tasks, allowing for a probabilistic mapping of various brain specializations. Other utilities include the anatomical assessment of whole-brain structural and functional connectivity, as derived from T1-weighted sequences, and resting state-fMRI, respectively. Moreover, the template is a valuable platform for detailed evaluation of anatomical and functional homologies between humans and non-human primates, and for the interpretation of human research in light of studies conducted in non-human primates.

Title: Cortical morphology can be predicted universally by a model with only three parameters: number of symmetric and assymetric cell divisions, and average neuronal cell volume

Authors: *B. MOTA, S. HERCULANO--HOUZEL;
Univ. Federal Do Rio De Janeiro, Rio de Janeiro, Brazil

Abstract: The mammalian cerebral cortex is extremely variable. Across species, grey and white matter volume (V_g and V_w), total (A_T) and exposed surface area (A_e), numbers of neurons (N_n) and neuronal density (D) vary by several orders of magnitude, and average cortical thickness (T) and folding index (F) vary by one order of magnitude.
Although it has been known for some time that these variables correlate to some extend, both universally and across phylla, only recently some strict universal relations have been found: By modelling the self-avoiding nature of the cortical surface and the plastic properties of axonal

elongation, we have proposed a model that predicts a power-law relation between A_e, A_T and T, and have verified that this relation holds true for both gyrified and lysencephalic cortices of dozens of different species [1]. Using the same data, we also verify that the overall outer shape of the cortex changes only slowly, and systematically with size. This implies a strict relation between A_e and total volume V [1]. Finally, we have also previously shown there is a universal relation between total number of neurons and glia numbers and average cell mass [2]
Cortical diversity is presumably generated in evolution as changes occur in some of the parameters that regulate those developmental processes that build the cerebral cortex. Taking these relations as a starting point, here we show that a three-parameter model predicts all major morphological features of the cerebral cortex (A_e, At, D, F, N_n, N_g, T, V_g and V_w) from variations in the number of symmetric (N_s) and asymmetric (N_a) divisions of progenitor cells in early development, and in the average volume (v_n) of neurons. Notably, we show that N_a varies much more across species than N_s, and the three parameters exhibit different relationships across mammalian orders. It is thus possible that evolutionary diversity in cortical morphology occurs simply through variations in these three parameters.

Title: Density and distribution of oxytocin and vasopressin receptors in male and female Richardson's ground squirrels

Authors: ***J. ARAUJO**[1], A. NGWENYA[1], G. PROUNIS[2], A. G. OPHIR[2], A. N. IWANIUK[1]; [1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Psychology, Cornell Univ., Ithaca, NY

Abstract: The neuropeptides oxytocin (OT) and arginine vasopressin (AVP) affect many different behaviors, especially in relation to pair bonding. The neural expression of receptors for OT (OTR) and AVP (V1aR) has been of particular interest because the density and distribution of these receptors varies among species and individuals in relation to their degree of promiscuity. Little, however, is known about whether OTR and V1aR expression is also related to non-reproductive social interactions, such as those occurring in multi-male, multi-female social systems. Richardson's ground squirrel (*Urocitellus richardsonii*) is an excellent species in which to explore the relationship between receptor expression and social behaviour unrelated to pair bonding. Unlike previously studied polygamous and monogamous rodents, this species has a polygamous mating system, but there are social bonds among females. The objective of this study is therefore to investigate the anatomical distribution of OTR and V1aR in the brains of wild female and male Richardson's ground squirrels, and test for sex differences in receptor expression. Wild ground squirrels were trapped during the breeding season (Feb-Mar), their brains flash frozen, sectioned and processed using autoradiography. Compared to previously studied species, ground squirrels have different patterns of expression for OTR and V1aR. Specifically, there was much more V1aR than OTR and frequently V1aR was found in brain regions where OTR is typically found in voles and other rodents (such as nucleus accumbens and hippocampus). We also see expression of these receptors in parts of the midbrain (superior colliculus), hindbrain (spinal trigeminal nucleus and nucleus prepositus), which have been little explored in other species. The specific relationship between some of the regions expressing OTR and V1aR and social behaviour in this species is unclear, but our results lay the foundation for testing the roles of OT and AVP in modulating social behavior in ground squirrels and beginning to explore the evolution of social and mating system diversity across squirrel species.

Title: Quantitative analysis of the distribution of neurons, glial cells and vasculature in the mouse brain.

Authors: *L. VENTURA ANTUNES[1], L. BOTELHO[1], J. MALDONADO[2], S. HERCULANO-HOUZEL[1];
[1]Federal Univ. of Rio De Janeiro, Rio De Janeiro, Brazil; [2]MBF Biosci., Williston, VT, VT

Abstract: Mammalian brains vary 100,000-fold in volume, with neuronal densities that are highly variable across brain structures and also across species. In contrast, non-neuronal cell densities are nearly invariant and shared across brain structures and species. The small variation in non-neuronal cell densities points to a universal set of rules determining how glial cells are added to brain tissue and distributed within it. Non-neuronal cells, however, comprise both glial cells and endothelial cells. It is thus possible that the shared scaling rules found for non-neuronal cells as a whole apply not to glial cells, but to the endothelium. It has been estimated that vasculature occupies no more than 4% of the cortical volume (Schuez and Palm, 1989). Finding that endothelial cells represent a similarly small proportion of all non-neuronal cells would support a conserved scaling of glial cells. Here we sought to quantify the proportions of endothelial and glial cells in different structures of the mice brain by using systematic random sampling of 3D stacks of microscopic images of tissue whose blood vessels were stained previously by venous injection of FITC-dextran. Neurons were identified by immunocytochemistry to NeuN, and all cell nuclei were visualized by staining with DAPI. Vascular fraction was determined by applying the area fraction fractionator. We find that the fractional microvascular volume is indeed small, but variable across brain structures. The relative vascular volume is highest in the gray matter of the cerebral cortex, at 2.24% of tissue volume, and lowest in the white matter, at 0.65%. Between these values we find the molecular layer of cerebellum (2.04%), the dentate gyrus of the hippocampus (1.71%), and thalamus, striatum, hypothalamus, cerebellar and hippocampal granular layers (1.3%-1.5%). In contrast, endothelial cells represent between 2.80% and 14.5% of all cells in these structures. Nevertheless, only 9.4-28.1% of non-neuronal cells are endothelial, meaning that about 80% of non-neuronal cells are glial cells. Neuronal and endothelial densities are correlated across brain sites, suggesting that local variations in neuronal density are accompanied by a corresponding variation in the density of endothelial cells, that is, by increased vascularization. Endothelial cells are thus more common than expected from the volume they occupy, which indicates that they are small cells compared to other cell types in the brain. Still, endothelial cells are uncommon enough amongst non-neuronal cells that we can safely conclude that the universal scaling rules that we have found to apply to non-neuronal cells also apply to glial cells in particular.

Title: Neurochemical compartmentalization within the pigeon basal ganglia

Authors: *L. L. BRUCE[1], J. T. ERICHSEN[2], A. J. REINER[3];
[1]Biomed. Sci., Creighton Univ., Omaha, NE; [2]Sch. of Optometry and Vision Sci., Cardiff Univ., Cardiff, United Kingdom; [3]Dept. of Anat. and Neurobio., The Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: The objectives of this study were to use multiple informative markers to define and characterize the neurochemically distinct compartments of the pigeon basal ganglia, especially striatum and accumbens. To this end, we used antibodies against 10 different neuropeptides, calcium-binding proteins or neurotransmitter-related enzymes that are enriched in the basal ganglia. Our results clarify boundaries between previously described basal ganglia subdivisions in birds, and reveal considerable novel heterogeneity within these previously described subdivisions. Sixteen regions were identified that each displayed a unique neurochemical organization. Four compartments were identified within the dorsal striatal region. The neurochemical characteristics support previous comparisons to part of the central extended amygdala, somatomotor striatum, and associational striatum of mammals, respectively. The medialmost part of the medial striatum, however, has several unique features, including prominent pallidal-like woolly fibers and thus may be a region unique to birds. Four neurochemically distinct regions were identified within the pigeon ventral striatum: the accumbens, paratubercular striatum, ventrocaudal striatum, and the ventral area of the lateral part of the medial striatum that is located adjacent to these regions. The pigeon accumbens is neurochemically similar to the mammalian rostral accumbens. The pigeon paratubercular and ventrocaudal striatal regions are similar to the mammalian accumbens shell. The ventral portions of the medial and lateral parts of the medial striatum, which are located adjacent to accumbens shell-like areas, have neurochemical characteristics as well as previously reported limbic connections that are comparable to the accumbens core. Comparisons to neurochemically identified compartments in reptiles, mammals, and amphibians indicate that, although most of

the basic compartments of the basal ganglia were highly conserved during tetrapod evolution, uniquely avian compartments may exist as well.

Title: Desert rodents have fewer neurons in their cerebral cortex: energetic constraints?

Authors: ***F. B. CUNHA**[1], D. MESSEDER[2], P. MANGER[3], S. HERCULANO-HOUZEL[2]; [1]Univ. Federal Do Rio De Janeiro, Rio De Janeiro, Brazil; [2]Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [3]Univ. of the Witwatersrand, Johannesburg, South Africa

Abstract: Rodents are by far the most diverse order of mammals representing 40% of all current mammal species with more than 2,200 species. They occupy a huge range of ecological niches, from tropical forests to deserts and tundras. Using the isotropic fractionator to determine numbers of brain neurons in 11 species of rodents, we found previously that all of these species shared the same power law relating number of cortical neurons to the mass of the cerebral cortex, except for one: the naked mole-rat (*Heterocephalus glaber*), which has half the expected number of cortical neurons.

Why is this species an exception? One hypothesis raised by our group is that the strongly hypoxic, subterranean environment of this species puts these rodents under an extreme metabolic constraint that causes a reduction in its number of cortical neurons.

To test this hypothesis, we analyzed eight other African subterranean species and six African non-subterranean species, predicting reduced numbers of neurons in the subterranean compared to non-subterranean species of similar cortical mass. We determined the number of neuronal and non-neuronal cells through the isotropic fractionator method for the cerebral cortex, cerebellum, olfactory bulb and rest of the brain.

Our results show that, contrary to what we predicted, there is no systematic reduction in the number of cortical neurons in subterranean compared to nonsubterranean rodents. There is also

no systematic difference between African and American species. Rather, the results suggest that rodents - subterranean or not - inhabiting deserts or dry savannas present a number of neurons below the expected for their cerebral cortex mass, while those that inhabit forests match the predicted neuronal composition for non-African species.
In all species examined, however, cerebellum and other brain structures have numbers of neurons that match the expected for other rodents. Because cortical neurons cost on average 20 times more than other neurons, our results suggest that rodents living in severe environmental conditions have reduced numbers of neurons in their cerebral cortex due to energetic constraints.

Title: The orientation of regional expansion in the human cerebral cortex.

Authors: *D. S. MARGULIES[1], C. DELETTRE[1], S. OLIGSCHLÄGER[1], R. TORO[2], O. COULON[3,4], G. AUZIAS[3];
[1]Max Planck Inst. For Human Cognitive and Brain Sci., Leipzig, Germany; [2]Human Genet. and Cognitive Functions, Inst. Pasteur, Paris, France; [3]Inst. de Neurosciences de la Timone, [4]Lab. des Sci. de l'Information et des Systèmes, UMR 7296, Aix Marseille Université, CNRS, Marseille, France

Abstract: Phylogenetic theories of cortical expansion hypothesize growth along specific directions. While several studies have characterized local variation in expansion across individuals as well as species, here we instead investigated the orientation of variance in cortical morphometry. To address this question, we assessed where geodesic distance between a set of individually-specified cortical landmarks covaried with overall cortical surface area.
We conducted the analysis on a subset of the 1422 datasets made available by the Brain Genomics Superstruct Project. T1-weighted MRI images were processed using the standard FreeSurfer cortical surface extraction pipeline. FreeSurfer outputs were then imported to BrainVISA 4.5 for further processing through the Mars Atlas pipeline (BrainVISA Cortical Surface Toolbox), which derives a parcellation based on latitude and longitude lines derived from individual cortical morphology. The points at the corners of parcels provide consistent individual landmarks. The shortest geodesic distance between corners of the same parcels were

then computed along the cortical surface. The group-level statistical analysis was based on the ratio of the variance explained by a model including both cortical volume and total surface area versus a model containing only volume. The f-ratio values were thresholded at p-value < 0.01, Bonferroni-corrected for the number of distance segments. The results thus indicate how each distance segment covaries with overall surface area independent of cortical volume. Distance segments were categorized by longitude and latitude orientation, as well as their location within primary/unimodal or heteromodal cortex.
Significant distance segments were generally consistent across both hemispheres and predominantly aligned with sulcal lines. The ratio of longitude- to latitude-oriented segments was 2:1; however, the primary factor accounting for this orientation was the type of underlying cortical area (primary/unimodal or transmodal), which also demonstrate orthogonal sulcal orientation. Several exceptions of significant segments traversing gyri were also present within the operculum, prefrontal, and inferior parietal cortex.
The current results suggest that cortical expansion across individuals is primarily related to variance in expansion along sulci lines, with several notable exceptions in higher-order regions. We further consider these results in relation to theories of cortical phylogeny, which suggest that trends of areal differentiation are oriented orthogonal to sulci.

Title: Figuring out why crows are smart - Area specific analysis of neuron numbers in corvid and non-corvid species

Authors: *F. STROECKENS[1], K. NEVES[2], S. HERCULANO-HOUZEL[2], O. GUNTURKUN[1];
[1]Inst. of Cognitive Neuroscience, Biopsychology, Ruhr-University Bochum, Bochum, Germany; [2]Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Over the recent years, growing evidence has been collected indicating that birds in the corvid family possess extraordinary cognitive skills matching those of non-human primates. However, little is known about how these species can achieve such impressive behaviors. It has been suggested that higher cognitive abilities in primates could be based on the total number of neurons within their telencephalon. Even though the anatomy of the avian telencephalon differs vastly from mammals, such an increase in neuron numbers could also be responsible for the advanced cognitive skills in corvids. Preliminary studies on cellular composition of bird brains have shown that neuronal densities in the whole avian telencephalon are higher than in mammals. However, it is unknown if numbers and densities of neurons are evenly distributed over the whole avian telencephalon. We assume that neuronal numbers in areas involved in higher cognitive functions (like Nido- and Mesopallium) scale to a greater extent with cognitive skills than in areas which are of lesser importance for cognition. To investigate this hypothesis, we delineated six telencephalic brain areas (Hyper-, Meso-, Nido-, and Arcopallium, Hippocampus, Striatum) in corvid (Carrion Crow, Hooded Crow, Rook) and non-corvid species (Chicken, Pigeon, Ostrich) and analyzed their cellular composition using the isotropic fractionator method. In this method, delineated brain areas were homogenized and samples were stained with DAPI to acquire total cell numbers or NeuN to obtain neuron numbers. Counts were performed using a Neubauer counting chamber and obtained numbers were used to calculate absolute numbers, cell densities, percentage of total telencephalic cells and neuron/glia ratios. Absolute cell and neuron numbers differed vastly between brain areas and species with a general correlation between size of an area and cell numbers. Overall, highest absolute cell numbers could be obtained in Hyper-, Meso- and Nidopallium of Ostriches and in Nidopallium of all corvids. In contrast, cell densities differed not that greatly between species for one area. Ostriches, however, showed massively reduced cell densities in comparison to all other species over all areas. In addition, there were slightly higher cell densities in the Meso- and Nidopallium of corvid species in comparison to non-corvid birds as well as a higher percentage of total telencephalic cells allocated to these areas in corvids. This data indicates that the cognitive abilities of corvids are at least to some extent based on higher relative cell and neuron numbers and densities in brain areas which are relevant for the execution of higher cognitive skills.

Title: A systematic relationship between intracortical myelin and functional connectivity in the human cerebral cortex

Authors: *J. M. HUNTENBURG[1], P.-L. BAZIN[2], A. GOULAS[3], D. S. MARGULIES[1];
[1]Max Planck Res. Group Neuroanatomy and Connectivity, [2]Dept. of Neurol., MPI for Human Cognitive and Brain Sci., Leipzig, Germany; [3]Inst. for Computat. Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Research in macaques suggests a systematic relationship between microarchitecture and interareal connections in the cerebral cortex, which has yet to be investigated in the human brain. Here we explore this link in the human cerebral cortex using two high-resolution MRI measures: resting state functional connectivity (FC), enabling non-invasive assessment of cortical connectivity, and quantitative T1 maps, which reflect intracortical myelin content and provide an in vivo proxy for cortical architecture.
MRI datasets of 8 subjects were acquired at 7 Tesla, comprising a T1 map (MP2RAGE, voxel=0.5mm³) and 4 resting state scans (BOLD, voxel=1.5 mm³, 300 volumes, TR=3s). After preprocessing, structural and functional data were sampled and smoothed (FWHM=3mm) on the individual's mid-cortical surface and projected onto a study-specific template. Whole brain FC was averaged across subjects and sessions. To determine the main gradients of variance in FC, nonlinear dimensionality reduction was performed using diffusion embedding, resulting in 10 components (FC 1 to 10) which are ordered by the amount of variance they explain. Each component represents a cortical map, in which similar values signify similar connectivity patterns. T1 values were sampled on 11 intracortical surfaces and averaged across subjects. To reduce partial volume effects only 5 central surfaces were averaged for intracortical T1. One or multiple FC components were used as predictors in a general linear model to fit T1.
The topography of FC 1 shows marked similarity to the distribution of intracortical T1 (Pearson's r=.56 , R^2=.31), but deviates in posterior cingulate, posterior temporal and inferior parietal cortex. A high overall fit is achieved when employing FC 1-10 to model T1 (Pearson's r=.81, R^2=.65). To rule out that every smooth cortical map can be explained by a linear combination of FC components, random, smoothed datasets were modelled in the same way as the T1 data. Even with large smoothing kernels the fit to the random data remains below that for the real T1 data.
We demonstrate a systematic relationship between intracortical T1 and FC in the human cerebral cortex. These findings are in line with extensive reports linking microarchitecture and connectivity in macaques and extend them to the human brain. It has been proposed that architectonic differentiation reflects the phylogenetic age of cortical areas. The observed relationship might thus be rooted in the simultaneous emergence of distributed areas upon a common environmental demand, resulting in a functional entity of strongly interconnected areas with comparable microarchitecture.

Title: Comparison of estimates of neuronal number in the telencephalon of day old chicks (Gallus gallus domesticus) using the isotropic fractionator method and unbiased stereology

Authors: *A. NGWENYA, J. NAHIRNEY, E. STREIBEL, A. N. IWANIUK;
Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The isotropic fractionator (IF) method is a recently developed method of cell counting that allows for the rapid quantification of neurons and non-neurons in the nervous system (Herculano-Houzel and Lent, 2005). The method relies on immunocytochemical detection of neuronal nuclear antigen (NeuN) in homogenous suspensions of mechanically dissociated nuclei to estimate the proportion of neurons (i.e. NeuN-positive nuclei) from the total cell number. Homogenisation of tissue eliminates the need for extensive sampling and neuronal number can be obtained by counting relatively few cells. One of the criticisms of the method is that neuronal number may be underestimated as a result of dissociation/homogenisation of tissue. This may occur both in cases of over-homogenisation (when a large number of nuclei are disrupted and not included in the total cell number) and under-homogenisation (where nuclei form large clusters and individual nuclei are difficult to distinguish). Validation studies have demonstrated that this is not the case; similar estimates of neuronal number were obtained using the IF method and unbiased stereology. However, IF has only been validated in 3 primate species and whether it can provide accurate estimates of neuron numbers in non-mammalian species has yet to be tested. In this study we aimed to validate the IF method in a non-mammalian species by comparing estimates of the number of NeuN immunostained neurons in the telencephalon of day old chicks (*Gallus gallus domesticus*) using the IF method and unbiased stereology. In general, we found greater variation in neuron numbers obtained using the IF method when compared with stereology. The number of neurons estimated by the IF method was also generally lower than stereological estimates but, both methods produced similar averages of neuronal number. In addition, the IF allowed for neuron quantification in the optic lobes and cerebellum where heterogeneous neuronal distribution and high neuronal density (i.e., granule cells) make stereological counts more challenging. Our results suggest that the IF is a reliable method to estimate neuron numbers in birds. Further, our estimates of neuronal number lay the foundation for future developmental and experimental studies in chicks.

Title: Comparative distributions and domains of human and mouse oligodendrocyte progenitor cells in the cortex and white matter

Authors: *J. OSÓRIO[1], K. HEFFERNAN[3], S. GOLDMAN[2,4];
[1]Univ. of Copenhagen, Kobenhavn N, Denmark; [2]Ctr. for Basic and Translational Neurosci., Univ. of Copenhagen, Copenhagen, Denmark; [4]Ctr. for Translational Neurosci., [3]Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: When transplanted to the neonatal mouse brain, human oligodendrocyte progenitor cells colonize the host, and ultimately replace the murine glial progenitor population. To assess the anatomic correlates to these events, we evaluated the morphometric characteristics of human and mouse NG2-defined oligodendrocyte progenitor cells (OPCs) in the cortex and white matter, and asked whether the size or domain distributions of OPCs differed between mice and men, and whether any such differences might be a function of the brain compartment in which the cells were resident, whether cortical grey or subcortical white matter. To this end, we used thick sections of humanized chimeric mice (N=5, males, age 59,9 ± 0.1 weeks old) and control mice (N=5) to map individual NG2-stained and confocal imaged OPCs and analyse their volume and complexity. Human OPCs are more complex than murine cells in both the cortex (271.1 ± 25.2 vs 200.0 ± 9.1 ramifications, $p<0.05$, n=12) and corpus callosum (202.2 ± 14.6 vs 152.9 ± 11.7 ramifications, $p<0.05$, n=12) and they are larger than mouse cells within the cortex (168,419.4 ± 24,632.3 vs. 73,249.0 ± 7,358.1 μm^3, $p<0.05$, n=12), although displaying similar size within the corpus callosum (86,794.9 ± 8,024.4 vs 73,249.0 ± 7,358.1; $p>0.05$, n=12). The larger domain sizes and intradomain fiber complexity of human OPCs resembles what was previously observed with human astrocytes and might contribute to the competitive advantage of human OPCs over their murine counterparts. In both the cortex and white matter, the human and mouse OPCs each exhibited a domain architecture, with their fibers displaying minimal overlap. Both human OPCs in the chimeric mouse brain and murine OPCs occupy larger domains in the cortex than cells in the corpus callosum (168,419.4 ± 24,632.3 μm^3 vs 86,794.9 ± 8,024.4 μm^3, $p<0.01$ for human cells and 97,001.7 ± 6,269.3 μm^3 vs 73,249.0 ± 7,358.1 μm^3; $p<0.05$, n=12 for mouse cells) and

also exhibited more ramifications (271.7 ± 25.2 vs 202.2 ± 14.6 ramifications, $p<0.05$ for human cells and 200.0 ± 9.1 vs 152.9 ± 11.3 ramifications; $p<0.01$, $n=12$ for mouse cells). Whether such regional differences reflect distinct properties is to be determined. Overall, we showed that human OPCs in the chimeric mouse brain are larger and more complex than murine OPCs and that both human and mouse cells in the cortex occupy larger domains and exhibit higher complexity than in the corpus callosum. The prospective identification and selection of appropriate subpopulations of OPCs may prove an important consideration in the preparation of OPCs as cellular therapeutics for the disorders of central myelin.

Title: Is there a precursor of the entorhinal cortex in reptiles?

Authors: E. DESFILIS, A. ABELLÁN, *L. MEDINA;
Univ. Lleida-IRBLleida, Lleida, Spain

Abstract: The entorhinal cortex of mammals is considered the main gateway of the hippocampal formation. Together with the latter, the entorhinal cortex is involved in memory formation and navigation. There is some consensus about the homology between the mammalian hippocampal formation and parts of the medial pallium of sauropsids, which seems to be also involved in memory and spatial navigation. In contrast, there are very few data about the homologue of the entorhinal cortex in sauropsids. In mammals, the entorhinal cortex includes two subdivisions with apparently distinct embryonic origins. Based on gene expression patterns during development, a pallial area comparable to the medial entorhinal cortex has been identified in chicken. Data in other sauropsids, as lizards, may help to understand the evolutionary origin of the entorhinal cortex. Therefore, we analyzed the expression of several developmental regulatory genes (including *Lhx2*, *Lhx9*, *Emx1* and *Tbr1*) in the embryonic telencephalon of a lacertid lizard, and compared these results with our previous data on pallial connectivity. Our results highlight a specific area of the lizard pallium, the lateral cortical superposition, having a remarkably strong expression of *Lhx9*. This area appears to be part of the lizard medial pallium, and is strongly and reciprocally connected with the hippocampal formation. Based on these data,

the lizard lateral cortical superposition resembles and may be a precursor of the medial entorhinal cortex. Sponsor: Spanish Ministry of Economy and Competitivity (MINECO) BFU2015-68537-R

Title: Functional network organization of the awake pigeon brain

Authors: ***M. BEHROOZI**, F. STROCKENS, X. HELLUY, E. GANC, O. GUNTURKUN; Psychology, Inst. of Cognitive Neurosci. , Biopsycholog, Bochum, Germany

Abstract: Despite the structural difference between the unlaminated avian brain and the laminated mammalian brain, there are striking parallels between the two species in function. Recent research on cognitive functions along with neurobiological discoveries in the avian brain demonstrated that the cognitive abilities of bird species are not inferior to mammalian species and that their brains' connectivity is functionally analogously organized. An important approach to investigate this functional analogy is the analyses of functional connectivity between forebrain sub-regions. Using resting state functional magnetic resonance imaging (rsfMRI) it is possible to analyze large-scale functional network including distinct modules. Here, we use rsfMRI along with graph theory in pigeons to identify for the first time of the avian functional connectome. MRI experiments were performed on 10 adult homing pigeons (*Columbia livia*). To assess the functional state of pigeon, resting data was acquired during 10 min. Resting state fMRI scans were performed using a RARE (Rapid Acquisition with Relaxation Enhancement) sequence to reduce the spatial distortions and signal losses due to magnetic effects of air-filled spaces inside the pigeon's skull. Functional images were preprocessed based on standard preprocessing procedures which included correction for head movement, slice time correction, temporal band-pass filtering ($0.01\ Hz < f < 0.1\ Hz$) and spatial smoothing (2 times the voxels size), regression of six parameters obtained by head movement correction, regression of whole brain signal. Functional scans were normalized to the pigeon brain atlas via individual 3D anatomical scan. Pearson correlation coefficient between pairs of averaged time courses within individual ROIs was used to form a 76×76 symmetric connectivity matrix. An average matrix across subjects was

utilized for graph definition. Computed graph characteristics of the correlation matrix were utilized for identifying subgraphs. The clustering coefficient was significantly higher than the clustering coefficient of the comparable random network. The results reveal the presence of between hemisphere correlation in visual, motor and somatosensory areas. We found the pigeon brain distinct functional network organization very similar to the ones found in mammalian brains. This similarity in functional network organization could be an explanation for the similar cognitive capacities in these two species and could represent a convergent evolution in the development of avian and mammalian complex cognition.

Title: Lateralized learning processes - Impact of commissural systems on one trial passive avoidance learning

Authors: ***A. SIMON**, R. KLOSE, O. GUNTURKUN;
Biopsychology, Ruhr-Universität Bochum, Bochum, Germany

Abstract: Cerebral lateralization is a widespread organizational principle in the whole animal kingdom. It is assumed that hemispheric asymmetries enhance the cognitive capacities. Such a task sharing makes a communication between both hemispheres indispensable. Commissural systems can provide the necessary interhemispheric cooperation and regulate information transfer.
Pigeons and chickens are classical animal models within laterality research. In spite of several neuroanatomic differences, chickens and pigeons show nearly the same distinct asymmetrical organization of their visual perception and visual driven learning processes. Additionally their commissural systems are organized in a similar manner: At telencephalic level the hippocampal and anterior commissure interconnect both hemispheres whereas the tectal and posterior commissure are located within mesencephalon.
The single exposure of a novel food, coated with a bitter-tasting substance, leads to a permanent avoidance. This one trial passive avoidance learning (PAL) is a well-established paradigm in the juvenile chickens for investigating the neuronal foundations of memory consolidation. Lesion studies reveal that this visual driven learning process is left lateralized and it is assumed that

there is an information flow from the left to the right mesopallium and then bilateral to the medial striata.
In order to examine the impact of the commissural systems on visual driven learning processes several PAL experiments with normal (monocular and binocular conditions) and commissurectomized pigeons (anterior or posterior commissure) were conducted. The results of the binocular experiments show, that pigeons are excellent passive avoidance learners. Moreover the monocular testing confirms that PAL is a left-lateralized learning process. Furthermore, the findings of the commissurectomized pigeons indicate that the posterior commissure has no effect of the ability to avoid inedible food, whereas the anterior commissure plays a key role during this learning process. That supports the "memory flow theory" and shows that the integration of this process is organized exclusively at telecephalic level. We currently plan to examine the neuronal correlates of PAL with in situ hybridisation using the IEG arc. These results confirm the regulative and stabilizing character of commissural systems in general.

Title: Relative size of the pontine nuclei in birds and its relation with their visual environment.

Authors: *A. N. IWANIUK[1], C. GUTIERREZ-IBANEZ[2], D. WYLIE[3];
[1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Lehrstuhl für Zoologie, Technische Univ. München, Freising-Weihenstephan, Germany; [3]Neurosciences and Mental Hlth. Inst., Univ. of Alberta, Edmonton, AB, Canada

Abstract: As a bird flies through an environment cluttered with numerous objects, both global and local visual motion will occur across the retina. The global motion will occur simply because any form of self-motion will induce optic flow across the retina. The local motion is the motion parallax that occurs because objects and surfaces are at different distances from the observer. Global motion is processed by the accessory optic system, which is composed of two nuclei, the

nucleus lentiformis mesencephalic (LM) and the nucleus of the basal optic root (nBOR) and local motion is processed by the optic tectum (TeO). A prime candidate for the integration of global and local motion is the pontine nuclei. The medial (PM) and lateral pontine (PL) nuclei receive projections from nBOR and LM respectively and the PL receives projections from the TeO. Additionally, both pontine nuclei receive visual information from other sources, including the ventral thalamus, hyperpallium and arcopallium. Here we use a modern comparative approach to examine the relative size of the pontine nuclei, its main visual afferents (LM, nBOR, TeO, GLv), the telencephalon and the cerebellum across a wide variety of birds (107 species, 16 orders). Additionally we analyzed variation of the relative size of the medial spiriform nucleus (Spm), which receives visual projections from the telencephalon, projects to the cerebellum and has been considered a "displaced pontine nucleus". We predicted that the relative size of the pontine nuclei, particularly the lateral pontine, will be larger in species that live in environments that require obstacle avoidance during flight. Our results show that flightless species, but not birds that live in open environments, have relatively small PL when compared to birds that live in visually cluttered environments. Additionally our results suggest that the relative size of the pontine nuclei and Spm vary with the size of visual nuclei and the cerebellum, but not with the relative size of the telencephalon. This is in contrast with mammals where the size of the pontine nuclei and cerebellum seem to be closely related to the size of the telencephalon. Our results therefore have implications for understanding some of the differences between mammalian and avian brains and the evolution of the avian brain in relation to flight.

Abstract: The neurogenesis process during development and growth gives organisms the capacity to increase its abilities and/or to renew old cells. Here we have chosen to study the dynamics of neurogenesis in a cephalopod, *Sepia officinalis*, because of its continuous growth throughout adult life and its highly centralized and hierarchical brain allowing rich behavioral repertoires comparable to those of several mammals.

To test the hypothesis of a relationship between the dynamics of brain neurogenesis and the cognitive abilities acquisition at different steps of the biological cycle, we used the isotropic fractionator and immunocitochemistry to NeuN and Nurr1 to determine how neurons numbers in the brain (N_{BR}) and the optic lobes (N_{OLs}) vary as structure mass increases in development (M_{BR} and M_{Ols}) in 58 animals between embryonic day (E)24 and adulthood (Ad), ranging in mass from 0.001g to 0.700g for M_{BR} and from 0.001g to 1.950g for M_{OLs}. For 54 animals, we also analyzed these parameters in the stellate ganglia (N_{SG}, M_{SG}), with mass increasing from 0.001g to 2.099g. We also examined the functional differentiation of neurons focusing on the dopaminergic system, which plays a key role in learning and memory processes. Additionally, we explored tissue expression of these markers by *in situ* hybridization in order to establish the cartography of their expression in the nervous system.

We find that the developing cuttlefish BR contains an average of 1,498,779±729,704 neurons at E24 and reaches an average of 20,082,662±11,044,194 at Ad, representing an increase in average N_{BR} of 13.5-fold. In the same period, N_{OLs} increases 39-fold from 2,804,026±1,620,741 to 108,425,664±24,488,997, and N_{SG} increases 186-fold, from 85,664.5±14,976 to 15,920,756±5,893,054. Ols and SG thus gain neurons faster than the BR, in relationships that can be described as $N_{BR}^{1.226}$ and $N_{BR}^{1.884}$ between E24 and Ad.

Addition of neurons to these structures is continuous between E24 and Ad, with no significant increase in N_{BR}, N_{OLs} and N_{SG} (Wilcoxon, p=0.2453). Moreover, older specimens have relatively more neurons in their BR, OLs and SG (Spearman ρ=0.809, 0.773 and 0.929, respectively; p=0.0026, 0.0053 and 0.0009). Along development, M_{BR}, M_{OLs} and M_{SG} increase with $N_{BR}^{1.426}$, $N_{OLs}^{1.351}$ and $N_{SG}^{1.430}$, that is, these structures gain mass faster than they gain cells.

We found a significant increase of the $Nurr^{+}$-cells between E24 and Ad only in the BR, from 1,008,356±1,026,108 to 7,989,907±11,074,131 (Wilcoxon, p=0.0453). These cells are localized mainly in the olfactory organs, statocysts, optic lobes and the sensory motor lobes of the BR confirming a precocious set up of the sensory system control.

Title: The canonical circuit of the avian sensory forebrain

Authors: *M. STACHO, O. GUNTURKUN;
Biopsychology, Ruhr-University Bochum, Bochum, Germany

Abstract: Up to the end of the 20th century, birds were thought to have limited cognitive abilities and their forebrain was mostly thought to be constituted by hypertrophied basal ganglia with only a minimal fraction of the forebrain recognized as pallium. These facts together with the knowledge about the basal ganglia function at that time resulted in the conclusion that birds were only capable of instinctive behavior. Nowadays, scientific evidence about the avian cognition and modern neuroanatomical studies unequivocally disproved this view and shed light on a radically different picture. Although birds do not possess a six-layered neocortex, detailed studies of the visual and auditory system in chicken uncovered columnar-like organization and canonical circuits akin to neocortical columns and canonical circuits in mammals. To confirm and further extend these results, we performed in-vitro tracing on the visual and trigeminal system as well as the somatosensory and visual hyperpallium (H) in pigeons. We found that the thalamo-recipient sensory areas Field L2 (auditory), entopallium (visual), and nucleus basalis (trigeminal) were directly interconnected with dorsal and ventral mesopallium. The intercalated nidopallium was reciprocally connected with both the primary sensory areas and the mesopallium. The nido- and mesopallium were the sources of projections to arcopallium - the output region of the avian forebrain. Interestingly, the H showed a conspicuously different organization. In contrast to nido/mesopallial areas, the H (both visual and somatosensory components) did not display such a strict columnar organization and showed strong within-layer connections. Moreover, the interstitial part of the H apicale (IHA, the thalamo-recipient layer of H) directly projected to the apical part of H (HA), the output layer of the H, and did not project to mesopallium. The intercalated part of the H (HI) was reciprocally connected to IHA, HA and to adjacent densocellular part of the H (HD). HD further projected to HA and IHA, and together with HI and HA also to the mesopallium. In turn, the mesopallium projected to all layers of H. Despite profound differences between the H and the nidopallial circuit, some similarities in the connectivity can be pointed out. The canonical pathway from IHA to HA via HI with feedback connections at each level is similar to the organization centered around the nidopallium. Thus, the avian sensory forebrain seems to be characterized by a single canonical circuit that has some

local variations. Future studies have to show how similar the avian canonical circuit is to its mammalian cortical counterpart.

Abstract: Sexual dimorphism exists at all levels of the nervous system, from genetic, anatomical, and system levels. These sex differences could underlie gender-related differences in behavior and neuropsychological function, as well as, the sex differences in the prevalence of various mental problems such as autism, attention deficit, and schizophrenia. The corpus callosum (CC) is the largest of the brain commissures, which connects the cerebral cortices of the two hemispheres, and provide interhemispharic connectivity for information transfer and processing between cortical regions. Alteration in the structure of CC will alter interhemispheric connectivity and commonly documented in several psychiatric disorders. The CC consists of myelinated and unmyelinated axons, glial cells, and blood vessels. Several functional studies have reported that CC function is associated with its axon size and density as well as their myelination properties. The sexual dimorphism in the axonal content of the CC has always been controversial, hence, the aim of this study was to analyze he ultra-structural differences of the CC between male and female rats. To assess that, five pairs of adult male and female rats were perfused and the CC was sectioned. Then four sections from different subregions of the corpus callosum that represent the genu, anterior body, posterior body, and splenium of the CC were stained and electron microscopic images were captured using stereological guidelines. Later, the total axon density and the myelinated/unmyelinated ratio was calculated for each subregion and

compared between males and females. Furthermore, the axons characteristics including axon diameter, myelin thickness and G-ratio was calculated for each subregion and compared between males and females. Our preliminary findings of the present study indicate a higher total axon density in female rats compare to males, with region specific differences in the distribution of myelinated and unmyelinated axons and their characteristics in the CC between male and female rats.

Title: Differential gene expression patterns suggest a distinct embryonic origin of the medial and lateral parts of the entorhinal cortex

Authors: *A. ABELLAN, E. DESFILIS, L. MEDINA;
Univ. of Lleida - IRBLLEIDA, Lleida, Spain

Abstract: The entorhinal cortex forms part of a functional network that is essential for navigation and memory. It includes two subdivisions: (1) a medial part related to spatial navigation and memory; and (2) a lateral part that processes non-spatial, contextual information, being critical for novel object-context recognition. While both have ample connections with the hippocampal formation, they show differences regarding their connections with the neocortex and the amygdala. For example, only the lateral entorhinal cortex has strong connections with the basal amygdalar complex. In order to understand the origin of these connectivity and functional differences, we studied in mouse and chicken the expression of a battery of transcription factors and other regulatory proteins during development, including *Lef1*, *Lhx2*, *Lhx9*, *Lmo3*, *Lmo4*, *ER81*, *Dbx1*, *Jagg1* and *Sfrp2*. The combinatorial expression of these genes allowed identification of the major pallial domains, such as medial, dorsal, lateral and ventral pallia. During early development of mouse, the anlage of the medial entorhinal cortex showed a gene expression profile (*Lef1*, *Lhx2*, *Lhx9*, *Lmo4*) very similar to that of the hippocampal primordium. Based on this and their adjacent topological location on the medial side of the telencephalic vesicles, we suggest that both structures originate in the medial pallium. In contrast, the lateral

entorhinal cortex showed a gene expression profile different from that of the medial pallium, but also from the ventral, lateral and dorsal pallium. The distinct embryonic origins of medial and lateral parts of the entorhinal cortex are likely behind their different developmental trajectories and connectivity patterns. Comparison with the expression of the orthologous genes in chicken in combination with other data suggested the existence of an area comparable to the medial entorhinal cortex. However, our data did not allow identification of the lateral entorhinal cortex in chicken. MINECO Grant BFU2015-68537-R.

Title: Anterior to posterior distribution of neurons across the cerebral cortex of infant macaques

Authors: ***M. GABI**, E. C. TURNER, D. J. MILLER, J. H. KAAS;
Psychology Dept., Vanderbilt Univ., Nashville, TN

Abstract: During brain development, the cerebral cortex is under striking changes including prenatal neurogenesis, sudden death of most of neurons in the first postnatal week, followed by an increase in neuronal number. However, not all brains are built in the same way. For instance, neuronal proportions of rodents and primates brains do not scale universally with structure size and little research has evidenced how these differences arise during development, specifically across the functional areas of the cerebral cortex.
In this study, we initiate a systematic comparison of the anterior-posterior distribution of neurons and other cells along the surface of the cerebral cortex of infant macaque monkeys, aiming to determine the pattern in which the cells are allocated in the different areas of the cortex during early stages of postnatal development. An anterior-posterior gradient of neuron densities has been described in various species of adult primates, but how this will be comparable when most of the cortical neurons are being generated, and considerable cortical growth will yet occur is still a question.
One cortical hemisphere of three infant *Macaca mulatta* of different ages (stillborn, 4 days old and 11 days old) was embedded in agar and sliced into a series of 2mm thick coronal sections. The grey matter of each section was separated from the underlying white matter and weighed. To

determine the total number of neuronal and other cells in the grey matter we applied the isotropic fractionator.
The cerebral cortex of the three macaques exhibits a heterogeneous distribution of neuronal densities, which increased systematically 4-fold along the anterior-posterior axis. This distribution shows a single neuronal gradient across the different areas, with the lowest densities in the frontal regions and the highest towards the posterior area. The distribution of other cells density shows a 5-fold variation along the anterior-posterior axis. In contrast, the glia/neuron (g/n) ratio varies over 2-fold among cortical regions in all ages, but does not show a simple gradient distribution. The g/n ratio varies as a negative power function of neuronal density, decreasing as neuronal density increases, exactly as found in previous data for adult primates. This suggests that the number of glial cells per neuron in each section increases with the increasing average size of neurons.
Overall, the results are similar to those reported for adult macaques, and support that an adult-like pattern of neuron distribution and total number of neurons exists in postnatal macaques from the time of birth. A more detailed analysis could reveal additional features of the pattern of neuronal distribution.

Title: Molecular imaging of multitasking processes in the pigeon (Columba livia)

Authors: *S. LETZNER[1], O. GUNTURKUN[1], C. BESTE[2];
[1]Ruhr-University Bochum Inst. For Cognitive Neurosci., Bochum, Germany;
[2]Universitaetsklinikum, Dresden, Germany

Abstract: Multitasking is a common psychological phenomenon. Every day people switch from one task to another in response to changes in the environment. Thereby an executive goal (GO1) is induced, stopped (STOP) and replaced by a second executive goal (GO2). To what extent the single executive components in this process are processed serial or parallel and which brain areas are activated during the different components is still unknown. A well-established paradigm in humans to analyze multitasking processes is the stop change paradigm, in which the response for a primary GO1 goal had to be stopped and replaced by a response for a secondary GO2 goal. Thus this paradigm allows the analysis of the three cognitive goals involved in the multitasking

process: GO1 goal, STOP goal and GO2 goal. We adopted this paradigm to pigeons to analyze on behavioral level to what extent a serial or parallel information processing is existent. Additionally, different to humans the pigeon model gives us the opportunity to analyze the anatomical correlates which are activated during a stop change paradigm by molecular imaging. In our task each trial was initialized by pecking on a pecking key at the left panel of a conditioning chamber directly followed by the presentation of a green GO1 stimulus on the front panel. Pecking on the GO1 stimulus results in a food reward. On some trials a STOP signal (red house light) is shown. The delay between the GO1 and the STOP signal is adjusted that in 50% the reaction to GO1 can be executed and in the other 50% the reaction to GO1 is inhibited and a white stop change stimulus (GO2) is presented on a further pecking key. To differentiate the essential processes GO1, STOP and GO2 we used three groups of pigeons. The first group only performed the GO1 trials and served as control group for the neuronal activation. For the separation of STOP and GO2 processes a second experimental group performed GO1 and STOP but no GO2 of the paradigm, while a third experimental group performed the whole paradigm. When the pigeons successfully performed the paradigm they were directly decapitated after the session and the brains fixated for immunohistochemical staining of the molecular activity marker ZENK. Like this, we are able to directly compare behavioral results across different species, namely pigeons and humans, and study underlying brain function in a detailed manner that would not be possible in humans.

Title: Volumes of claustrums are not directly proportional to volumes of forebrains across the mammalian radiation

Authors: *J. I. JOHNSON[1], B. A. FENSKE[2], H. YORK[3];
[1]RADIOLOGY: ANATOMY, Michigan State Univ. Dept. of Radiology, East Lansing, MI; [2]Michigan State Univ., East Lansing, MI; [3]Neurosci. Associates, Inc., Knoxville, TN

Abstract: In the brains of mammals, most of the connections of the claustrum are with the forebrain. To investigate whether the sizes of claustrums reflect a consistent relationship with the sizes of the connected forebrains, we computed volumes of claustrums and volumes of their connected forebrains in representative species from most mammalian orders. We used digital

three-dimensional reconstruction programs to render volumes of claustrums and forebrains from the areas of claustrums and forebrains measured in regular series of sections through these structures observed in tissue sections stained with the Nissl method.
We found no consistent relationship of sizes of claustrums and forebrains, meaning that individual taxa have developed more or less unique size relationships between these brain components. For example, grizzly bears *Ursus arctos)* and domestic pigs *(Sus scrofa)* exhibit extraordinarily large claustrums for their size of forebrain, while colugoes *(Cynocephalus volans)*, and mongoose lemurs *(Eulemur mongoz)* have smaller claustrums than would be predicted from the sizes of their forebrains.
A larger than expected claustrum is often associated with the development of a large "puddle" of claustral tissue. This suggests that regional intraclaustral specializations related to neurobehavioral specializations have arisen in certain species.

Title: Semantic categories in the pigeon's nidopallium frontolaterale: a reverse engineering approach

Authors: *R. PUSCH[1], C. KOENEN[2], A. AZIZI[3], J. KELLERMANN[4], F. BROKER[2], S. THIELE[2], S. CHENG[3], O. GUNTURKUN[2];

Abstract: Pigeons are well known for their ability to categorize objects but the neuronal mechanisms guiding this behavior remain poorly understood. So, how do pigeons see the world? And how do they cope with all the varieties of visual objects they are confronted with in their avian environment? In the present study we are interested in the central representation of different objects addressing one key question: Are neuronal mechanisms of visual object representation comparable across different classes of vertebrates ranging from avian species to human and hon-human primates?
Addressing this question we recorded single neurons in the pigeon's nidopallium frontolaterale (NFL), a higher visual area and the putative analog to the inferior temporal (IT) cortex of primates. During our experiments we presented different sets of stimuli to freely moving and

behaving pigeons while recording single cell activity from the NFL. Instead of training pigeons on predefined categories, we simply presented stimuli and analyzed the neural output. Resulting categories were built post-hoc based on computations of the neuronal pattern elicited by each stimulus. We used basic visual stimuli, i.e. simple forms in different colors as well as gratings varying in their spatial frequencies and contrasts. Additionally, we showed pictures of real-world objects representing different categories. Kriegeskorte et al. (2008) presented these pictures of real-world objects to humans and monkeys and revealed an activity pattern in IT in line with semantic categories. Moreover, category clusters where highly similar between man and monkey, recorded with fMRI and single cell recording, respectively. With our approach we investigate the neural basis of perceptual discrimination in the NFL of pigeons. Based on our results we compare to what extend neuronal mechanisms of object categorization are shared by these different classes of vertebrates.

Title: The neural circuit underlying extinction learning in pigeons - evidence from pharmacological studies

Authors: *M. GAO[1], D. LENGERSDORF[1], M. C. STUTTGEN[2], O. GUNTURKUN[1]; [1]AE Biopsychology, Ruhr-University Bochum, Bochum, Germany; [2]Inst. of Pathophysiology, Univ. Med. Ctr. Mainz, Mainz, Germany

Abstract: Extinction learning is an essential learning mechanism that enables constant adaptation to the ever changing environmental conditions. The underlying neural circuit was mostly studied with rodent models using fear conditioning tasks. In order to uncover the variant and the invariant neural properties of extinction learning, we adopted pigeons as an animal model in an appetitive sign-tracking paradigm. The animals firstly learned to respond to two stimuli in two different contexts (CS-1 in context A and CS-2 in context B) and then extinguished their conditioned responses to the corresponding stimulus in the opposite contexts (CS-1 in context B and CS-2 in context A). Finally, they were tested for both stimuli in both

contexts. Before the extinction training, we locally injected the sodium-channel blocker tetrodotoxin (TTX) or the N-methyl-D-aspartate receptor (NMDAR) antagonist 2-Amino-5-phospho-novalerianacid (APV) in specific areas to investigate their involvement in the extinction learning process. With this within-subject renewal design, we discovered that the extinction learning does not only engage the neural circuit of the nidopallium caudolaterale (NCL; the avian equivalent structure to the mammalian PFC), hippocampus, and amygdala, but also involves arcopallium, the avian motoric area, and the nidopallium frontolaterale (NFL), one of the avian higher visual-processing areas. Importantly, our findings suggested that the encoding of extinction memory requires the activation of NCL, amygdala, and NFL: the learning process during extinction was slowed down after drug injection before the extinction training. While the consolidation process involves NCL, hippocampus and arcopallium which can be observed from an unaffected learning dynamic in extinction training after injection but an elevated spontaneous recovery during testing.

Title: Metabolic changes in the bilateral visual cortex of monocular blindness macaque monkeys: a multi-voxel proton magnetic resonance spectroscopy study

Authors: ***Z. TANG**, L. WU;
radiology, Eye & ENT Hosp. of Fudan Univ., Shanghai, China

Abstract: PURPOSE
To study adaptive plasticity and reorganization in the visual cortex of the monocular blind macaque using multi-voxel proton magnetic resonance spectroscopy study (^{1}H-MRS).
METHOD AND MATERIALS
Four healthy neonatal macaques were randomly divided into 2 groups. One group served as control group (group A). Optic nerve transecting was performed in the right eye of the other group (group B), to establish the monocular blind model. Sixteen (group B^{16M}) and thirty-two (group B^{32M}) months after monocular optic nerve transecting, multi-voxel 1H-MRS was performed on the bilateral visual cortex of all monkeys, respectively. We compared NAA/Cr, Ins/Cr, Cho/Cr and Glx/Cr in the visual cortex between group A and group B as well as between

the left and right visual cortices of group A and B in each time points, respectively. All of the metabolic changes detecting by multi-voxel ^{1}H-MRS were further compared with the immunofluorescent staining findings.
RESULTS
Compared with group A, in bilateral visual cortex, NAA/Cr in both group B^{16M} and group B^{32M}, as well as Glx/Cr in group B^{32M} were all significant decrease ($p<0.05$), whereas the Cho/Cr and Ins/Cr of group B^{32M} were significant increase ($p<0.05$). Meanwhile, significant difference of NAA/Cr in group B^{32M} was found between the left and right visual cortex, whereas no statistical difference of Ins/Cr, Cho/Cr and Glx/Cr between the left and right visual cortex was found in both group B^{16M} and group B^{32M}. All of these ^{1}H-MRS findings (with the exception of group B^{16M}) were further confirmed by the immunofluorescent staining.
CONCLUSION
Multi-voxel ^{1}H-MRS was able to detect the different metabolic changes in the visual cortex, which was valuable for investigating its adaptive plasticity and reorganization.

Title: Domestication affects Purkinje cell size and foliation in the cerebellar cortex in laboratory rats (Rattus norvegicus)

Authors: ***L. WILLIAMS**[1], T. SALIK[1], R. STRYJEK[2], K. MODLINSKA[2], W. PISULA[2], S. M. PELLIS[1], A. N. IWANIUK[1];
[1]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Inst. of Psychology, Polish Acad. of Sci., Warsaw, Poland

Abstract: Domestication is the process by which wild organisms are adapted for human use. Over time, isolated populations raised in captivity begin to phenotypically diverge from their wild counterparts in both morphology and behaviour. The lab rat, an important model organism in scientific research, is the result of domestication of the wild Norway rat *(Rattus norvegicus)*. Similar to other domesticated animals, lab rats have relatively smaller brains compared to wild rats. In addition, lab rats exhibit less spontaneous motor behaviour and acrobatic play than their

wild counterparts. Such variation in motor behavior likely reflects underlying changes in regions that coordinate and regulate motor activity, such as the cerebellum. Although the "ecological niche" of a domesticated lifestyle produces changes in brain size, the effects of domestication on the cerebellum are not well understood. Here, we compared the cerebella of female wild-caught Norway and Long-Evans rats to assess the effect of domestication on cerebellar folding (foliation), cerebellar volume, the number of Purkinje cells, and Purkinje soma size. Sagittal sections were stained for Nissl substance and quantified with unbiased stereology. Our analyses indicate that lab and wild rats have similar cerebellar volumes, but wild rats had a significantly higher degree of folding in the cerebellar cortex. Wild rats also had significantly larger Purkinje neurons compared to domestic rats, but there was no clear effect on the number of Purkinje neurons. These results suggest that the cerebellum of laboratory rats has indeed undergone anatomical changes in response to domestication. Further, our results suggest that the reduction in cerebellar folding observed in lab rats was driven by a decrease in soma size, but not a decrease in the number of neurons. One implication of having a more foliated cerebellum with larger cells is that wild rats presumably retain a greater capacity to process and modulate muscular activity compared to laboratory rats. Similarly, those motor functions governed by the cerebellum may be less ecologically relevant in a domestic setting than in the wild. This knowledge will help to improve our understanding of how domestication affects brain morphology and the putative role of the cerebellum in modulating play behavior.

Title: Three-dimensional brain atlas of pygmy squid, Idiosepius paradoxus

Authors: ***N. TANAKA**[1], M. KOIZUMI[1], S. SHIGENO[2];
[1]Hokkaido Univ., Sapporo, Japan; [2]JAMSTEC, Yokosuka, Japan

Abstract: Cephalopods have very unique behaviors, for example camouflage and also show some intelligent behaviors such as observational learning. Although these behaviors have fascinated many biologists, the brain functions underlying these behaviors still remain unclear.

To understand the mechanisms, we have started to analyze the brain circuit of pygmy squids, *Idiosepius paradoxus*, as a model, because it has the small-size brain among cephalopods and because it can be raised easily in still sea water. In addition, this smallest species has similar behaviors such as camouflage as observed in other squids. By immunolabeling the central brain with anti-*Drosophila* SYNAPSIN and anti-*Tetrahymena* TUBULIN antibodies, we three-dimensionally reconstructed the whole brain and analyzed the pathways between lobes. We could identify one new lobe in the brain and also revealed that as has been reported on the other cephalopod species, in *I. paradoxus* the juvenile brain is much (more than 35 times) bigger than the hatchling one and the relative size of the vertical lobe, which is concerned with learning and memory of visual and tactile tasks, is four times bigger in the juvenile than in the hatchling. We are currently developing neurotracing and calcium imaging techniques to visualize the sensory maps in a live squid.

Abstract: The purpose of this research it to investigate whether the frogs already have melanocytes and chromophores, if melanocytes become chromophores and to find where the chromophores are coming from. Frog embryos at different stages of development were collected. Some of the embryos were injected with DiI, while others were left as is. The embryos were stained with the antibody HNK1 as a marker to see if the chromophores were present at each stage in development. Different technique are being used to obtain a clear idea of the embryos

anatomy and to be able to see if the cells are present. We have used whole mount of the embryos, vibratome sections and we are currently working on paraffin sections. Upon examination, unique cells were seen, but we have yet to determine that these cells are chromophores. Funding was by NIH/NINDS AREA grant 2R15NS060099-02A1 to MEdB and a BUILD/PODER scholarship to DP.

Authors: E. M. REMBETSKI[1], T. M. MCCARTHY[2], *A. K. PACK[3];
[1]Neurosci., [2]Biol., [3]Utica Col., Utica, NY

Abstract: Freshwater snails use vision, but it is not clear in all species when their eyes/retinas form. We observed movement in the freshwater snail *Physa acuta* (N=9) before hatching (i.e., still in the egg mass) 2-5 days after the eggs were laid. *P. acuta* moved more while exposed to light in the egg than dark-exposed controls (Chi-square test, $X^2 = 38.025$, $p < 0.001$). This was not a response to temperature, warm water did not increase activity (Wilcoxon, $p = 0.317$). Unhatched snails, therefore, are already sensitive to light. This has implications for behavior and light pollution studies.

Title: Of mice and pigeons-a comparative view of adult neurogenesis in two different animal models

Authors: *J. MEHLHORN[1], I. MASSON[1], K. AMUNTS[2,3], C. HEROLD[2];
[1]Inst. of Anat. I, Univ. of Düsseldorf, Duesseldorf, Germany; [2]C. & O. Vogt Inst. of Brain Research, Univ. of Düsseldorf, Düsseldorf, Germany; [3]Inst. of Neurosci. and Med. INM-1, Res. Ctr. Jülich, Jülich, Germany

Abstract: Adult neurogenesis is a dynamic process that includes the generation and proliferation of neurons in the brain over lifespan and across species. While in mammals particularly the dentate gyrus (DG) and the olfactory bulb (OB) integrate newborn neurons into functional circuits, in birds it is known that adult neurogenesis occurs in several telecenephalic structures. Further, birds seem to have a higher number of immature neurons indicating a wider range in plasticity and possible recovery mechanisms. Here we show differences and similarities of adult neurogenesis in C57BL/6 mice (*Mus musculus*) that were housed in cages with enriched environment and free flying homing pigeons (*Columba livia* f.d.). Both groups were treated with 5-bromo-deoxyuridine (BrdU) to label dividing cells and sacrificed about three months after injection. Brains were dissected and immunohistochemically processed to a) examine cell proliferation with Nestin, SOX2 and doublecortin (DCX), b) show newly generated neurons or glia, visualized by NeuN/BrdU or S100/BrdU double labelling and c) get information about apoptosis, with TUNEL detection. In pigeons, BrdU-positive (BrdU-ir) and DCX-positive (DCX-ir) neurons were widely distributed in the telencephalon, with the highest numbers in the ventricular zone, in the ventrolateral part of the V-complex and the dorsolateral region of the hippocampal formation, along the mesopallial lamina, the superior and supreme frontal lamina, the caudolateral and central nidopallium, the olfactory bulb and the striatum. Thereby, the number of DCX-ir cells was much higher compared to BrdU-ir cells and comparable to markers of early stages of progenitors like Nestin-ir cells. No signs of increased apoptosis were observed. In mice the highest numbers of newborn neurons were detected in the subgranular zone of DG and in the OB. A few BrdU/NeuN-ir cells were also observed all over the cortex. Most DCX-ir neurons were detected in the ventricular zone, the subgranular zone of DG, the OB, and lower numbers in CA3, CA2 and the ventral striatum. A few DCX-ir cells were also counted along the alveus and the corpus callosum. TUNEL-labelling showed no signs of increased apoptosis. Our findings suggest that species-specific or even class-specific differences in anatomy, behaviour, ecological niche etc. may have a larger influence on brain plasticity as assumed and that it would be interesting to investigate the functional consequences of adult neurogenesis into more detail. Besides, our findings may introduce the pigeon as a new model organism in comparison to humans, because both species show newborn neurons during adulthood in the striatum.

Title: Cerebral white matter development in rhesus macaque during the early postnatal phase as measured via diffusion MRI

Authors: *J. YOUNG[1], Y. SHI[1], C. COE[2], R. KNICKMEYER[1], M. STYNER[1];
[1]Univ. of North Carolina At Chapel Hill, Chapel Hill, NC; [2]Univ. of Wisconsin-Madison, Madison, WI

Abstract: Diffusion tensor imaging provides a unique way for researchers to capture the microstructure of white matter tracts throughout the brain and examine developmental trajectories. Additionally, the rhesus macaque (*Macaca mulatta*) is one of the most commonly used nonhuman primates for translational investigations, and provides a unique opportunity to study normal brain maturation, especially in early infancy, where crucial information about formative developmental trajectories is still missing in young children. Here, we have created a detailed longitudinal diffusion tensor atlas, along with characterizing the corresponding white matter fiber tracts in the rhesus macaque at 0.5 to 36 months of age from the UNC-Wisconsin Neurodevelopment Rhesus Macaque Database. We employed the UNC NA-MIC DTI Analysis Framework: to: 1) build the subject specific longitudinal atlases, 2) combine these atlases into a single population atlas space, 3) propagate prior white matter tracts from a high resolution atlas, and 4) extract fiber bundle profile measurements. Our results show that the macaque white matter tracts continue to change throughout this maturational period at varying rates with a spatially varying pattern from birth to puberty. Examples of this variation include the inter-hemispheric tracts of the corpus callosum, which show a much larger rate of change as compared to other tracts. All data and atlases, both raw and processed, are being disseminated publically to serve as a resource for the neuroimaging and neurodevelopmental communities.

Title: The molecular evolution of plasticity and the human hippocampus.

Authors: *B. M. SCHILDER[1], B. J. BRADLEY[2], C. C. SHERWOOD[2];
[2]Ctr. for the Advanced Study of Human Paleobiology, [1]George Washington Univ., Washington, DC

Abstract: The hippocampus is a neuroanatomical structure critical for long-term memory and spatial navigation. The human hippocampus has evolved in terms of both relative volume expansion and changes in gene expression compared to nonhuman primates (NHPs). However, little is known regarding how the constituent subfields of the hippocampus have been modified in the human lineage. We analyzed microarray data from the Allen Brain Atlas to compare the expression of four candidate genes important for plasticity and adult neurogenesis (doublecortin [*DCX*], brain-derived neurotrophic factor [*BDNF*], glial fibrillary acidic protein [*GFAP*], and ephrin-B1 [*EPHB1*]) across the hippocampal subfields of humans and rhesus macaques. While gene expression did not always differ between species at the level of whole-hippocampus (i.e. DCX; $p > 0.05$), analyses of the individual subfields revealed many interspecies gene expression differences for all four candidate genes ($p \leq 0.05$).
Furthermore, we explored whether these gene expression differences could be attributed to evolutionary changes in the protein-coding DNA sequences of these candidate genes. Aligned orthologous sequences of 12 primates and 3 non-primates were downloaded from the UCSC Table Browser, filtered to exclude regions of questionable homology using Block Mapping & Gathering with Entropy (BMGE), and tested five different substitution models of positive selection detection using the HyPhy packages on the Datamonkey server (i.e. *Mixed Effects Model of Evolution*, *Fixed Effects Likelihood*, *Genetic Algorithm with branching*, *Branch-site Real Estimated Likelihood*, and *Adaptive Branch-Site Random Effects Likelihood)*. The only genes that showed any evidence of positive selection ($p \leq 0.05$) were *DCX* (S36N in the *Pan troglodytes* branch) and *GFAP* (G149A in the branch leading to the *Homo-Pan-Gorilla* clade, and G149T in the *Tupaia chinensis* branch). However, when the effects of these substitutions were modeled using PolyPhen2 and SNAP2 they were predicted to have no functional effect on the protein. In sum, while the pattern of gene expression of these key plasticity-regulating genes across the hippocampal subfields has evolved since the divergence of humans and macaques, this does not appear to be related to changes in protein-coding sequences of those genes. Future work should explore the evolution of regulatory-region sequence evolution as a potential source of these differences.

Abstract: The importance of the endocannabinoid signaling during vertebrate development of the central nervous system (CNS) has been extensively hypothesized but scarce studies have been published. The endocannabinoid signaling is mediated through the cannabinoid receptors 1 and 2 (CB1 and CB2). Knockout (KO) mice have been generated for the *cnr1* and *cnr2* genes that encode for the CB1 and CB2, respectively. Homozygote cnr1-/- and cnr2-/- animals are viable, arguing against a critical role for either of the genes in the overall nervous system development. However, more subtle thalamocortical axon misrouting and aberrant fasciculation have been found in CB1 KO mice but nothing has been documented in CB2 with regards of brain development. We hypothesize that CB2 plays a role in modulating the endocannabinoid signaling and therefore, plays important roles during early brain development.
We used CRISPR-Cas9 target-genome editing to generate *cnr2* KO zebrafish. We raised homozygotes carrying 2nucleotide deletion ($cnr2^{\Delta 2-/-}$) which is generating a frame-shift and an early stop codon. We will assess how the levels of the cnr2 gene products are affected. The predictions are that only non-functional truncated CB2 probably unstable will be made. We are currently testing an anti-CB2 specific antibody in whole-mount and in westernblot to validate the loss of function allele. Next, we will monitor neuronal wiring and axonal fasciculation formation through immunohistochemistry with a numbers of axonal markers in different developmental

stages of zebrafish embryos and larvae. In particular, we will focus in the diencephalon, telencephalon, hindbrain, and midbrain since CB2 has been reported to be expressed in those regions during embryonic stages of mice. This will allow us to highlight possible morphological changes caused by the absence of a functional CB2 receptor.

Title: Ancient origin and conservation of a bilateral map in the mammalian cortex

Authors: *R. SUAREZ[1], A. PAOLINO[1], L. MORCOM[1], P. KOZULIN[1], L. R. FENLON[1], N. KURNIAWAN[2], L. J. RICHARDS[1,3];
[1]Queensland Brain Inst., [2]Ctr. for Advanced Imaging, [3]Sch. of Biomed. Sci., The Univ. of Queensland, Brisbane, Australia

Abstract: Bilateral integration between the cerebral cortices is crucial for sensorimotor, associative and cognitive functions. In placental mammals this is achieved by axons forming the corpus callosum. Development of callosal circuits involves a *Satb2*$^{+}$*/Ctip2*$^{-}$ genetic program, an axonal arrangement based on the position of cell bodies within the cortex, and co-existence of mirror-image, homotopic connections with heterotopic and hyper-connected bilateral circuits. Whether these features are mechanistically related to the development and evolution of the corpus callosum in early placentals, or instead represent traces of an older bilateral map in the common mammalian ancestors remains unknown. Here we show that the main molecular, developmental and connectivity features of bilateral cortical circuits were already present in mammals before the evolution of the corpus callosum. We found that cortical connections through the anterior commissure of monotremes and marsupials share a callosal-like topography, whereby axons connecting main cortical regions cross the midline through spatially segregated subdomains. These axons arise from *Satb2*$^{+}$*/Ctip2*$^{-}$ cortical neurons in marsupial pouch-young,

and establish a bilateral map that includes homotopic and heterotopic connections, as well as hyperconnected hubs at the medial (cingulate) and temporal (claustro-insula) margins of the neocortex. Thus, our results suggest an ancient origin and conservation of a bilateral cortical map in the mammalian brain, predating the origin of the corpus callosum by at least 40 million years. The conservation of a connectivity map despite significant alterations in the route taken by axons suggest that evolution of the corpus callosum likely involved key but subtle innovations, possibly including exaptation of pre-existing mechanisms not primarily involved in circuit formation.

Title: The unusual structure and function of the African naked mole rat endocannabinoid system

Authors: ***B. M. BROWE**[1], E. KEIMPEMA[2], T. HARKANY[2], J. LARSON[1], T. J. PARK[1]; [1]Biol. Sciences- Neurobio., Univ. of Illinois At Chicago, Chicago, IL; [2]Med. Univ. of Vienna, Vienna, Austria

Abstract: The endocannabinoid system is a major regulator of synaptic transmission in many brain areas and cannabinoid receptors are the most highly expressed GPCRs in the mammalian brain. Pharmacological manipulation of the endocannabinoid system has shown promise in medical treatments of many diseases including epilepsy, cancer, Alzheimer's, and hypoxic injury. However, there are still many mechanisms of the endocannabinoid system that are yet unknown, in part because the widespread, subtle nature of this regulatory system makes parsing out individual aspects difficult. We examined the endocannabinoid system of the African Naked Mole-Rat (NMR), a long-living mammal (lifespans reaching >30 years) with high resistance to many of these previously stated diseases including: cancer, dementia, and hypoxia. Here, we show that the developmental regulation of endogenous cannabinoid ligands (endocannabinoids) and cannabinoid receptors is very different in NMRs compared to typical laboratory rodents (mice). In mice, cannabinoid receptor expression decreases in early postnatal development and

endocannabinoid levels increase with maturation while in NMRs the pattern of change is opposite to this. Furthermore, this change in expression is correlated with a profound age-dependent change in the behavioral response to synthetic cannabinoids (WIN55) in NMRs. Up to 9 months old, NMRs show a dose-dependent decrease in locomotion, as seen in other laboratory mammals. However, after 1 year of age, NMRs no longer respond to WIN55. The NMR's age-related differential expression of endocannabinoids and cannabinoid receptors and changes in behavioral sensitivity to exogenous ligands has potential to clarify the mechanisms by which cannabinoids affect behavior by providing alternative phenotypes to manipulate. In addition, species-specific alterations in the endocannabinoid system may participate in the resilience of NMRs to hypoxic brain damage and cancer, and help to explain their extraordinary longevity. These results encourage further exploration of the endocannabinoid system's link to neuroprotection and longevity.

Title: Prosomeric interpretation of the developing hypothalamus in Xenopus laevis

Authors: *A. GONZALEZ[1], R. MORONA[2], J. M. LÓPEZ[2], N. MORENO[2];
[2]Cell Biol., [1]Univ. Complutense Madrid, Madrid, Spain

Abstract: Most studies in mammals and birds have demonstrated common patterns of hypothalamic development highlighted by the combination of developmental regulatory genes (genoarchitecture), supporting the notion of the hypothalamus as a component of the secondary prosencephalon, topologically rostral to the diencephalon, and consisting of alar and basal parts. In our comparative analysis we have summarized the data on the expression patterns of different transcription factors and neuroactive substances, used as anatomical markers, in the developing hypothalamus of the amphibian *Xenopus laevis*. This analysis served to highlight the organization of the hypothalamus in the of anamniote/amniotic transition. We have identified paraventricular (Pa; dorsal) and the subparaventricular (SPa; ventral) regions in the alar part of the hypothalamus, and tuberal (Tu; dorsorostral) and mamillary (M; ventrocaudal) regions in the

basal hypothalamus. Main distinct features are: 1) The Pa region is defined by the expression of Otp and the lack of Nkx2.1/Isl1. It is subdivided into rostral, rich in Otp and Nkx2.2, and caudal, only Otp-positive, portions. 2) The SPa area contains catecholaminergic cell groups and lacks Otp, and can be further divided into rostral (rich in Nkx2.1 and Nkx2.2) and a caudal (rich in Isl1 and devoid of Nkx2.1) portions. 3) Expression of Nkx2.1 and Isl1 define the Tu hypothalamus and only the rostral portion expresses Otp. 4) Its caudal boundary is evident by the lack of Isl1 in the adjacent M region, which expresses Nkx2.1 and Otp. In summary, the genoarchitecture of the hypothalamus observed in *Xenopus* shows major common features with amniotes.

Abstract: The posterior cingulate cortex is characterized by widespread functional connectivity and early activation in the emergence of conscious states. Similar widespread connectivity is also a feature of the claustrum, which has been hypothesized to play a role in modulation of consciousness. Here we examine the topography of claustrum connections to the posterior cingulate region of the common marmoset (*Callithrix jacchus*) using microinjections of neuroanatomical tracers. Nine injections in four animals were performed under general anaesthesia in accordance with a protocol approved by the Monash Animal Research Ethics Committee. Cell counts, topographic organization, and 3-D reconstructions of the claustrum

were obtained following fluorescent tracer injections into A23b, A23V, PGM, and 19M. All areas received strong claustrum input, especially from the dorsal claustrum. Topographic organization was evident in the A23b connections, with more caudal injections yielding denser label in the caudal-most claustrum sections. Posterior cingulate areas obtain negligible input from the insular cortex, which may interpretation of activation patterns in imaging studies. The pattern of claustrum connections partially overlapped the portion of the claustrum that we have previously demonstrated to project to medial prefrontal areas. The location and connectional strength of claustrum projections to the posterior cingulate cortex is consistent with a role for the claustrum in modulation of resting state functional networks.

Brain Mapping by Integrated Neurotechnologies for Disease Studies (Brain/MINDS) from AMED

Title: A grayordinate pipeline for magnetic resonance imaging of marmoset brain

Authors: ***T. HAYASHI**[1], M. GLASSER[2], C. YOKOYAMA[1], T. OSE[1], C. TAKEDA[1], A. KAWASAKI[1], J. AUTIO[1], D. VAN ESSEN[2];
[1]RIKEN Ctr. For Life Sci. Technologies, Kobe, Japan; [2]Washington Univ. in St Louis, St Louis, MO

Abstract: There is increasing interest in using marmosets for animal studies in neuroscience. Several technologies such as neural tracing and genetic manipulation are recently available for this species, however, non-invasive imaging technique is not well established, nor are analyses

standardized across species. Here, we introduce a preprocessing pipeline for marmoset MRI data adapted from that for the Human Connectome Project (HCP). In six anesthetized marmosets, we obtained T1 weighted and T2 weighted MRI images (spatial resolution of 0.35 x 0.35 x 0.35 mm^3) of the brain using a 3T MRI scanner (MAGNETOME PRISMA, Siemens Healthcare, Erlangen, Germany) and a custom-made 16-channel array coil (Takashima Seisakusho KK, Hino, Japan). The images were corrected for bias field, brain extracted, non-linearly registered to a standard atlas space, segmented into gray (cortical and subcortical) and white matter areas based on supervised classification, and then estimated for cortical surface boundaries. Cortical surface was co-registered across subjects based on the folding pattern. Estimated surface was minimally inflated to allow the visualization of sulcal area of cortical folding. The data was embedded in the standardized grayordinates of 164k or 32k, where metric data can be evaluated either at vertices of cortical surface or at voxels of subcortical structures (basal ganglia, thalamus, brainstem and cerebellum). Of note, some of the animals showed variant cortical folding pattern in the lateral fissure (corresponding to the Sylvian fissure in human) despite scarce gyral formation in this species. The cortical surface myelin contrast, as assessed by T1w/T2w, was high in the visual, sensorimotor, auditory, and MT areas, similar to that in human, chimpanzee and macaque using the HCP pipeline (Glasser et al. 2013). The current findings support the idea that cross-species homology exits at least in the cortical myelin distribution of marmoset brain. Future work should extend this technique to analyze other modalities such as resting-state functional and diffusion MRI, potentially useful for investigating marmoset connectome and its association with genetic, molecular, or histological aspects.

Title: *In vivo* cortical dopamine D2 receptor binding in human, macaques and marmosets

Authors: *C. YOKOYAMA, J. AUTIO, T. OSE, A. KAWASAKI, C. TAKEDA, K. TAKAHASHI, A. IGESAKA, H. DOI, T. HAYASHI;
RIKEN Ctr. For Life Sci. Technologies (CLST), Kobe, Japan

Abstract: Cortical dopamine function is of particular interest for investigating higher cognitive processing in humans and non-human primates. Dopamine D2 receptor has been widely measured in vivo by positron emission tomography (PET) with ^{11}C-raclopride, however, assessment of the cortical binding has been limited by insufficient accuracy largely caused by partial volume (PV) effect and low spatial resolution of the detector. Here, we visualize PV-corrected, cortical binding potential (BP) of ^{11}C-raclopride in three primate species, enabled by high-resolution magnetic resonance (MR) images. A PET scan with ^{11}C-raclopride as well as T1- and T2-weighted MR images were obtained in humans (n=4), rhesus macaques (n=4) and common marmosets (n=6). Animals were scanned under generalized isoflurane anesthesia, and humans under consciousness. We used a PET scanner for human (Biograph-16, Siemens, Germany) and that for animals (microPET220, Siemens, Germany), and a 3T MR scanner for all species (MAGNETOM Prisma, Siemens, Germany). MR and PET images were processed using the Human Connectome Project (HCP) pipeline, and PV-correction of radioactivity was performed with a region-based voxel-wise method (Thomas et al., 2011) using Freesurfer. The BP of ^{11}C-raclopride was calculated with a simplified reference tissue model (Gunn et al., 1997), and mapped onto the inflated cortical surface. Cross-species cortical mapping of ^{11}C-raclopride BP revealed a similar pattern of distribution, i.e., high in the insular, middle temporal and anterior cingulate cortices and low in the visual cortex. The distribution was consistent with previous postmortem studies in humans and macaques. Humans tend to have highly variable binding around the perisylvian areas as compared with monkeys, potentially associated with evolution of language abilities. Our findings suggest that cortical ^{11}C-raclopride binding can be assessed quantitatively and used for investigation of cognitive function in primates despite limited availability of cortical D2 receptors.

Title: Neural Crest Derived Chromatophores in Red-Eyed Tree Frogs

Authors: *P. SANGUANVICHAIKUL[1], M. E. DE BELLARD[2], M. LUEVANOS[2], M. REYES[2];
[1]biology, California State Unversity Northridge, Panorama City, CA; [2]biology, CSUN, northridge, CA

Abstract: The Red-eye Tree Frog has striking skin colors that allow it to select mates. Skin coloration comes from neural crest stem cells that give rise to melanocytes and chromatophores. Although chromatophores had been studied in other organisms like chameleons and fish, their location and phenotype has not been studied in these green tree frogs. The purpose of this study is to develop skin histology methods and identify neural crest derived cells in the Red-eye Tree Frog. For this, we used immunofluorescence and standard hematoxylin to label different skin cells. Thus, we were able to identify poison and mucous glans as well as chromatophores in the skin of adult frogs. We are beginning to collect similar samples from pre-metamorphosized tadpoles. We plan to continue mapping the histology during the different stages of development. By doing so, we can follow the development of melanocytes and chromatophores to determine which of these cells are derived from neural crest cells like those of other organisms. Funding was by NIH/NINDS AREA grant 1R15-NS060099-02 to MEdB and a BUILD/PODER scholarship to PS.

Title: Oxytocin (OT) and arginine-vasopressin (AVP) cell bodies and fibers in the social behavior neural network in rhesus macaque, chimpanzee, and human brains

Authors: *C. ROGERS[1,4,6], A. P. ROSS[7,6], J. DOOYEMA[5,6], M. A. CREE[5,6], S. P. SAHU[4,6], E. SIEGEL[4,6], E. G. STOPA[8,6], J. K. RILLING[1,2,3,6,4], H. E. ALBERS[7,6], T. M. PREUSS[5,9,6,3]; [1]Anthrop., [2]Psychiatry and Behavioral Sci., [3]Ctr. for Translational Social Neurosci., Emory Univ., Atlanta, GA; [5]Div. of Neuropharm. and Neurodegenerative Dis., [4]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [6]Ctr. for Behavioral Neurosci., [7]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [8]Pathology (Neuropathology) and Neurosurg., The Warren Alpert Med. School, Brown Univ., Providence, RI; [9]Pathology and Lab. Med., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: The neuropeptides OT and AVP are strongly implicated in the regulation of social behavior in mammalian species. While oxytocin- and vasopressin-producing cells are consistently located in the hypothalamus across species, less is known about variation in the distribution of extra-hypothalamic cell bodies and processes. Moreover, the anatomical distribution of these neuropeptides in great apes, such as chimpanzees, the animals most closely related to humans, has not been studied to date. We used immunohistochemistry to identify cell bodies and fibers containing OT and AVP within the social behavioral neural network in fixed, postmortem tissue from humans (n= 3), chimpanzees (n=3), and rhesus macaques (n=3). All three species showed labeling for OT and AVP cell bodies in the hypothalamus. Rhesus macaques showed a wider distribution of labeling for AVP than chimpanzees or humans, with cell bodies distributed throughout the caudate and putamen as well as fibers in the lateral septum and periaqueductal gray of the midbrain. Across the three species, labeling for OT cell bodies was more restricted, being mainly localized to the hypothalamus. Our results suggest that primates differ from many rodent species (e.g., mice, rats, and voles), which have prominent AVP-containing cell bodies in the medial amygdala and bed nucleus of the stria terminalis that send dense fiber projections to several forebrain areas. Our results also suggest that the distribution of AVP cell bodies and fibers may have been reduced over the course of evolution in great apes and humans.

Med. and Genet., Wayne State Univ. Sch. of Med., Detroit, MI

Abstract: The compartmentalization and association of lactate dehydrogenase (LDH) with specific cellular structures (e.g., synaptosomal, sarcoplasmic, or mitochondrial) may play an important role in brain energy metabolism. Our previous research revealed that LDH in the synaptosomal fraction shifted towards the aerobic isoforms, LDH-B, among the large-brained haplorhine primates compared to strepsirrhines. Here, we further analyzed the subcellular localization of LDH in primate forebrain structures using quantitative Western blotting and ELISA. We show that in cytosolic and mitochondrial subfractions from haplorhines**,** LDH-B expression level was elevated and LDH-A declined compared to strepsirrhines. LDH-B expression in mitochondrial fractions of the neocortex was preferentially increased, showing a particularly significant rise in the ratio of LDH-B to LDH-A in apes. We also found a significant correlation between the protein levels of LDH-B in mitochondrial fractions from haplorhine neocortex and the synaptosomal-associated LDH-B that suggests LDH isoforms shift from a predominance of A-subunits toward B-subunits as part of a system that spatially buffers dynamic energy requirements of brain cells. Our results indicate that there is differential subcellular compartmentalization of LDH isoenzymes that evolved among different primate lineages to meet the energy requirements in neocortical and striatal cells.

Title: Cerebrovascular beta-dystroglycan in vertebrates: its immunonegativity in anurans and advanced teleostei

Authors: D. LORINCZ[1], V. JANCSIK[2], E. OSZWALD[1], O. SEBőK[1], *M. KALMAN[3]; [1]Semmelweis University, Dept. of Anatomy, Histology and Embryology, Budapest, Hungary; [2]Szent István University, Fac. of Vet. Sci., Budapest, Hungary; [3]Semmelweis Univ., Budapest, Hungary

Abstract: Dystroglycan has pivotal function in the gliovascular connections. Its transmembrane beta subunit forms a complex of receptors and ion channels and connects them to the cytoskeleton. It's alpha subunit anchors this complex to the basal lamina. In the mammalian and avian brains the beta-dystroglycan immunopositivity (bDG+) delineates the vessels, although dystroglycan is localized in the vascular astroglial end-feet. Our former investigations proved the cerebrovascular bDG+ in Chondrichthyes (Kálmán and Ari, 2010, 6th European Congress of Comparative Neuroanatomy, Valencia, Spain). Further studies failed to detect bDG+ along the cerebral vessels in teleost fishes (less advanced ones: e.g. catfish, *Ameiurus nebulosus*, goldfish, *Carassius auratus*; and most advanced ones: e.g. cichlid perch *Amatitlania nigrofasciata*) as well as in frogs, e.g *Pelophylax ridibundusxlessonae* (formerly *R. esculenta*) (Sebők and Kálmán, 2010, 7th Europ. Congr. of Comp. Neuroanatomy, Budapest). Our recent investigations has extended on urodeles: *Ambystoma mexicanum, Pleruodeles waltly* and reptiles (turtle, *Trachemys scripta,* lizards, e.g. *Eublepharis macularis* and snakes*,* e.g. *Python regius).* some ancient-type fishes were also examined: a lungfish (*Protopterus annectens,* Dipnoi), an early representative of the tetrapoda clad; bicirrh (*Polypterus senegalensis,* Cladistia)*,* one of the closest extant relatives of the stock-actinopterygians; sterlet (*Acipenser ruthenus*, Chondrostei) and butterfly fish (*Pantodon buchholzi* Osteoglossiformes), one of the most ancient types of Teleostei. Animals were obtained from breeders, anaesthetized, then transcardially perfused with buffered 4% paraformaldehyde. Serial transversal sections were cut by vibratome from agarose embedded brains, and immunohistochemical reactions were performed with anti-bDG (monoclonal, Novocastra), according to both immunoperoxidase and immunofluorescent protocols. As positive and negative controls rat and primer-serum free medium were applied. Results obtained until now refers to that in each species bDG+ delineates the vessels. Pre-embedding immunoelectronmicroscopy on *Heterodontus japonicus* shark brains demonstrated that bDG is localized in the perivascular glial end-feet in Elasmobranchii despite the divergent construction of their blood-brain barrier. It refers to that bDG- is an apomorphic, secondary phenomenon

emerged separately in anurans and in teleosts. Western blot probes however, demonstrated the bDG even in the brains of frogs and teleosts. It may be due to the non-perivascular dystroglycan dissipated throughout the brain.

Abstract: Evolution of the human brain shows pronounced changes in gene expression patterns, which may underlie some of the differences in behavior and cognition with our closest living relatives, the chimpanzees. To further characterize the interspecific differences in gene expression, we examined expression patterns of neurotrophin genes in human and chimpanzee brains. Neurotrophins are growth factors that promote survival, differentiation, and myelination of neurons during development. Using qPCR, we assessed differences in expression of *NGF* (nerve growth factor) and *BDNF* (brain-derived neurotrophic factor) in frontal, temporal, and cerebellar cortices of humans and chimpanzees. *NGF* expression was elevated in temporal lobe compared to frontal lobe in humans, but showed decreased expression in temporal lobe relative to frontal lobe in chimpanzees. *BDNF* expression showed similar patterns in all cortices in both species.

Title: Analysis of construction mechanism of medaka telencephalon by post-hatch neurogenesis.

Authors: *Y. ISOE[1], T. OKUYAMA[1], Y. SUEHIRO[1], K. NARUSE[2], M. KINOSHITA[3], Y. KAMEI[2], S. NONAKA[2], A. SHIMIZU[4], T. KUBO[1], H. TAKEUCHI[5];

Abstract: In vertebrates, the basic brain neural networks are defined during embryonic development. The brain growth spurt occurs postnatally, accompanied by the rapid increases in cell number and brain volume. It remains unknown, however, how postnatal (post-hatch) neurogenesis contributes to the organization of neural network required for social behaviors. To address this subject, I focused on medaka fish (*Oryzias latipes*), which is a model animal for molecular genetics and show prominent post-hatch brain growth and behavioral development. First, I examined transgenic medaka fish in which post-hatch neurogenesis can be genetically modified and used the transgenic line (*HuC*:loxP-*DsRed*-loxP-*GFP*) that *HuC* promoter drives specifically in newborn neural progenitors in the adult brain. Further when stochastic recombination was induced by micro-injection of Cre mRNA into the Tg embryos at the 1 cell stage, it resulted that visualization of clonally-related cells in compartmented regions in the telencephalon in the adult medaka brain. Also, heat induction of transgenic embryo (*HSP*:*Cre*) led to Cre-recombination in the nervous system. Interestingly, by using this both lines (*HSP:Cre* and *HuC*:loxP-*DsRed*-loxP-*GFP*), heat induction can induce different Cre-recombination pattern depending on the developmental stages when heat induction was performed. As a result of systematic analysis of stochastic recombinated samples, I identified that the telencephalon of adult brain was constituted by almost 40 clonal units and that the traditional anatomical regions were constituted by a few clonal units. In addition, the morphological pattern of clonal units was different between dorsal and ventral anatomical regions. In order to investigate the molecular

mechanism of the structural difference, I performed ATAC-seq and RNA-seq and examined the gene expression regulation specific to dorsal or ventral telencephalon.

Abstract: While the laminar (radial) organization of the cortex is similar across mammalian species, increased cell production during development and an enormous tangential expansion of cortical surface area accompanied the transformation of smooth cerebral cortex to the highly folded primate cortex. Based on our previous studies of cortical development in non-mammalian species (reptiles, birds), mammalian species with lissencephalic cortex (rodents), and mammalian species with gyrencephalic cortex (ferret, macaque, human), we hypothesized that a two-step pattern of neurogenesis played an important role in the expansion of the cerebral cortex. However, we still lack an appropriate comparative animal model of species that are closely related - evolved within the same family. For this reason many questions on cortical development and evolution remain unanswered, and our hypotheses lack sufficient predictive power. To address this problem we are introducing a new animal model for studies of brain evolution. We are using, for the first time, the developing bat brain as a tool to understand the evolution of developmental programs that guide formation of the cerebral cortex in mammals. Our novel data regarding the developing cerebral cortex of bats allowed us to identify mechanisms that contribute to gyri formation and drive tangential expansion of the cerebral cortex.

Abstract: Despite extensive investigations of the neocortex in the domestic cat, little is known about neuronal morphology in larger felids. To this end, the present study characterized and quantified the somatodendritic morphology of neocortical neurons in prefrontal, motor, and visual cortices of the Siberian tiger (*Panthera tigris altaica*) and clouded leopard (*Neofelis nebulosa*). After neurons were stained with a modified Golgi technique ($N = 194$), dendritic branching and spine distributions were analyzed using computer-assisted morphometry. Qualitatively, aspiny and spiny neurons in both species appeared morphologically similar to those observed in the domestic cat. Although the morphology of spiny neurons was diverse, with the presence of extraverted, inverted, horizontal, and multi-apical pyramidal neurons, the most common variant was the typical pyramidal neuron. Gigantopyramidal neurons in the motor

cortex were extremely large, confirming Brodmann's (1909) observation of large somata for these neurons in carnivores in general, and felids in particular. Quantitatively, a MARSplines analysis of dendritic measures differentiated typical pyramidal neurons between the Siberian tiger and the clouded leopard with 93% accuracy. In general, the dendrites of typical pyramidal neurons were more complex in the tiger than in the leopards. Moreover, dendritic measures in tiger pyramidal neurons were disproportionally large relative to body/brain size insofar as they were nearly as extensive as those observed in much larger mammals (e.g., African elephant). Comparison of neuronal morphology in a more diverse collection of larger felids may elucidate the comparative context for the relatively large size of the pyramidal neurons observed in the present study.

Title: The connectional architecture of the mouse, cat, rat and macaque cortex in the light of the theory of the dual origin of the cortex.

Authors: *A. GOULAS[1], G. BEZGIN[2], C. C. HILGETAG[1,3];
[1]UKE/Institute For Computat. Neurosci., Hamburg, Germany; [2]McConnell Brain Imaging Centre, MNI, McGill Univ., Montreal, QC, Canada; [3]Dept. of Hlth. Sciences, Boston Univ., Boston, MA

Abstract: Understanding the organization of the cortex requires uncovering the fundamental principles pertaining to its different levels of architecture including the macroscale connectional architecture. One such principle postulates that the cortex of reptiles and mammals has a dual origin with cortical areas originating from two different primordial formations: the piriform cortex (paleocortex) and the hippocampus (archicortex). The dual origin of cortical areas has

been inferred from the observation that cortical areas constitute streams of stepwise myelo- and/or cytoarchitectonic changes from these primordial formations. Such studies on brains of monotremata, marsupials, reptiles, human and non-human primates can be traced back at least to the first decades of the last century (Shellshear, 1929; Dart, 1934; Abbie, 1940; Abbie, 1942; Sanides, 1962). Importantly, the duality of the cortex is also reflected in the organization of the cortico-cortical connections of the macaque monkey (Pandya and Yeterian, 1985). The dual connectional architecture of the cortex was conceptualized and quantified as the presence of topologically symmetric structures (Bezgin et al, 2014). Here, we applied this definition and approach to all available mammalian connectomes: the macaque monkey (Markov et al, 2014), cat (Scannel et al, 1995), mouse (Oh et al, 2014; Zingg et al, 2014) and rat (Bota and Swanson, 2007). First, we investigated the presence of a dual connectional architecture in the aforementioned species. Second, we exploited the detailed transcriptional data for the mouse cortex (Lein et al, 2007) and investigated if the dual architecture defined on a connectional basis is also reflected on its transcriptional architecture. Our results demonstrate the presence of the dual connectional structure in all examined mammalian species, setting apart areas presumably derived from the piriform cortex (insula, gustatory cortex) and the hippocampus (retrosplenial, cingulate cortex). We also show that the connectivity-based dual structure in the mouse constitutes a major axis of organization of its transcriptome reflecting 12% of its variance. We conclude that the dual structure of the adult cortex constitutes a fundamental principle of its organization, possibly reflecting histogenetic gradients and patterning centers during telencephalic development.

Title: Functional test of PCDHB11, the most human-specific neuronal surface protein

Authors: *G. B. DE FREITAS, R. A. GONCALVES, M. D. GRALLE;
Federal Univ. of Rio De Janeiro, Rio DE Janeiro, Brazil

Abstract: Background
Brain-expressed proteins that have undergone functional change during human evolution may contribute to human cognitive capacities, and may also leave us vulnerable to specifically human diseases, such as schizophrenia, autism or Alzheimer's disease. In order to search systematically for those proteins that have changed the most during human evolution and that might contribute to brain function and pathology, all proteins with orthologs in chimpanzee, orangutan and rhesus macaque and annotated as being expressed on the surface of cells in the human central nervous system were ordered by the number of human-specific amino acid differences that are fixed in modern populations.
Results
PCDHB11, a beta-protocadherin homologous to murine cell adhesion proteins, stood out with 12 substitutions and maintained its lead after normalizing for protein size and applying weights for amino acid exchange probabilities. Human PCDHB11 was found to cause homophilic cell adhesion, but at lower levels than shown for other clustered protocadherins. Homophilic adhesion caused by a PCDHB11 with reversion of human-specific changes was as low as for modern human PCDHB11; while neither human nor reverted PCDHB11 adhered to controls, they did adhere to each other. A loss of function in PCDHB11 is unlikely because intra-human variability did not increase relative to the other human beta-protocadherins.
Conclusions
The brain-expressed protein with the highest number of human-specific substitutions is PCDHB11. In spite of its fast evolution and low intra-human variability, cell-based tests on the only proposed function for PCDHB11 did not indicate a functional change.

Title: Calcium imaging in Hydra

Authors: ***C. DUPRE**, S. SALWI, S. LEONG, R. YUSTE;
Columbia Univ., New York, NY

Abstract: To tackle the function of neural circuits it would be ideal to record the activity of every neuron in a behaving animal and understand how it relates to behavior. We have achieved this with the cnidarian Hydra vulgaris. Yet using genetically engineered animals and calcium imaging to measure the activity of essentially all of its neurons in behaving animals. While the nervous system of Hydra is traditionally described as a simple nerve net, we surprisingly find instead a series of independent neural networks that are anatomically non-overlapping and are associated with specific behaviors. Three major functional networks extend through the entire animal and are activated selectively during contractions, elongations in response to light and egestion. These results demonstrate the functional sophistication of apparently simple nerve nets, and the potential of Hydra and other basal metazoans as a model system for neural circuit studies.

Title: Evidence for generative homology of cerebellum and cerebellum-like structures in a basal vertebrate

Authors: *C. SURIANO, D. BODZNICK;
Biol. Dept., Wesleyan Univ., Middletown, CT

Abstract: Most of the neurons located in the mammalian brain reside within the cerebellum. Yet, the evolutionary origins of the cerebellum are not well understood. There are several different sensory nuclei present across vertebrates collectively termed cerebellum-like structures due to a shared anatomy and physiology with the cerebellum. Common structure and function may arise due to a shared genetic toolkit used during development to create a common geno-architecture. We have studied three critical genes from the proposed toolkit; *Pax6*, *Clbn1*, and *Grid2* to link these areas in a generatively homologous relationship. Within the mammalian cerebellum *Pax6* is critical for polarizing granule cell axons to form the molecular layer. *Clbn1* is used to form granule cell-principal cell synapses. *Grid2* is used to form synapses via the extra-cellular N-terminus and used in AMPAR endocytosis creating cerebellar LTD via the intra-cellular C-terminus. In order to determine if cerebellum and cerebellum-like structures are generatively homologous we tested whether these three critical proteins are expressed in the cerebellum and cerebellum-like structures of a basal vertebrate, *Leucoraja erinacea*. We found that granule cells of the cerebellum and granule cells of the dorsal granular ridge that supply the cerebellum-like structures both express *Pax6* and *Clbn1*. If *Pax6* and *Clbn1* perform the same function in the skate cerebellum and cerebellum-like structures as they do in the mammalian cerebellum, then these structures may develop using a shared genetic toolkit. We also found dendrites in the cerebellar molecular layer as well as dendrites in the molecular layer of cerebellum-like structures expressing *Grid2*. In addition to measuring protein expression in the skate cerebellum and cerebellum-like structures, protein sequence data from several vertebrates was used to compare the evolution of these genes to their prescribed function during the genesis of the cerebellum from the rhombic lip early in vertebrate phylogeny. While *Pax6* and *Clbn1* are well conserved throughout the species tested, *Grid2* has undergone major changes correlated with two whole rounds of genome duplication and the advent of the cerebellum in the gnathostomes. Within the gnathostomes there appears to be a stable elongation of the *Grid2* N terminus and C terminus allowing for more extra-cellular and intra-cellular protein-protein interactions thus allowing increased synaptic complexity in these regions. Before the genesis of the cerebellum, in the lamprey lineage, *Grid2* appears truncated, missing several key protein domains.

Abstract: The regulatory significance of epigenetic modifications is increasingly appreciated. However, the ways in which epigenetic modifications change and impact phenotypes in evolution remain as a fundamental yet unresolved question in biology. In particular, previous studies suggested that epigenetic evolution of human brains has deeply impacted human cognition and neuropsychiatric diseases. However, to fully understand the role of epigenetic divergence on human brain evolution, it is critical to examine epigenetic variation in a large panel of individuals, and to employ unbiased epigenome-wide methods and include outgroup species. Here we report comprehensive identification and analyses of differentially methylated regions (DMRs) in human brains. We used comparative whole genome bisulfite sequencing (WGBS) of human, chimpanzee and rhesus macaque prefrontal cortices (n=8), unbiased non-parametric tests, as well as targeted deep genomic and bisulfite sequencing in an independent panel of 37 individuals across six primate species. Our comparative approach identified hundreds of DMRs. We demonstrate, using a subset of DMRs, that the unique epigenetic profiles of the human brain are indeed supported in a large number of samples across multiple species. Intriguingly, evolutionary epigenetic modifications preferentially occur at genomic regions related to transcriptional regulation, as evidenced by chromatin features and transcription factor binding profiles. In particular, we identify many loci annotated as intergenic yet exhibiting conspicuous chromatin signatures of active transcription in brains, indicating that they represent currently unannotated loci of human brain-specific transcription. Remarkably, a large number of DMRs are found in a spatially clustered manner and tend to participate in active chromatin loops, indicating evolutionary remodeling at the higher-order chromatin structure. Analyses of previously generated gene expression and epigenetic data also support a role of DMRs in

regulation of transcription. Substantial reprogramming of the epigenomic landscape at regulatory regions appears to contribute to the evolutionary specializations in our brains.

Title: Neuronal and astrocytic monoacylglycerol lipase limit the spread of endocannabinoid signaling in the cerebellum

Authors: ***Y. CHEN**[1,2], X. LIU[1], C. R. VICKSTROM[1], M. J. LIU[1], L. ZHAO[2], A. VIADER[3], B. F. CRAVATT[3], Q.-S. LIU[1];
[1]Med. Col. of Wisconsin, Milwaukee, WI; [2]Beijing Sport Univ., Beijing, China; [3]The Scripps Res. Inst., La Jolla, CA

Abstract: Endocannabinoids are diffusible lipophilic molecules that may spread to neighboring synapses. Monoacylglycerol lipase (MAGL) is the principal enzyme that degrades the endocannabinoid 2-arachidonoylglycerol (2-AG). Using knockout mice in which MAGL is deleted globally or selectively in neurons and astrocytes, we investigated the extent to which neuronal and astrocytic MAGL limit the spread of 2-AG-mediated retrograde synaptic depression in cerebellar slices. A brief tetanic stimulation of parallel fibers in the molecular layer induced synaptically evoked suppression of excitation (SSE) in Purkinje cells, and both neuronal and astrocytic MAGL contribute to the termination of this form of endocannabinoid-mediated synaptic depression. The spread of SSE among Purkinje cells occurred only after global knockout of MAGL or pharmacological blockade of either MAGL or glutamate uptake, but no spread was detected following neuron- or astrocyte-specific deletion of MAGL. The spread of endocannabinoid signaling was also influenced by the spatial pattern of synaptic stimulation as it did not occur at spatially dispersed parallel fiber synapses induced by stimulating the granular layer. The tetanic stimulation of parallel fibers did not induce endocannabinoid-mediated synaptic suppression in Golgi cells even after disruption of MAGL and glutamate uptake,

suggesting that heightened release of 2-AG by Purkinje cells does not spread the retrograde signal to parallel fibers that innervate Golgi cells. These results suggest that both neuronal and astrocytic MAGL limit the spatial diffusion of 2-AG and confer synapse-specificity of endocannabinoid signaling.

Title: NO/cGMP signaling via Guanylyl Cyclase isoform 1 (NO-GC1) modulates presynaptic transmitter release in somatosensory cortex of mice.

Authors: Q. WANG[1], *S. C. THAL[1], E. MERGIA[2], D. KOESLING[2], T. MITTMANN[1]; [1]Johannes Gutenberg-University, Mainz, Germany; [2]Inst. für Pharmakologie und Toxikologie, Medizinische Fakultät MA N1, Ruhr-Universität Bochum, Bochum, Germany

Abstract: Synapse function is critical for sensory perception, cognition and memory in mammalian brains and these functions can be modulated by several factors. In this context, it is well known that NO can generate cGMP via two isoforms of the NO-sensitive guanylyl cyclases (NO-GCs) (NO-GC1 and NO-GC2) to regulate downstream proteins, thereby altering synaptic transmission and long-term synaptic plasticity. For example, NO is well known to act as a retrograde messenger in hippocampus. However, the role of NO-GC1 for pre- and postsynaptic functions in other brain regions like the somatosensory cortex is not fully understood. By using knockout (KO) mice lacking the NO-GC1 isoform, the present study analyzed glutamatergic and GABAergic synaptic transmission between pyramidal neurons in layers II/III of somatosensory cortex. We observed a reduced frequency of miniature excitatory and inhibitory postsynaptic currents (mEPSCs and mIPSCs) together with an increased paired-pulse ratio (PPR) and a decreased input-output curve of electrically evoked EPSCs and IPSCs, which strongly suggest a functional impairment of presynaptic release of glutamate and GABA in NO-GC 1 KO mice.

The altered neurotransmission in KO mice was rescued to WT-like levels by bath application of the cGMP analog 8-Br-cGMP. Accordingly, an inhibitor of NO-GCs, ODQ, reduced the glutamate and GABA release in wild-type mice to the level of KO-mice. Moreover, we have evidence that NO is mainly produced postsynaptically in response to NMDA receptor activation and acts as a retrograde messenger to modulate GABA release. In conclusion, NO-GC1-cGMP signaling modulates glutamatergic and GABAergic synaptic neurotransmission, which could alter information processing in the somatosensory cortex.

Title: Identification of enzymes involved in endocannabinoid synthesis and metabolism in Hirudo verbana

Authors: *B. D. BURRELL[1,2], E. KABEISEMAN[1], R. MISKIMINS[1];
[1]Basic Biomed Sci., Univ. of South Dakota, Vermillion, SD; [2]Ctr. for Brain & Behavior Res., Vermillion, SD

Abstract: Endocannabinoids are lipid neurotransmitters found throughout the animal kingdom, but there has been relatively little in the way of comparative studies in how these signaling molecules function in the nervous system. *Hirudo verbana* (the medicinal leech) provides an excellent model system for such studies. It has a well-described central nervous system (CNS) in which it is possible to record from single, identifiable neurons and link changes in individual

neurons and synapses to changes at the behavioral level. Pharmacological studies have demonstrated endocannabinoid-based modulation of synapses and behavior in *Hirudo* (e.g., Yuan & Burrell, 2013, *J. Neurophysiol.* 110:2607). In this study, we provide the first report of the genes in *Hirudo* that encode proteins responsible for the synthesis and metabolism of 2-arachidonoylglycerol (2-AG), an endocannabinoid transmitter known to be present in the *Hirudo* CNS. A sequence corresponding to the 2-AG synthesizing enzyme, diacylglycerol lipase (DAGL; accession #KU500007), was found to have 34 and 39% amino acid sequence identity when compared to mouse and human DAGL-beta genes, respectively. A sequence corresponding to the 2-AG metabolizing enzyme, monoacylglycerol lipase (MAGL), was found to have 40 and 41% amino acid sequence identity when compared to mouse and human MAGL. The regions corresponding to the predicted active site serine for both *Hirudo* DAGL (hirDAGL; S431) and hirMAGL (S118) were conserved between the *Hirudo* and mammalian versions of these proteins. When expressed in HEK cells both hirDAGL and hirMAGL are localized in the membrane, similar to their mammalian orthologues. Experiments using a natural fluorescent substrate assay (Van der Wal *et al.*, *J Lipid Res* 56: 927) indicate that hirMAGL converts 2-AG into arachidonic acid. Similar assays are currently being conducted to test whether hirDAGL can convert 1-stearoyl-2-arachidonol-*sn*-glycerol (SAG) into 2-AG. Future experiments will focus on examining how hirDAGL and hirMAGL activity is modulated (e.g. by phosphorylation), validating pharmacological agents that act on these enzymes, and their functional contribution to synaptic and behavioral plasticity.

Title: Characterization of NADPH-diaphorase- and doublecortin-positive neurons in the lizard hippocampal formation

Authors: *M. M. LIMA[1], H. C. PIMENTEL[2], L. C. R. F. LINS[3], G. G. VIOLA[3], M. A. M. FREIRE[4], M. MARCHIORO[3];

Abstract: The lizard cortex has remarkable similarities with the mammalian hippocampus. Both process memories, have similar cytoarchitectural properties, and are important neurogenic foci in adults. Lizards show striking levels of widespread neurogenesis in adulthood and can regenerate entire cortical areas after injury. Nitric oxide (NO) is an important regulatory factor of mammalian neurogenesis and hippocampal function. However, little is known about the role of NO in non-mammalian neurogenesis. Here, we analyzed the distribution, morphology and complexity (Neurolucida reconstructions) of NO-producing neurons through NADPH-diaphorase (NADPHd) activity, and their relationship with doublecortin (DCX)-expressing neurons in the hippocampal formation of the neotropical lizard *Tropidurus hispidus*. NADPHd-positive neurons were present in two clusters: one with small somata and low intensity of staining; and one with inversely correlated soma size and intensity. Moreover, NADPHd-positive neurons in the dorsomedial cortex (DMC; homologous to CA3) were more numerous and complex than the ones in the medial cortex (MC; homologous do the dentate gyrus). We found NADPHd-positive DMC neurons send long projections into the MC. Interestingly, NADPHd-positive neurons were absent in the MC's granular cell layer. In contrast, DCX-positive neurons were scarce in the DMC, but highly numerous in the MC, particularly in the granular cell layer. We hypothesize that NO-producing neurons in the DMC provide important input to proliferating/migrating neurons in the highly neurogenic MC.

Title: Differential contribution of diacylglycerol lipase-alpha to phasic and tonic endocannabinoid signaling at hippocampal GABAergic synapses

Authors: *K. KENESEI[1], M. LEDRI[1], B. TÓTH[2], B. DUDOK[1,3], G. HORVAI[2], I. KATONA[1]; [1]Momentum Lab. of Mol. Neurobio., Inst. of Exptl. Medicine, HAS, Budapest, Hungary; [2]Dept. of Inorganic and Analytical Chem., Budapest Univ. of Technol. and Econ., Budapest, Hungary; [3]Sch. of Ph.D. Studies, Semmelweis Univ., Budapest, Hungary

Abstract: Retrograde endocannabinoid signaling via presynaptic CB1 cannabinoid receptors (CB1R) play an essential role in the activity-dependent calibration of neurotransmitter release probability at various synapses throughout the brain. Recent investigations have also unfolded multiple different molecular mechanisms of how cannabinoid signaling can control synaptic transmission in a phasic or tonic manner. In addition, several serine hydrolase enzymes are known to regulate synaptic levels of the most common endocannabinoid messenger 2-arachidonoyl-glycerol (2-AG) raising the possibility of a molecular division of labor in different forms of endocannabinoid signaling. To mechanistically explore the contribution of diacylglycerol lipase-alpha (DGL-alpha), the predominant 2-AG synthesizing enzyme to phasic and tonic endocannabinoid signaling at perisomatic GABAergic synapses in the mouse hippocampus, we performed paired whole-cell patch-clamp recordings between presynaptic perisomatic interneurons and postsynaptic CA1 pyramidal cells. These physiological investigations have also been complemented by the detailed nanoscale analysis of cell-type-specific CB1R numbers and hippocampal endocannabinoid levels using stochastic optical reconstruction microscopy (STORM) super-resolution imaging and liquid chromatography/tandem mass spectrometry (LC-MS/MS), respectively. In agreement with prior studies, a significant decrease to 23% of wild-type 2-AG levels was observed in DGLα knockout mice. In addition, depolarization-induced suppression of inhibition (DSI), a widespread form of phasic endocannabinoid signaling was absent in DGLα knockout mice, whereas DSI was robust and could be blocked with the CB1 receptor antagonist/inverse agonist AM251 in wild-type animals. Despite the reduced basal tissue 2-AG levels, CB1 receptor numbers on presynaptic interneuron terminals as well as the baseline amplitude of unitary inhibitory postsynaptic currents (uIPSCs) and success rates of unitary synaptic events remained identical between littermate wild-type and DGLα knockout mice suggesting that tonic 2-AG signaling may still be functional in the absence of DGLα. Indeed, AM251 could significantly increase GABAergic synaptic transmission between perisomatic interneurons and CA1 pyramidal cells in DGLα KO mice. Together, these findings are consistent with the prevailing view that DGLα produces synaptic 2-AG for phasic endocannabinoid signaling, but also raise the intriguing possibility that tonic endocannabinoid signaling operates via a DGLα-independent molecular mechanism.

Title: Endocannabinoid regulation of glutamatergic input onto corticotropin releasing neurons in the central nucleus of the amygdala

Authors: *N. HARTLEY[1], A. JAMESON[2], S. PATEL[1];
[1]Vanderbilt Univ. Med. Ctr., Nashville, TN; [2]Vanderbilt Univ., Nashville, TN

Abstract: The central amygdala (CeA) is a limbic brain structure largely responsible for the generation of threat adaptive behaviors. Corticotropin releasing factor (CRF) signaling within the CeA has been shown to positively regulate fear and anxiety phenotypes, and the use of knock in and transgenic reporter lines has allowed for reliable identification of CRF expressing (CRF+) neurons in this region. Recently, we have demonstrated that endocannabinoid (eCB)-mediated retrograde synaptic suppression is prevalent at excitatory synapses in the CeA. However, how the excitability of CRF+ neurons and the eCB system interact in the CeA remains largely unexplored. Here, we use optogenetic circuit mapping to assess eCB-signaling at ascending and descending glutamatergic inputs onto CRF+ neurons in CeA. We report that CRF+ neurons receive the greatest input from descending cortical-like structures, over ascending inputs from the parabrachial nucleus, and that cannabinoid signaling capacity is greatest at these descending inputs. Furthermore, we identify forms of short-term and long-term eCB-mediated plasticity at specific inputs, suggesting that eCBs regulate CeA function via suppression of glutamate release onto CRF+ neurons.

Title: Molecular, morphological and physiological properties of different CB_1 cannabinoid receptor-expressing interneuron types of the hippocampus

Authors: *B. DUDOK[1,2], V. MICZÁN[1,3], K. KENESEI[1], M. LEDRI[1], K. KELEMEN[1], B. BARTI[1], M. KISFALI[1], M. WATANABE[4], I. KATONA[1];

Abstract: Specific GABAergic interneuron types play fundamentally different roles in the regulation of network activity in cortical circuits. Prior studies have classified specific interneuron types based on the characteristic differences in their neurochemical markers, morphological features, cell physiological properties and firing activity patterns during distinct brain and behavioral states. However, the comprehensive classification of cortical interneurons has not been completed yet, and novel methods, such as single-cell transcriptomics suggest a greater variability of cortical cell types than previously expected. A major population of cortical GABAergic interneurons expresses high levels of CB_1 cannabinoid receptors and can usually be divided into two morphological subpopulations of perisomatically- and dendritically-targeting interneurons. In accordance, previous studies have shown that the vesicular glutamate transporter VGluT3 is also present only in a selected subpopulation of CB_1-positive interneurons. In order to establish how these molecular and morphological differences are associated with specific physiological properties of distinct CB_1-positive interneuron populations, we used a combination of paired whole-cell patch-clamp recordings together with correlated confocal and STORM super-resolution imaging. The data showed that vGluT3 is expressed by selected subtypes of perisomatically- and dendritically-targeting interneurons defined by their non-overlapping bouton distribution index (see Dudok et al., 2015, Nature Neuroscience, 18:75-86) in the mouse CA1 hippocampus. The gross axonal and dendritic morphology, and the intrinsic physiological properties of VGluT3-positive or VGluT3-negative interneurons were indistinguishable. In contrast, VGluT3-expressing cells had larger boutons, which contained significantly more CB_1

receptors. Surprisingly, VGluT3-positive perisomatic interneuron synapses onto CA1 pyramidal neurons exhibited lower baseline synaptic efficacy and release probability compared to VGluT3-negative perisomatic connections. The remarkably smaller amplitude of unitary inhibitory synaptic currents and the lower success rate of synaptic events are likely due to high constitutive CB_1 receptor activity present at VGluT3-containing perisomatic synapses, but not at VGluT3-negative perisomatic or dendritic interneuron synapses. These distinct molecular, morphological and synaptic properties suggest that CB_1-positive interneuron types may contribute to hippocampal network activity and behavior in a more complex manner than anticipated before.

Title: μ-opioid mediated changes of neuronal iron levels may upregulate Ferritin Heavy Chain protein in specific cortical neurons

Authors: *B. S. NASH[1], R. A. NOLAN[2], K. TARN[2], O. MEUCCI[2];
[2]Pharmacol. & Physiol., [1]Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: HIV associated neurocognitive disorder is a common complication of HIV infection, and can be exacerbated by mu-opioid drug abuse. A potential mechanism of mu-opioid induced cognitive impairment examines negative regulation of the homeostatic chemokine receptor CXCR4 by mu-opioids. Morphine and DAMGO induce upregulation of Ferritin Heavy Chain protein in cortical neurons in vitro and in vivo, which is colocalized with CXCR4 and correlated with reduced activation of the receptor and its homeostatic downstream signals. The work presented here further characterizes mu-opioid induced FHC expression in cortical neurons. Morphine induced FHC from a dose range of 0.1 to 1 μM in vitro, and fractionation studies revealed that cytoplasmic FHC levels increase, while nuclear FHC levels remained constant. Rats sacrificed 24 hours after a single 20mg/kg morphine s.c. injection had elevated neuronal FHC levels in cortical neurons, with notable variability between individual cells, suggesting a

subpopulation of neurons is more susceptible to this effect. In vitro calcein imaging studies show that intracellular free labile iron concentrations are increased as early as 30 minutes after 1 μM morphine treatment, and sustained over 24 hours. Changes in neuronal iron levels may be a driver of mu-opioid mediated FHC protein expression, since they both regulate FHC expression post-transcriptionally. Additionally, we show that FHC expression is dependent on intracellular iron, and cannot be induced by morphine in the presence of the iron chelator Deferroxamine. Morphine can upregulate FHC if only extracellular iron is chelated, highlighting the importance of intracellular iron in this process. Subsequently, we show neurons that are iron loaded with 50 μM Ferric Ammonium Citrate, but not treated with morphine, both upregulate FHC and partially inhibit downstream mediators of CXCR4 signals. These experiments suggest a novel mechanism of regulation between the opioid and iron regulatory systems that coordinate to modulate downstream homeostatic signals from CXCR4. This has potential implications for HIV+ patients who are prescribed opioid medications or abuse opioid drugs, and may describe a novel avenue of cognitive impairment in this patient group. Future studies will examine and characterize neuronal subtypes susceptible to FHC upregulation in order to identify circuit specific elements that may be impaired among opioid abusers.

Title: Expression of cannabinoid type 1 receptors in the rat spinal cord following surgical incision

Authors: *P. PRASOON[1], R. KUMAR[2], M. GAUTAM, 110029[2], S. RAY[2];
[2]Anat., [1]AIIMS, New Delhi, India

Abstract: Background: The active principal of cannabis known as $^{9}{}_{\alpha}$ -Tetrahydrocannabinol (THC) binds to cannabinoid (CB) receptors, which are classified into CB1 and CB2 subtypes. These belong to the G-protein coupled receptor family. Cannabis has a prominent analgesic action in humans and has been recommended for the treatment of cancer pain. Recently, activation of CB1 receptors has also been observed to produce relief in neuropathic pain.

However, little is known about the role of CB1 receptors in postoperative pain. Hence, the expression of these receptors was studied in the rat spinal cord following surgical incision on the hind paw. **Materials and Methods:** Sprague-Dawley rats were subjected to incision on the plantar surface of the right hind paw. Behavioural assessment of nociception was done. Spinal cords (L4-5 segments) were processed for immunohistochemical localization of CB1 receptors. Western blotting was also done. Expression of CB1 receptors in Rexed's lamina I-II of dorsal horn was quantified by NIS-Element software. **Results:** Both allodynia and hyperalgesia were highest, immediately after incision. Expression of CB1 receptor in laminae I-II increased at all post incision time points though significant increase was observed at 2 h and day 3. Result of Immunoblot confirmed these finding. **Conclusions:** Up-regulation immediately after incision suggests that these receptors could be important in the initial part of postoperative pain. Previous studies indicate that these receptors inhibit the release of excitatory neurotransmitters from presynaptic terminals, which decrease the transmission of pain. Further studies are in progress for evaluation of the precise role of CB1 receptors. **Key words**: CB1 receptor, hindpaw incision, Postoperative pain, CB2 receptor, Neuropathic Pain. **Acknowledgment:** Financial support has been provided by Department of Biotechnology (Grant no-BT/PR14279/MED/30/452/2010), Government of India

Title: Hippocalcin promotes neuronal differentiation and inhibits astrocytic differentiation in neural stem cells

Authors: *S.-Y. PARK[1], M.-J. KANG[1], S. JUNG[2], J.-S. HAN[3];
[1]Signal transduction networking, [3]Biochem. and molecular biology, [2]Hanyang University, Biomedicine Inst., Seoul, Korea, Republic of

Abstract: Hippocalcin is a calcium-binding protein that is restricted to nervous tissue and contributes to neuronal activity. However, the mechanisms by which hippocalcin regulates neuronal differentiation in neural stem cells (NSCs) are poorly studied. We report that, in addition to inducing neurogenesis, hippocalcin inhibits astrocytic differentiation of NSCs. It promotes neurogenesis by regulating protein kinase Cα (PKCα) activation by translocating to the membrane and binding to phosphoinositide-dependent protein kinase-1 (PDK1), which induces PKCα phosphorylation. We also found that phospholipase D1 (PLD1) is implicated in the hippocalcin-mediated neurogenesis pathway; this enzyme promotes dephosphorylation of STAT3 (Y705), which is necessary for astrocytic differentiation. Moreover, we found that the tyrosine phosphatase SHP-1 acts upstream of STAT3. SHP-1 acts as a negative regulator of STAT3, which is required for neurogenesis. Importantly, this SHP-1-dependent STAT3 inhibitory mechanism is closely involved in neurogenesis and suppression of gliogenesis by hippocalcin. Taken together, these observations suggest that hippocalcin promotes neuronal differentiation through activation of the PKCα/PLD1 cascade followed by activation of SHP-1, which dephosphorylates STAT3 (Y705), leading to inhibition of astrocytic differentiation.

Title: Circuit specific modulation of corticotrophin releasing factor in ventral tegmental neurons

Authors: ***J. R. DRISCOLL**[1,2], H. L. FIELDS[3,2], E. B. MARGOLIS[3];
[1]Univ. of California San Francisco, San Francisco, CA; [2]Helen Wills Neurosci. Inst., Univ. of California, Berkeley, Berkeley, CA; [3]Univ. of California, San Francisco, San Francisco, CA

Abstract: A major hypothesis in the pathology of addiction is that maladaptive behaviors result from a disruption in the homeostatic balance between stress and reward circuitry. Several rodent models of stress (i.e. footshock, foot pinch, restraint stress, and social defeat stress) increase the activity of VTA neurons and result in an increase in dopamine in terminal regions of VTA neurons. Corticotrophin releasing factor (CRF) is released in the VTA during stress and is

reported to increase the firing rate of dopamine neurons, yet decrease dopamine release in the Nucleus Accumbens (NAc). These results suggest that CRF differentially modulates VTA neurons with different projection targets. However, the synaptic action of CRF on specific subsets of VTA neurons and their role in influencing behavior has yet to be characterized. We made *ex vivo* whole cell current clamp recordings to examine the synaptic actions of CRF. We measured responses to (100 nM to 1 mM) CRF in both TH(+) and TH(-) neurons from throughout the VTA. CRF consistently increased the firing rate of spontaneously active neurons (n=22/25). However in quiescent neurons we observed either depolarizations (40%) or hyperpolarizations (35%). Firing rate increases were not dependent on HCN channel function, as blocking them using 10nM ZD7288 did not prevent this increase (n=5/6). To analyze circuit specificity of CRF, recordings were made in labeled neurons 7 days after the retrograde fluorescent marker DiI was injected into VTA terminal regions including medial prefrontal cortex (mPFC), NAc, and amygdala (AMY). AMY-projecting VTA neurons were consistently excited by CRF, whether firing spontaneously or quiescent (n=5/5). We also observed an increase in the amplitude of evoked glutamatergic EPSCs in response to CRF in this projection (n=4/5, 240% increase amplitude). In contrast, mPFC and NAc projecting neurons did not show a consistent response pattern in quiescent neurons (n=14 for mPFC, n=17 for NAc). Spontaneously active neurons in all projections were consistently excited by CRF (n=7). These findings demonstrate that the effect of CRF on VTA neurons is heterogeneous and depends on both the state of the neuron and its projection. Cells that are firing spontaneously fire more, strengthening ongoing activity. In neurons that are not firing, CRF is biasing a subset of VTA neurons that will respond to an excitatory input. Both dopaminergic and non-dopaminergic neurons are modulated. To understand how these effects modulate behavior, further work must be done to probe the contribution of AMY-projecting VTA neurons by activation of this projection in tasks that explore the role of stress in modulating aversion and reward.

Title: NPY receptor characterization in guinea pig intracardiac neurons: Evidence for multiple receptor subtypes.

Authors: *J. C. HARDWICK[1], K. A. LUCKETT[2], M. GERUNTHO[1], S. A. ROSEN[1];
[2]Biol., [1]Ithaca Col., Ithaca, NY

Abstract: Chronic heart disease leads to imbalances within the autonomic nervous system, often resulting in an upregulation of sympathetic output with a concomitant decrease in central parasympathetic preganglionic activity. In addition to the increased release of norepinephrine from sympathetic fibers, there is also an elevation in the release of the neuropeptide, NPY. This study examined the function and responses of intrinsic parasympathetic postganglionic cardiac neurons to local application of NPY. Previous studies have shown that these neurons respond to NPY, but the receptors and mechanism underlying these responses are unknown. We used a multidisciplinary approach to determine which NPY receptors are present in the guinea pig intracardiac neurons and what functional responses they induce. Biochemical analysis of mRNA levels with RT-qPCR shows evidence for Y1 and Y5 receptors, and possibly Y2 receptors. Western blot analysis of protein expression from dissected guinea pig cardiac ganglia and atrial muscle show evidence for Y4 and Y5 receptors. Intracellular voltage recordings from individual neurons supported previous results, where NPY induces a hyperpolarization of the membrane potential and reduces the time course of the afterhyperpolarization (AHP) phase in single action potentials. Using specific Y1, Y2 and Y5 antagonists, we determined that the Y5 receptor appears to mediate the change in AHP time course. The hyperpolarization of the membrane potential appears to have heterogeneous receptor mediation, since some cells showed significant inhibition with Y5 antagonists and others showed no significant inhibition to any antagonist tested. In separate experiments examining ganglia from animals with a surgical model of chronic myocardial infarction (MI), we found significant (~2.5 fold) upregulation of NPY mRNA in the ganglion. We also saw an increase in NPY-induced neuronal excitability with depolarizing current pulses in these MI animals. These results indicate that NPY expression in neurons is altered with chronic heart disease. Additionally, the neurons of the cardiac ganglion express multiple NPY receptors and these receptors may also show differential expression levels following the induction of a chronic MI.

Title: Increased Toll-like receptors in the prefrontal cortex of depressed suicide

Authors: *X. REN, H. S. RIZAVI, H. ZHANG, G. N. PANDEY;
Dept. of Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Abnormalities of the immune function in depression and suicide are based in part on the observation of increased levels of proinflammatory cytokines in the serum and in the postmortem brain of depressed and suicidal patients. Several studies suggest dysregulation of the immune system in suicide as increased microgliosis has been reported in postmortem brain of suicide subjects and increased levels of proinflammatory cytokines in the cerebrospinal fluid (CSF) of suicidal patients. The observed abnormality of cytokines in suicide may be related to altered innate immune receptors known as Toll-like receptors (TLRs). We have earlier reported a significant increase in the protein and mRNA levels of TLR3 and TLR4 in depressed and suicide brain. To further examine the role of TLRs in suicide we have now studied the expression of TLR1, TLR2, TLR6, TLR7, TLR8, TLR9 and TLR10 in depressed suicide subjects. We determined the protein expression of TLR1, TLR2, TLR5, TLR6, TLR7, TLR8, TLR9, and TLR10 in the prefrontal cortex (PFC) of 24 depressed suicide victim and 24 normal control subjects. The postmortem brain tissues were obtained from the Maryland Brain Collection and the psychological autopsies were performed for the diagnosis of the subjects using DSM-IV-SCID. Protein expression was determined using Western blot technique. When we compared the protein expression of different TLRs, we found that the protein expression of TLR2, TLR6, TLR7 and TLR10 was significantly increased in the PFC of depressed suicide victims compared with normal control subjects, while there was no difference in protein expression of TLR1, TLR5, TLR8 and TLR9 in depressed suicide victims compared with normal control subjects. These results suggest that protein overexpression of TLR2, TLR6, TLR7 and TLR10 may be in part related to the abnormalities of proinflammatory cytokines in the brain of suicide victims and that abnormalities of innate immunity are associated with suicide.

Title: Potentiation of ASIC channel currents by high affinity endogenous opioids, independent of mu opioid receptor stimulation, in rat sensory neurons

Authors: M. FARRAG[1], H. L. PUHL[2], *V. RUIZ-VELASCO[1];
[1]Anesthesiol., Penn State Col. of Med., Hershey, PA; [2]Lab. of Mol. Physiol., Natl. Inst. of Health, Natl. Inst. on Alcohol Abuse and Alcoholism, Bethesda, MD

Abstract: The naturally occurring endomorphins 1 and 2 (E-1 and E-2) exhibit high affinity and selectivity for mu opioid receptors (MOR) over kappa and delta receptors. Both of these tetrapeptides have been shown to exert analgesic properties in some animal models of pain. E-1 and E-2 release is enhanced under ischemic and inflammatory conditions. Additionally, a pH drop in ischemic tissue activates the H^+-gated acid sensing ion channels (ASIC). ASIC are expressed primarily in peripheral and central nervous system. Some reports have shown that DRG neurons express primarily ASIC1 and ASIC3 isoforms. ASIC3 channel currents are characterized by two components: fast component that rapidly desensitizes and a slow, sustained current that lasts as long as the external pH remains acidic. The purpose of the present study was to examine the effect of E-1 and E-2 peptides on ASIC channel currents employing the whole-cell variant of the patch-clamp technique. In acutely isolated rat DRG neurons, exposure to either 10 μM E1 or E2 (pH 6.0) enhanced the sustained ASIC currents 76±29% (n=11) and 113±35% (n=17), respectively, when compared to activation by pH 6.0 alone. The sustained ASIC currents also were potentiated (115±39%, n=5) by E-2 (10 μM) in DRG neurons pretreated overnight with pertussis toxin—suggesting that MOR were not involved in this signaling event. To better understand the effect of endomorphins on ASIC3 homotrimers, mouse ASIC3 (mASIC3) channels were heterologously expressed in the mouse fibroblast L cell line that does not natively express MOR or ASIC channels. Either 10 μM E-1 or E-2 greatly potentiated ASIC3 currents (1700±252%, n=9; 2033±456%, n=5) when compared to pH 6.0 alone. The pH-dependent activation was shifted to more alkaline pH while the pH-dependent inactivation was shifted to a more acidic pH, resulting in an amplification of the window current. Given that endomorphins are released under ischemic conditions, we next ligated the femoral artery in rats to produce muscle ischemia. Following a 72 hr ligation period, the rat DRG neurons were isolated and the effect of endomorphins on ASIC currents was examined. When compared to control DRG neurons exposed to either 10 μM E-1 or E-2 (pH 6.0), E-1 or E-2 application (pH 6.0) resulted in a significantly ($p<0.05$) greater ASIC current potentiation of 194±68% (n=10) and 244±60% (n=9), respectively. Overall, these results suggest that endogenous endomorphins potentiate sustained ASIC3 currents—an effect that is enhanced under ischemic conditions.

Title: Glucocorticoid receptor exon 1F and dynamics of DNA methylation in teenage suicide

Authors: *H. S. RIZAVI, D. R. GRAYSON, H. ZHANG, X. REN, G. N. PANDEY;
Univ. Illinois Chicago, Chicago, IL

Abstract: Impaired hypothalamic-pituitary-adrenal (HPA) axis function is linked to depression and increased susceptibility to suicide. Dysregulation of HPA axis function observed in depression and suicide may be due partially to a disturbed feedback inhibition by endogenous corticoids. Glucocorticoid receptors (GR) play an important role in the regulation of stress response when endogenous levels of glucocorticoids are high. In this study, our goal was to understand the regulation of GR exon 1_F expression and the dynamic epigenetic mechanisms that may alter the expression of this promoter. Gene expression and methylation levels were measured in the postmortem prefrontal cortex (PFC) of 22 teenage suicide victims and 22 teenage normal control subjects. Our results show that GR exon 1_F expression was decreased while methylation levels were increased and hydroxyl-methylation levels were decreased in teenage suicide victims as compared to normal controls. Expression of TET1 and TET2 was decreased with no change in TET3 in teenage suicide victims as compared to normal controls. In addition, DNMT1 and DNMT3a expression was increased with no change in DNMT3b in teenage suicide victims as compared to normal controls. Our data supports the hypothesis that epigenetic variations caused by aberrant regulation of DNMT and TET lead to higher methylation levels in $GR1_F$ and affect $GR1_F$ mRNA levels. Our data indicate that dynamic epigenetic mechanisms are involved in gene regulation and contribute significantly to understanding the neurobiology of teenage suicide.

Title: Galanin receptor expression and origins of galanin input from noradrenergic nuclei to the bed nucleus of the stria terminalis

Authors: *A. GARGIULO[1], J. R. BARSON[1], B. D. WATERHOUSE[2];
[1]Dept. of Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Cell Biol., Rowan Univ. Sch. of Med., Stratford, NJ

Abstract: Reinstatement of drug-seeking is one of the greatest challenges in treating addiction, and roughly half of individuals treated for it relapse within a year of cessation. Medical approaches for treating relapse are lacking because the mechanisms underlying relapse are multifactorial and poorly understood. Stress is a common cause of relapse with devastating consequences for recovering addicts. Brief exposure to various stressors have been shown to induce relapse experimentally, and our laboratory is interested in characterizing the role of galanin that originates from noradrenergic nuclei in this behavior. The bed nucleus of the stria terminalis (BNST), a brain region involved in integrating hypothalamus-pituitary-adrenal (HPA) axis signaling as well as fear- and reward-neurocircuitry, is heavily involved in stress-induced relapse behavior. This region is important in that it receives extensive noradrenergic innervation and is responsive to infusion of galanin and norepinephrine (NE) agonists and antagonists, yet much about its cytoarchitecture, especially with respect to patterns of galanin receptor distribution and galanin innervation remains to be thoroughly examined. Galanin has been shown to be an important anxiolytic neuropeptide, and increased galanin expression in locus coeruleus, the major source of NE to the forebrain, has been shown to promote resilience to stress. Therefore, we used immunohistochemical procedures to explore galanin receptor expression throughout BNST subregions, with particular focus on the ventral and lateral portions of the nucleus which receive a prominent noradrenergic innervation. Male, Sprague-Dawley rats were sacrificed, perfused, and brain slices processed with primary antibodies against galanin receptors 1 (GalR1) or 2 (GalR2) to detect galanin receptor expression, as well as co-stains for glutamic acid decarboxylase (GAD67) and Ca^{2+}/Calmodulin-dependent protein kinase II (CaMKII) to identify expression of galanin receptors on GABA-ergic and glutamatergic BNST cells, respectively. In line with *in situ* hybridization and genetic cell targeting studies of other laboratories, we noted galanin receptor expression in subregions and subsets of cells in the

BNST. These findings suggest that regional expression of galanin receptors in BNST underlie the neuromodulatory effects of galanin on stress-induced reinstatement of drug-seeking behavior. Additional retrograde tract tracing studies are focused on identifying of the source of galanin projections to these sub-regions.

Title: Neuropeptide and protease systems in stress-responsive dense core secretory vesicles analyzed by mass spectrometry-based peptidomics, proteomics, and protease activity profiling

Authors: ***C. B. LIETZ**[1], D. J. GONZALEZ[1,2], A. J. O'DONOGHUE[1], Z. JIANG[1,3], T. TONEFF[1], N. BANDEIRA[1,4], V. HOOK[1,2,5];
[1]Skaggs Sch. of Pharm. and Pharmaceut. Sci., [2]Pharmacology, Sch. of Med., [3]Chem. and Biochem., [4]Computer Sci. and Engin., [5]Neurosciences, Sch. of Med., Univ. of California San Diego, La Jolla, CA

Abstract: Stress induces the release of bioactive neuropeptides and catecholamines from sympathetic adrenal medullary chromaffin cells for intercellular signaling regulation of physiological responses in ‘fight or flight’ stress reactions to environmental changes. Dense core secretory vesicles secrete stress-regulating neuropeptides which include, among others, enkephalins, Neuropeptide Y (NPY), and chromogranin-derived peptides such as catestatin. Neuropeptides are co-released with the catecholamines dopamine, norepinephrine, and epinephrine. This study applied an integrated “omics” strategy combining high-resolution liquid chromatography-mass spectrometry (LC-MS) peptidomics, proteomics, and protease activity profiling of DCSVs isolated from primary bovine chromaffin cells. Analysis of these DCSVs will help provide a greater understanding of the vital functions performed by proteases and other DCSV proteins related to neuropeptide biosynthesis, storage, and release.
LC-MS data was subjected to bioinformatics analysis by PEAKS and MSGFDB. Results identified endogenous peptides derived from chromagranins, proenkephalin, pro-NPY, and Kininogen (bradykinins), among others. Preliminary bottom-up proteomic experiments of isolated DCSVs identified 2328 unique proteins. These proteins include 78 putative proteases

from the cysteine, aspartyl, metallo, and serine protease subclasses. Several of these proteases are known to participate in pro-neuropeptide processing, however many new proteases not previously identified in these DCSVs were also found. Activity profiling using a diverse set of fluorescent peptide substrates and class-specific protease inhibitors, determined that multiple proteases are active at pH 5.0 - 5.5, which corresponds to the internal pH of DSCVs. Systems biology analyses of these multi-omics DCSV data illustrate the complex network of protein functions involved DCSV stress responses.

Title: Naloxone blocks the neurogenesis, evaluated by double labelled cells, induced by paced mating in the olfactory bulb of the female rat.

Authors: *M. SANTOYO ZEDILLO[1], R. G. PAREDES G.[2], W. PORTILLO MARTINEZ[2]; [1]Inst. de Neurobiologia, UNAM, Queretaro, Mexico; [2]Dept. de Neurobiologia Conductual y Cognitiva, Inst. de Neurobiologia,UNAM, Queretaro, Mexico

Abstract: Neurogenesis is a process that occurs continuously in the adult mammalian brain. But environmental conditions or internal states can modify different stages of this process.
Our group has demonstrated that when female rats are allowed to pace the sexual interaction, there is an increase in the number of newborn cells BrdU inmunoreactive (BrdU-IR), in the accessory olfactory bulb (AOB). Some of this cells are also positive for NeuN IR (nuclear neuronal marker), suggesting that they differentiate into neurons. Moreover, females that pace

their sexual interaction develop a positive affective (reward) state, which has been evaluated by the conditioned place preference paradigm (CPP). This reward state is mediated by opioids because we showed that the intraperitoneal injection of naloxone (NX, opioid receptor antagonist) blocks CPP induced by paced mating.
In the present study we evaluated if blocking the opioid receptors with naloxone could reduce the number of new cells that incorporate to the AOB, that are generated during the first paced mating sexual interaction. Sexually-naïve female rats, bilaterally ovariectomized and hormonally supplemented were randomly assigned to one of five groups: 1) without sexual contact injected with saline, 2) without sexual contact injected with NX, 3) females that mated without pacing the sexual interaction injected with saline, 4) females injected with saline before paced mating and 5) females injected with NX before paced mating.
Females treated with saline that paced the sexual interaction, showed an increase in newborn cells and an increase in double labeled cells BrdU IR and NeuN IR in the AOB when compared to the other groups. NX administration before paced mating blocked the increase in the number of BrdU-IR cells and of double labelled cells BrdU-NeuN IR.
These data support that opioid peptides, have a fundamental role in the neurogenesis in the AOB induced by paced mating in the female rat. Further research will evaluate if these newborn cells are involved in the physiology of reproduction.

Title: Characterization of L-to-D peptide isomerase activity in *Aplysia* californica

Authors: ***H.-C. TAI**, I. LIVNAT, J. W. CHECCO, E. V. ROMANOVA, P. M. YAU, J. V. SWEEDLER;
Univ. of Illinois At Urbana-Champaign, Urbana, IL

Abstract: Neuropeptides are cell-to-cell signaling molecules that mediate the activity of most neuronal circuits. Neuropeptides are derived from larger protein precursors, and undergo a range of post-translational modifications to form the bioactive peptides. Importantly, post-translational conversion of an L-amino acid residue into a D-amino acid residue in a neuropeptide can substantially alter the three dimensional structure and modify the bioactivity and metabolism of the resulting D-amino acid-containing peptide (DAACP). Current research into peptide isomerization is limited because this PTM is not easily detected in mass spectrometry-based peptidomics experiments due to the lack of an associated mass shift. Therefore, we have established protocols to screen for and characterize DAACPs in a non-targeted manner. Three novel DAACPs were identified in *Aplysia californica* using this approach. Our results suggest that the peptide isomerase responsible for the L-to-D modification in *A. californica* works only on the second amino acid residue from the N-terminus but is promiscuous in terms of peptide length as well as specific residue to isomerize. To advance our understanding of this fascinating enzyme, an assay for characterizing peptide isomerase activity was developed. Initial efforts focused on dissecting known DAACP expressing regions in specific neural ganglia and incubating the homogenate with all-L-peptide substrates. Peptide samples post incubation were analyzed with liquid chromatography coupled to multiple-reaction-monitoring mass spectrometry, and the L- or D- peptide isomer assigned based on matching retention times to synthetic standards. Since the peptides NdWFa, GdFFD and GdYFD are known to exist as DAACPs in *A. californica,* the all-L-forms of these peptides were used as substrates to evaluate peptide isomerase activity. The corresponding DAACPs were detected post incubation, suggesting that isomerase activity is indeed active in the homogenates. Importantly, formation of DAACPs was not observed when the homogenate was heated in boiling water prior to incubation, which strongly suggests that the isomerization was the result of an enzymatic process rather than spontaneous isomerization. Isomerase activity was observed in the presence of ethylenediaminetetraacetic acid (EDTA), which implies that the isomerase is not metal-dependent. Additional cofactors are being evaluated for their impact on isomerase activity, and enzyme purification for sequencing and further characterization is currently underway.

Title: Role of central acetylcholine release in the regulation of locomotion circuits

Authors: A. C. BLAKE, Jr[1], M. HEREDIA[1], *H. O. LAWAL[2];
[1]Biol. Sci., [2]Biol., Delaware State Univ., Dover, DE

Abstract: Impairment in cholinergic neurotransmission is associated with normal and pathological aging, making cholinergic release a subject of high interest to human biology. However, the precise role of changes in central acetylcholine release in mediating behaviors, such as locomotion, has not been fully elucidated. The vesicular acetylcholine transporter (VAChT) is present in many species, including worms, flies, and humans, and is responsible for the packaging of acetylcholine for exocytotic release. A complete loss of VAChT function is lethal, while severe mutations can cause decreased locomotive performance in *Drosophila*. Here, we hypothesize that deficits in VAChT function can be rescued by a pharmacological or genetic increase in VAChT function, which can be identified by a shift in the rate of locomotion towards normal. The overall purpose of this study was to determine an effective method of rescuing mutations in *Drosophila Vacht*. In order to rescue the locomotion deficit seen in *Vacht* mutants, cholinergic drugs in different concentrations were administered to the *Vacht* mutant larvae for a 2 hour time period; dimethyl sulfoxide or water were used as vehicle. Drug or vehicle-only fed larvae were then tested in two locomotion assays, using the automated MultiWorm Tracker, and the touch response assay. For a genetic rescue, a wildtype copy of the VAChT gene was expressed in the *Vacht* mutant background. Here we report that the expression of a wildtype copy of VAChT rescues one locomotion assay phenotype but not the other. Furthermore, our results indicate a differential effect of cholinergic agonist on the rescue of locomotion deficits in *Vacht* mutants. These results show that both genetic and pharmacological interventions are capable of ameliorating deficits caused by a loss of VAChT function. Together, these studies could pave way for future strategies to treat behavioral deficits associated altered cholinergic signaling.

Title: Cortical disinhibition by ChAT expressing interneurons

Authors: *A. J. GRANGER[1], B. L. SABATINI[2];
[2]Neurobio., [1]Harvard Med. Sch., Boston, MA

Abstract: Acetylcholine is a major neurotransmitter and neuromodulator in the mammalian forebrain, important for maintaining alertness, directing attention, promoting learning, and mediating detection of salient sensory cues. In the cortex, acetylcholine can provide phasic depolarization of postsynaptic neurons through excitatory ionotropic receptors or tonic metabotropic modulation of cellular excitability and synaptic plasticity. However, we have recently shown that many cholinergic neurons also have the potential to transmit the inhibitory neurotransmitter GABA, fundamentally altering our view of how cholinergic neurons influence cortical circuits. To study the function of GABA/ACh cotransmission, we have focused on local ChAT-expressing cortical interneurons. In addition to ChAT, these neurons also express vasoactive intestinal peptide (VIP), and share a similar morphology and laminar distribution as previously described VIP interneurons. Activation of cortical ChAT interneurons results in GABA release onto all other classes of cortical interneurons, most prominently onto somatostatin-expressing interneurons, without inhibiting nearby pyramidal neurons. This suggests that ChAT neurons provide a GABAergic disinhibitory signal that acts in concert with acetylcholine release to promote cortical activity and plasticity.

Title: Effects of cholinergic activation on hippocampal local field potentials and a long-term spatial memory task

Authors: C. S. TANG, *O. PAULSEN;
Univ. of Cambridge, Cambridge, United Kingdom

Abstract: A variety of experiments have implicated the cholinergic system in attention, learning and memory. The hippocampus, which is important for spatial memory in rodents, receives a major cholinergic input from the medial septum. Here, we used transgenic mice expressing channelrhodopsin (ChR2) selectively in cholinergic neurons to investigate the effects of activation of medial septal cholinergic neurons on local field potentials (LFP) recorded in the hippocampus *in vivo* and how the activation of these neurons at various phases of a long-term spatial memory task impacted learning. This study used offspring of the ChAT-Cre line (mice expressing the Cre recombinase under the control of the choline acetyl-transferase promoter) crossed with the Cre-reporter Ai32 line bearing a Cre-dependent, enhanced YFP-tagged ChR2-containing expression cassette. For LFP recordings, mice were anaesthetised with urethane (1.2 gkg^{-1} i.p.) and their head fixed in a stereotaxic frame. An extracellular tungsten microelectrode (127 μm diameter, 2 MΩ) was lowered into the CA3 of the hippocampus for electrical recording and a stripped optical fibre (200 μm diameter, 0.22 NA) coupled to a 470 nm laser was lowered into the medial septum for optical activation. The appetitive Y-maze task was used to test spatial long-term memory. Mice were implanted with a 4 mm-long fibre optic cannula (200 μm, 0.22 NA) lowered into the medial septum and secured to the skull using dental cement. Activation of cholinergic neurons in urethane-anesthetized mice increased the power in the theta band (2–6 Hz) by 325 ± 85% (n = 10) and slow gamma band (20–40 Hz) by 225 ± 48% (n = 10), while slow oscillations (0.5–2 Hz) were suppressed to 58 ± 10% (n = 10). In the Y-maze task, in which the mice learned which arm of a 3-arm maze contains a food reward, cholinergic activation throughout the task significantly impaired learning. By day 3 of the testing period, the control group (n = 6) chose the rewarded arm in 92 ± 4% of trials while the group with cholinergic activation throughout the task (n = 6) chose the rewarded arm in only 60 ± 10% of trials (p = 0.02). Cholinergic activation only in the reward area also significantly impaired learning; these mice (n = 6) chose the correct arm in 55 ± 6% of trials on day 3 (p = 0.005), while mice receiving cholinergic activation during exploration only (n = 5) were largely unaffected, choosing the correct arm in 88 ± 6% of trials (p = 0.982). These results show that 1) cholinergic activation increases the power in the theta and slow gamma band while suppressing slow oscillations; and 2) tonic cholinergic activation, especially during reward consumption can impair learning of a long-term spatial memory task.

Title: Brain wide projectome of cholinergic neurons of the mouse basal forebrain

Authors: *Y. KIM[1,2], H. PI[2], S. RANADE[2], A. NARASIMHAN[2], P. OSTEN[2], A. KEPECS[2]; [1]Col. of Medicine, Penn State Univ., Hershey, PA; [2]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Cholinergic neurons in the basal forebrain play important roles in numerous brain functions, such as arousal and learning, while their degeneration has been implicated in brain disorders, including Alzheimer's disease. Previous studies have revealed the broad projection patterns of the cholinergic neurons across the brain, but quantiative knowledge on their projection patterns across the entire brain is limited. Here, we utilized serial two-photon tomography (STPT) based whole-brain imaging at cellular resolution to obtain complete brain-wide projection maps of basal forebrain cholinergic neurons. First we determined the distribution of all cholinergic neurons by crossing cholinergic neuron specific Cre driver (Chat-cre) with cre-dependent reporter labeling nucleus of the cells (LoxP-Stop-LoxP-H2B-GFP). STPT imaging with automated cell counting revealed the number and density of cholinergic neurons in the basal forebrain area; about 5,000 cell/mm3 in Magnocellular nucleus and diagonal band nucleus, and about 2,000 cell/mm3 in substantia innominata and medial septal nucleus. Second, we constructed brain wide projectome of the basal forebrain cholinergic neurons. To label axonal projections from cholinergic neurons, Cre-dependent adeno-associated virus expressing GFP was injected in Chat-cre mice systematically throughout the entire region of the basal forebrain. We quantified the GFP labeled axonal projections and determined their patterns of projection density across different regions ("projectome") across the entire brain. We found that cholinergic neurons along the anterior to postural basal forebrain axis (DB-SI-NB) provide topographic cortical projections in a diagonal pattern along a anterior-medial to posterior-lateral axis. Moreover, distinct subregions of cholinergic basal forebrain project to distinct sets of anatomical regions throughout the entire brain. In summary, the current results provide a comprehensive map of anatomical organization of cholinergic neurons in the basal forebrain.

Title: Pharmacological identification of cholinergic receptor subtypes in modulation of a sensory-motor circuit in *Drosophila melanogaster*

Authors: *C. MALLOY[1], A. OMAR[2], E. SOMASUNDARAM[2], R. COOPER[2];
[1]Biol., [2]Univ. of Kentucky, Lexington, KY

Abstract: Acetylcholine (ACh) is an abundant neurotransmitter found in many species across various taxa. In mammals, it is known to be integral in modulating neural circuits underlying important processes such as learning, memory, and reward processing. In *Drosophila melanogaster*, ACh and the components mediating cholinergic signaling, exhibit comparable importance. It is the neurotransmitter used in peripheral sensory neurons and is the primary excitatory neurotransmitter within the CNS. The receptors that facilitate synaptic transmission at cholinergic synapses are divided into two broad subtypes: the ionotropic nicotinic acetylcholine receptors (nAChRs) and the metabotropic muscarinic acetylcholine receptors (mAChRs). This receptor classification is shared in both mammals and insects; however, both the pharmacological and functional characterization of these receptors within the *Drosophila* nervous system has lagged behind its mammalian model counterparts. In order to further classification of these receptors in the nervous system of a model organism that has become vital to neuroscientists across the globe, we have used a combined behavioral and electrophysiological approach to identify important cholinergic receptor subtypes within the *Drosophila* CNS that may be crucial in modulating defined neural circuits. We have exposed intact *Drosophila* 3rd instar larvae to various concentrations of ACh agonists and antagonists by way of feeding to observe modulation of locomotion. In addition, we have utilized a well-characterized electrophysiological approach to assess the efficacy of a defined sensory-CNS-motor circuit in the presence of cholinergic agonists and antagonists exposed directly to the CNS of a semi-intact larval preparation. Preliminary results suggest that exposing the CNS directly to ACh and agonists, nicotine and muscarine, enhances electrical activity of a sensory-CNS-motor circuit. Conversely, acute feeding of nicotine and acetylcholine suppresses locomotion. These results suggest both nAChRs and mAChRs within the CNS may act to modulate a motor circuit which mediates general locomotion in larval *Drosophila*.

Title: Overexpression of vesicular acetylcholine transporter in ChAT-ChR2-EYFP transgenic mice alters short-term synaptic plasticity at cholinergic synapses

Authors: *J. O'MALLEY, R. DASGUPTA, F. SEIBT, M. BEIERLEIN;
Neurobio. and Anat., McGovern Med. Sch. At Uthealth, Houston, TX

Abstract: Release of acetylcholine from cholinergic afferents controls diverse cognitive functions, including learning and memory, sensory processing, and attention. Our understanding of cholinergic signaling and its role in controlling distinct cell types, neuronal circuits, and behavior has greatly benefited from genetic strategies aimed to express channelrhodopsin-2 (ChR2) specifically in choline acetyltransferase (ChAT) positive neurons. One such strategy has been the development of bacterial artificial chromosome (BAC) transgenic mouse models that express ChR2 under the control of the ChAT promoter (ChAT-ChR2-EYFP). However, ChAT-ChR2-EYFP mice also carry several additional copies of the vesicular acetylcholine transporter gene (VAChT), resulting in overexpression of functional VAChT. Behaviorally, ChAT-ChR2-EYFP mice display enhanced motor endurance and a number of cognitive defects, including impaired attention and memory. It remains unknown how VAChT overexpression influences cholinergic synaptic signaling. We have addressed this question by characterizing electrical stimulation-evoked cholinergic synaptic responses in neurons of the thalamic reticular nucleus (TRN), in slices of wild-type (WT) and ChAT-ChR2-EYFP transgenic mice. For both mouse lines, single stimuli led to biphasic E-I responses mediated by nicotinic ACh receptors (nAChRs) and muscarinic ACh receptors (mAChRs), respectively. However, isolated nAChR-mediated EPSCs (nEPSCs) displayed faster decay kinetics in transgenic animals as compared to WT. Furthermore, we found that for transgenic animals nEPSCs evoked by stimulus trains displayed reduced short-term synaptic depression, suggesting more efficient synaptic vesicle refilling during ongoing synaptic activity. Our findings suggest that overexpression of VAChT leads to distinct alterations in cholinergic synaptic transmission and short-term plasticity.

Title: Modulation of cholinergic, but not noradrenergic, signaling in rat prefrontal cortex reverses traits of sevoflurane anesthesia

Authors: *D. PAL, B. H. SILVERSTEIN, D. LI, S. WISIDAGAMAGE, G. A. MASHOUR; Dept. of Anesthesiol., Univ. of Michigan, Ann Arbor, MI

Abstract: Systemic infusion of cholinergic and aminergic agents - as well as direct manipulation of subcortical sites in forebrain, thalamus, and brainstem - produce signs of behavioral arousal during general anesthesia.[1-6] However, the role of top-down or cortical processes in the states of arousal is not clear. In this study, we investigated the effect of increase in cholinergic and noradrenergic tone in rat prefrontal cortex (PFC) during sevoflurane anesthesia (2.0-2.2 %) on behavioral states. Male Sprague-Dawley rats (300-350g) were surgically implanted with 1) screw electrodes to record monopolar electroencephalogram (EEG) across the cortex, and 2) a guide tube in PFC for dialysis delivery of either carbachol (N=9, 5mM) or noradrenaline (N=9, 20mM), and simultaneous measurement of changes in local acetylcholine (ACh) levels. Carbachol-induced changes in local ACh levels were quantified using high performance liquid chromatography while noradrenaline-induced changes will be analyzed using mass spectrometry. We demonstrate that carbachol in rat PFC during sevoflurane anesthesia caused a significant increase in local ACh levels ($p<0.001$) and produced signs of behavioral arousal (limb and torso movements, increased respiratory rate) and EEG activation in all rats. In addition, 4/9 rats were able to regain righting reflex and showed complete mobility while still inhaling clinically-relevant concentrations of sevoflurane anesthesia. By contrast, infusion of noradrenaline into PFC did not produce any effect on behavioral state but did cause a transient desynchronization of EEG. These results suggest that cholinergic signaling in rat PFC contributes to top-down control of arousal state. **References:** 1. Meuret et al. (2000) Anesthesiology 93:708-717. 2. Hudetz et al. Title: Inhalation of cigarette smoking-relevant nicotine aerosol induces cardiac arrhythmia leading to systemic and uterine hemodynamic disruption in pregnant rats

Authors: *X. M. SHAO[1], H. E. LÓPEZ-VALDÉS[3], J. LIANG[2], J. L. FELDMAN[1];
[1]Neurobio., [2]Mol. and Med. Pharmacol., David Geffen Sch. Med. at UCLA, Los Angeles, CA;
[3]Res. Division,, Fac. of Medicine, Univ. Nacional Autónoma de México, Mexico City, Mexico

Abstract: Maternal smoking is associated with preterm delivery, low birth weight, sudden infant death syndrome and developmental defects of neonates. We tested the hypothesis that cigarette smoking-relevant nicotine exposure in pregnancy induces disruption of systemic and local uterine hemodynamics that decreases blood flow to the uterus and placenta leading to fetal ischemia. Blood pressure (BP) was continuously recorded via a femoral artery catheter and ECG was simultaneously recorded with subcutaneous needle electrodes from awake, constrained pregnant rats. A perivascular ultrasound flowprobe was chronically implanted on the uterine artery for continuous blood flow measurement. With a newly developed non-invasive, alveolar region-targeted aerosol method to deliver nicotine to pregnant rats, controllable amounts of nicotine got into the systemic circulation and the brain quickly producing nicotine pharmacokinetics in both arterial and venous blood resembling that of smoking a cigarette in humans. Nicotine aerosol inhalation induced cardiac arrhythmia and high magnitude irregular fluctuation of systemic BP. The arrhythmia included sinus bradycardia, sinus arrhythmia, atrioventricular (A-V) block 1^{o} and 2^{o} (Wenckebach), atrial premature beats, atrial tachycardia, ventricular premature beats, ventricular tachycardia. Nicotine aerosol inhalation also induced a reduction and high magnitude irregular fluctuation of uterine artery blood flow. These effects were transient, starting 3 to 10 seconds from the start of nicotine aerosol exposure with hemodynamics recovering within 1-2 min in the presence of nicotine. These effects could be blocked by i.p. injection of the nicotinic acetylcholine receptor (nAChR) antagonist mecamylamine. Our data suggest that nicotine aerosol exposure resulting in a rapid rise of arterial blood nicotine concentration with pharmacokinetics similar to cigarette smoking stimulates and then desensitizes nAChRs in the autonomic nervous system that induces cardiac arrhythmia leading to systemic and uterine hemodynamic disruption, as well as constriction of the uterine artery resulting in a reduction in uterine artery blood flow. Transient hemodynamic

disruption result from smoking can lead to placental and fetal ischemia that could potentiate the risk of pregnancy complications and developmental disorders known to associate with maternal smoking. In addition, arrhythmia and hemodynamic disruption can put adult life at risk by inducing cardiac ischemia, heart failure and stroke. These findings challenge the safety of inhalation of pure nicotine as an alternative for cigarette smoking, such as E-cigarettes.

Title: 7-Methoxytacrine - 4-pyridinealdoxime hybrid as novel prophylactic agent with reactivation properties in organophosphate intoxications

Authors: *O. SOUKUP[1], J. KORABECNY[2], E. NEPOVIMOVA[2], D. JUN[3], K. KUCA[4]; [1]Univ. of Defence, Hradec Kralove, Czech Republic; [2]Univ. of Def., Hradec Kralove, Czech Republic; [3]Univ. of Defese, Hradec Kralove, Czech Republic; [4]Univ. Hosp. Hradec Kralove, Hradec Kralove, Czech Republic

Abstract: Chemical warfare agents constitute an increasing threat to both military and civilian population. Therefore, effective prophylactic approach is urgently needed. Herein, we present novel hybrid compound able not only to keep acetylcholinesterase resistant to organophosphate (OP) inhibitors, but also to serve as enzyme reactivator in case of OP intoxication. We describe novel promising prophylactic approach exploitable in case of OP intoxications. Encouraging in vitro results should, however, be approved by in vivo tests prior to determination of its real therapeutic value.

Title: Role of membrane anchoring of RGS7 in regulating $GABA_B$-GIRK in hippocampus

Authors: *O. I. OSTROVSKAYA, C. ORLANDI, K. A. MARTEMYANOV;
Dept. Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: Disruption of G protein Coupled Receptor (GPCR) signaling substantially contributes to the etiology of mental disorders. Agonist-bound GPCRs initiate multiple signaling reactions by switching G proteins from inactive GDP-bound to active GTP-bound state. Regulators of G-protein signaling (RGS) proteins speed up GTP hydrolysis on an activated Gα subunit, thus ensuring sharp cessation of the signal. Recently, we discovered that a member of RGS family RGS7 is involved in hippocampal learning and memory by negatively regulating signaling from $GABA_B$ receptors to G protein gated Inwardly Rectifying K+ (GIRK) channels. It is thought that effective regulation of GPCR signaling requires targeting of RGS proteins to the plasma membrane. RGS7 has been shown to directly interact with two membrane proteins: R7BP and GPR158, which anchor RGS7 to the plasma membrane and impact its stability and activity. However, the relevance of these anchoring mechanisms to regulation of $GABA_B$-GIRK signaling in the endogenous setting is unknown. In this work we elucidated the role of GPR158 and R7BP in the ability of RGS7 to regulate hippocampal $GABA_B$-GIRK signaling. First, using in-situ hybridization we established that all hippocampal neurons coexpress R7BP and GPR158 together with RGS7. Knockout (KO) of R7BP or GPR158 alone had modest effects on membrane localization of RGS7, however concurrent elimination of both R7BP and GPR158 (DKO) resulted in almost complete loss of RGS7 from the membrane fraction. Next, using patch clamp whole-cell electrophysiology we studied the impact of GPR158 and R7BP ablation on GIRK channel kinetics in response to its activation by $GABA_B$ receptors in hippocampal primary cultures. While we detected impact of R7BP ablation on deactivation of GIRK currents, no such effect was present in GPR158 KO neurons. Furthermore, DKO pyramidal neurons were indistinguishable from R7BP KO, suggesting that GPR158 does not further contribute to GIRK regulation in neonatal neurons. Interestingly, we found that GPR158 expression undergoes induction late in brain development. Therefore, we next studied the impact of R7BP and GPR158 on $GABA_B$-GIRK signaling in slices from adult animals. Ablation of RGS7 significantly delayed the decay of slow Inhibitory Postsynaptic Currents (sIPSCs) in CA1 pyramidal neurons known to be mediated by $GABA_B$-GIRK. KO of either GPR158 or R7BP alone was similar to wild-type

neurons. However, DKO sIPSCs showed significantly delayed deactivation. Thus we conclude that R7BP and GPR158 play a redundant role in regulation of GABAB-GIRK signaling in hippocampal neurons by controlling membrane targeting of RGS7 complexes.

Title: The orphan receptor GPR158 is a novel stress-induced modulator of signaling in depression

Authors: *C. ORLANDI, L. P. SUTTON, C. SONG, B. S. MUNTEAN, K. A. MARTEMYANOV;
Neurosci., The Scripps Res. Inst. (TSRI), Jupiter, FL

Abstract: Mood disorders are among the most common and debilitating neurological disorders, but their molecular basis are not fully understood. The inability of dealing with enduring stressful events leads to depression in almost 7% of the U.S. population. Current antidepressant treatments potentiate serotonin (5HT) and norepinephrine (NE) neurotransmission by blocking their synaptic reuptake or degradation. Unfortunately these drugs require weeks to be effective and fail in 50% of the cases. The search for new potential targets is therefore a priority to generate more effective drugs. Most of the post-synaptic receptors of 5HT and NE are G protein coupled receptors (GPCR) hence understanding the G protein signaling regulation in critical brain regions such as the medial prefrontal cortex is fundamental to gain insight in the processes that lead to depression. We found that the expression of the orphan receptor GPR158 in the medial prefrontal cortex is induced by chronic stress. At the molecular level, GPR158 forms complexes with the Regulator of G protein Signaling 7 (RGS7) protein and serves as a positive modulator of its activity. Our working model suggests that GPR158-RGS7 complex negatively regulates the signaling of several GPCRs instead of activating G proteins as classical neurotransmitter receptors do. We found that stress up-regulates GPR158 levels resulting in increased recruitment of RGS7 to the plasma membrane. To investigate the physiological relevance of GPR158-RGS7 complex we generated GPR158 and RGS7 knockout (KO) mice and measured their performance in a battery of behavioral tasks. We found that both GPR158 KO

and RGS7 KO mice show a robust antidepressant- and anxiolytic-like phenotype compared to their wild type littermates. When exposed to chronic mild stress the KO mice showed resilience and these data were supported by a reduced stress-induced hyperthermia. To examine which GPCR signaling are modulated by GPR158-RGS7 we treated mice with antagonists of several GPCRs known to have a role in mood control. We found that treatments with α2A-adrenergic receptor antagonists reversed the antidepressant-like phenotype in GPR158 KO mice without affecting the performance of WT in the tail suspension test. We conclude that the GPR158-RGS7 complex regulates NE signaling in the brain. Our evidence suggests that the GPR158-RGS7 complex is a novel player with a unique role in mood regulation in response to chronic stress. We hope that these findings may lead to a better knowledge of the pathophysiology of depression while uncovering a new pharmacological target for preventing detrimental effects of chronic stress and improving treatments for mood disorders.

Title: Orphan receptor GPR158 modulates intrinsic excitability and synaptic transmission of layer 2/3 neurons in prelimbic cortex

Authors: *C. SONG, C. ORLANDI, L. P. SUTTON, K. A. MARTEMYANOV;
Dept. of Neurosci., The Scripps Res. Inst., Jupiter, FL

Abstract: G protein coupled receptors (GPCRs) are a large and diverse family of receptors that have become the most important targets in modern pharmacology. Growing evidence suggests that GPCRs play critical roles in mood disorders and their treatments. We have recently found that the orphan receptor GPR158 plays a role in emotional control and is highly expressed in the prefrontal cortex. The current study aimed at determining the cellular mechanisms of GPR158 action underlying behavioral effects. We utilized whole-cell patch-clamp recordings to examine the effect of GPR158 deletion (KO) on electrophysiological properties of pyramidal neurons in prelimbic (PL) area. We focused on these neurons because this area is critical for emotional control. First, we determined that GPR158 KO does not significantly change

electrophysiological properties of layer 5 PL neurons. In contrast, layer 2/3 neurons were significantly affected. Analysis of the data (48 neurons from 20 mice) revealed that the intrinsic excitability was significantly increased in GPR158 KO neurons compared to wild type (WT) neurons ($p < 0.01$), as evidenced by KO neurons firing more spikes in response to depolarizing current injection (all neurons were held at -70 mV). In addition, GPR158 KO neurons displayed larger input resistance and lower rheobase current ($p < 0.05$ for both measurements). Interestingly, increase intracellular cAMP levels by adding Sp-cAMPs into the internal solutions for WT but not KO neurons mimicked the effect of GPR158 KO, suggesting GPR158 suppresses intrinsic excitability through modulating intracellular cAMP level. Furthermore, the frequency but not amplitude of spontaneous excitatory postsynaptic currents (sEPSC) was increased in GPR158 KO neurons ($p < 0.05$), suggesting that GPR158 also modulates synaptic transmission. Consistent with this, the AMPA/NMDA current ratio was significantly increased in GPR158 KO neurons compared with WT neurons ($p < 0.05$). Analysis of confocal images from biocytin-labled neurons indicates that GPR158 KO significantly increases the spine density of apical dendrites. Taken together, these data suggest that GPR158 modulates both intrinsic excitability and synaptic transmission of L2/3 pyramidal neurons in prelimbic area, and may be a potential target for novel anti-depressants.

Title: M_4 activation reduces striatal dopamine release and has antipsychotic-like effects via a CB_2 cannabinoid receptor-dependent mechanism

Authors: *D. J. FOSTER[1], J. M. WILSON[1], M. S. MAHMOOD[1], D. H. REMKE[1], J. WESS[2], L. J. MARNETT[3], S. PATEL[4], C. M. NISWENDER[1], C. K. JONES[1], Z. XIANG[1], C. W. LINDSLEY[1], J. M. ROOK[1], P. J. CONN[1];

Abstract: Muscarinic receptors represent a promising therapeutic target for schizophrenia, but the mechanisms underlying the antipsychotic efficacy of muscarinic modulators are not well understood. Two seminal clinical studies have demonstrated that the M_1/M_4 preferring agonist xanomeline can provide significant therapeutic efficacy in treating psychosis in patients with Alzheimer's disease or schizophrenia. Unfortunately gastrointestinal side-effects, likely mediated by M_2/M_3 receptors, have removed xanomeline from consideration for clinical use. However, these studies suggest that compounds that selectively modulate M_1 and/or M_4 could be therapeutically beneficial in treating psychosis. Recent reports utilizing novel subtype-selective M_4 positive allosteric modulators (PAMs) have demonstrated efficacy in several preclinical models of psychosis. However, the mechanism whereby M_4 can mediate these antipsychotic-like effects is unclear. Here we report that activation of M_4 receptors on medium spiny neurons results in a novel form of dopaminergic regulation resulting in sustained depression of striatal dopamine release that is observed more than 30 minutes after removal of mAChR agonist. This suppression of dopamine release was not dependent on intracellular Ca^{2+} signaling but was completely blocked by pretreatment with the DAG-Lipase inhibitor DO34. Furthermore, both the M_4-mediated sustained inhibition of dopamine release and the antipsychotic-like efficacy in reversing disrupted pre-pulse inhibition were found to require intact signaling through CB_2 cannabinoid receptors. These findings highlight a novel mechanism by which striatal cholinergic and cannabinoid signaling leads to sustained reductions in dopaminergic transmission and concurrent behavioral effects predictive of antipsychotic efficacy.

Title: Tubulin acetylation translocates $G\alpha_s$ from lipid-rafts: a novel mechanism for antidepressant effects of HDAC-6 inhibitors

Authors: *H. SINGH[1], J. SCHAPPI[2], A. PRADHAN[3], M. RASENICK[4,5];
[1]Univ. of Illinois At Chicago, Chicago, IL; [2]Physiol. and Biophysics, [3]Psychiatry, Univ. of Illinois at Chicago, Chicago, IL; [4]Jesse Brown VAMC, Chicago, IL; [5]Physiol. and Biophysics, university of Illinois at Chicago, Chicago, IL

Abstract: Histone deacetylase-6 (HDAC-6) enzymes deacetylate α-tubulin and have been shown to be upregulated during depression. HDAC6 knockout or HDAC6 inhibitors displayed an antidepressant profile in animal models. Thus, while, a possible role for HDAC6 inhibitors in treatment of depression exists, the potential mechanism for this remains elusive. Previously, our group has shown that treatment of rats or C6 glioma cells with several classes of antidepressant drugs results in facilitation of the activity of the G-protein, $G\alpha_s$, by translocating it from membrane microdomains (lipid-rafts) inducing a sustained elevation in cAMP production. Studies have also demonstrated interplay between tubulin and $G\alpha_s$ in lipid-rafts. Once out of lipid-raft domains, $G\alpha_s$, couples with adenylyl cyclase 6 (AC6). Although $G\alpha_s$ interacts directly with tubulin to modify microtubule dynamics, tubulin also acts as an anchor for $G\alpha_s$ in lipid rafts. Based on established HDAC-6 roles in modifying tubulin acetylation and our data showing $G\alpha_s$ interactions with tubulin in lipid-raft domains, we hypothesized that acetylation of α-tubulin disrupts tubulin-$G\alpha_s$ anchoring, rendering $G\alpha_s$ free to activate AC. To test this, C6 glial cells were treated with the HDAC-6 inhibitor, tubastatin-A. Acetylation status of α-tubulin and localization of $G\alpha_s$ subunit in/out of lipid-raft membrane domains was studied. Chronic treatment with tubastatin-A not only increased acetylation of α-tubulin but also translocated $G\alpha_s$ from lipid-rafts, without changing total $G\alpha_s$. Fluorescence Recovery After Photobleaching (FRAP) on C6 cells stably expressing GFP-$G\alpha_s$, was conducted and cells treated for three days with tubastatin-A showed an "antidepressant signature". Finally, sustained elevation of cAMP was revealed by increased cAMP response element binding protein (CREB) phosphorylation and

increased expression of brain derived neurotrophic factor (BDNF). An increase in acetylated α-tubulin accompanied tubastatin-A treatment and acetylated α-tubulin prevented the formation of tubulin-$G\alpha_s$-complexes in lipid rafts. This did not appear to be a mechanism shared with other classes of antidepressants These findings suggest HDAC6 inhibition shows some commonality with traditional antidepressants. Therefore, compounds that decrease tubulin-$G\alpha_s$ interactions by increasing acetylation of a α-tubulin may show promise for antidepressant therapy.

Title: Sustained antidepressant treatment increases cAMP signaling by translocating $G\alpha_s$ from lipid rafts and increasing association with type 6 adenylyl cyclase (AC6): a process independent of monoamine transporters.

Authors: *J. SCHAPPI[1], M. RASENICK[2];
[1]Physiol. & Biophysics, Univ. of Illinois At Chicago, Chicago, IL; [2]Physiol. and Biophysics, Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Antidepressants of different chemical classes promote a sustained increase in cAMP, due, at least in part to the redistribution of $G_{\alpha}s$ from lipid rafts into non-raft membrane fractions. The net result of this redistribution is increased $G\alpha_s$ coupling with, and activation of, adenylyl cyclase (AC). This has been demonstrated, in both rats and cultured neural and glial cells by a number of techniques, including cell fractionation, functional assays, and imaging studies such as FRAP (Fluorescence Recovery After Photobleaching). Unlike animal models, C6 glioma lack monoamine reuptake transporters, suggesting that mechanisms of antidepressant response entails more than inhibition of neurotransmitter reuptake transporters or inhibition of monoamine breakdown. This is noteworthy, since inhibition of 5HT or NE uptake is quite rapid even though clinical effects of antidepressants require several weeks (and several days in the cellular models). Furthermore, while these neural and glial cells showed an "antidepressant response", $G\alpha_s$ localization and cAMP production in kidney epithelial cells like COS1 and HEK293 were unchanged by antidepressant treatment. Similarly, membranes from liver and kidney of rats treated chronically with antidepressant did not show the same response as brain from those same animals. In this study we sought to determine whether cellular antidepressant response, with respect to increased cAMP signaling and $G\alpha_s$ localization, is dependent on the type of AC isoform expression. Cell lines "insensitive" to antidepressant treatment, such as HEK293, become responsive after transfection with AC6, showing translocation of $G\alpha_s$ from lipid rafts, both by cell fractionation and by FRAP. Likewise, knockdown of AC6 but not other adenylyl cyclase isoforms abolishes the antidepressant response in responsive cell lines such as C6 glioma. Thus, it is suggested that AC6 performs an anchoring function for $G\alpha_s$ outside of rafts, affixing the translocated $G\alpha_s$ into the non-raft domain and facilitating an antidepressant-induced increase in adenylyl cyclase activity.

Title: A cellular model for ketamine antidepressant action reveals an NMDA-receptor independent mechanism: roles for $G\alpha_s$ lipid rafts and cyclic AMP

Authors: *N. WRAY[1], J. SCHAPPI[2], M. RASENICK[3];
[1]physiology and biophysics, Univ. of Illinois at Chicago Dept. of Physiol. and Biophysics, Chicago, IL; [2]Physiol. and Biophysics, [3]Physiol. and Biophysics, Psychiatry, Univ. of Illinois at Chicago, Chicago, IL

Abstract: Previous studies have demonstrated that all extant classes of antidepressants increase coupling between the G protein, $G\alpha_s$ and adenylyl cyclase, resulting in persistent cAMP elevation. This effect requires sustained drug treatment and is observed after 3 days in cultured neural or glial cells or 3 weeks in rats. This is apparently due to $G\alpha_s$ being released from constraints of a lipid raft environment to cholesterol-poor regions of the plasma membrane. Consistent with this, both peripheral tissue and postmortem brain from depressed human subjects show a greater proportion of $G\alpha_s$ in lipid rafts. While most antidepressants require several weeks for a clinical effect, ketamine appears to alleviate depression within hours, only to relapse after several days. In an effort to determine whether ketamine showed an antidepressant biosignature similar to other antidepressants, studies in cultured cells were initiated. It was hypothesized that ketamine would have an effect similar to antidepressants but along a shorter time course. C6 cells were treated with 1uM ketamine, harvested and lipid raft fractions prepared and the amount of $G\alpha_s$ was assessed by Western blot. C6 cells with a stable fluorescent $G\alpha_s$ fusion protein (GFP-$G\alpha_s$) was treated similarly with ketamine and the mobility of GFP-$G\alpha_s$ was determined by Fluorescence Recovery after Photobleaching (FRAP). Brief ketamine treatment evokes a biochemical hallmark (translocation of $G\alpha_s$) seen after prolonged treatment with several species of drugs with established antidepressant activity. This is not mimicked by other NMDA antagonists, suggesting an additional site for ketamine action. The ketamine induced $G\alpha_s$ translocation allows increased functional coupling of $G\alpha_s$ and adenylyl cyclase to increase intracellular cyclic adenosine monophosphate (cAMP). Furthermore, increased intracellular cAMP mediates phosphorylation of cAMP response element-binding protein (CREB), which increases BDNF levels. BDNF production was indeed dependent on cAMP as the cAMP antagonist Rp-cAMPS attenuated BDNF expression levels. Furthermore, BDNF expression was also seen in primary astrocytes after ketamine treatment and attenuated by Rp-cAMPs. These results reveal a novel antidepressant mechanism mediated by acute ketamine treatment in glial cells that may contribute to ketamine's antidepressant effect. Furthermore, the translocation of GFP-$G\alpha_s$ produced by ketamine and all tested compounds with antidepressant activity (but not mood-stabilizers, antipsychotics or anxiolytics) might serve as a useful platform for identifying compounds with potential antidepressant activity and for predicting clinical response.

Title: TIAM2S-mediated hippocampal neural circuitry shapes affective behaviors via non-canonical, GEF-independent signaling

Authors: *C.-H. CHU[1], J.-S. CHEN[2], H. S. SUN[1,2];
[1]Inst. of Mol. Medicine, Col. of Med., [2]Inst. of Basic Med. Sciences, Col. of Med., Natl. Cheng Kung Univ., Tainan, Taiwan

Abstract: Human T-cell lymphoma invasion and metastasis 2 (TIAM2), a member of the guanine nucleotide exchange factor (GEF) family, physiologically exists either in a long or short transcripts. The protein translated from short-TIAM2 mRNA (TIAM2S) has been noted for its ability to control the proliferation and metastasis of human cancer cells. However, it is unclear if this molecule plays a non-oncogenic role in regulating the function of normal physiology such as nervous systems. Our findings revealed that TIAM2S protein is abundant in normal brain, especially concentrating in neuronal cells of the limbic system such as hippocampus, where the long form of TIAM2 (TAIM2L) protein is undetectable. Up-regulation of TIAM2S protein induction was located in the nuclear during the period of NT2/N cells. Suppression of TIAM2S impacted on neurite outgrowth of NT2/N cells, but not its differentiation. By contrast, overexpressed TIAM2S prompted neurite outgrowth in SH-SY5Y neuroblastoma cells via a GEP-independent signals. To determine if dysregulation of TIAM2S can alter brain structural plasticity in order to cause any abnormal behaviors, transgenic mice for overexpressed human TIAM2S were created and examined by multiple animal behavioral tests plus magnetic resonance imaging (MRI) analysis with T2 and DTI pulse sequences. TIAM2S transgenic mice displayed increases of both locomotion activity and social interaction, along with depression-like behaviors. Furthermore, MRI analysis revealed that overexpressed human TIAM2S remodeled the axonal organization in the hippocampus. Taken together, our results indicated that the brain-enriched TIAM2S protein plays an important role in shaping affective behaviors via modulating formation of neuronal connections and plasticity in hippocampus regardless of GEF activity.

Title: A new class of lipid mediator: Phosphorylated N-acylethanolamines and their receptors

Authors: *Y. KIHARA[1], H. MIZUNO[2], D. SHEFFLER[3], R. RIVERA[2], J. CHUN[2];
[1]Mol. and Cell. Neurosci., [2]The Scripps Res. Inst., La Jolla, CA; [3]Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

Abstract: Lysophospholipids, such as lysophosphatidic acid (LPA) and sphingosine 1-phospate (S1P), are known as lipid mediators that regulate neural development, proliferation and differentiation. LPA and S1P bind to their specific G protein-coupled receptors (GPCRs), LPA1-6 and S1P1-5, respectively (Br J Pharmacol., 171:3575-94, 2014). We recently reported a crystal structure of LPA1, which identified phosphorylated-anandamide (pAEA) - a cannabinoid metabolite - as a signaling molecules acting through LPA1 (Cell, 161:1633-1643, 2015). Importantly, pAEA induced neurite retraction on rat B103 neural cell lines heterologously expressing LPA1, implying that pAEA is a new class of lipid neuromodulator. Found in mouse brain, pAEA is produced from N-arachidonoyl phosphatidylethanolamine through cleavage by phospholipase D. pAEA is subsequently dephosphorylated by phosphatases, resulting in anandamide (AEA), which acts on cannabinoid receptors, CB1 and CB2 (PNAS 103:13345-13350, 2006). Here, we evaluate the effects of phosphorylated N-acylethanolamines (pNEA) on additional LPA receptor subtypes. pNEA species transduce calcium signaling through LPA1 and LPA5 at concentrations equivalent to LPA, indicating crosstalk between LPA and endo-cannabinoid systems. Furthermore, we conducted a GPCR screen to identify novel pAEA receptors that successfully identified up LPA1 and LPA5, as well additional receptors hits, which are currently being validated. We propose that pNEA is a novel lipid mediator acting through GPCRs in the CNS, and provide biochemical linkage between the lysophospholipid and cannabinoid pathways.

Title: Role of gpr40 for pufa-mediated bdnf synthesis

Authors: *T. YAMASHIMA, A. MATHIVANAN;
Kanazawa Univ. Grad Sch. Med., Kanazawa-Shi, Japan

Abstract: Background: Polyunsaturated fatty acids (PUFA) are known to be crucial for learning and memory. However, the detailed mechanism of PUFA effects upon neuronal functions remains almost unknown except for the possible facilitation of membrane fluidity. G-protein coupled receptor 40 (GPR40) was found to induce Ca^{2+} mobilization in response to diverse PUFA. Thereafter, the authors found GPR40 expression in the newborn neurons of the monkey hippocampus after ischemia. This suggested implications of PUFA-mediated GPR40 signaling for adult neurogenesis underlying learning and memory.
Objective: This study aims at evaluating whether PUFA-mediated GPR40 activation can affect synthesis of brain-derived neurotrophic factor (BDNF) with the aid of its proteolytic enzyme furin.
Methods: Monkeys underwent 20 min transient whole brain ischemia by clamping both the innominate and left subclavian arteries. On days 7 and 15 after ischemia/reperfusion, when adult neurogenesis was shown to be maximal previously by the authors, the brain samples were resected. By the Western blotting analysis of mature-BDNF (m-BDNF), pro-BDNF and furin, syntheses of BDNF in response to two GPR40 agonists as well as selective GPR40 antagonist GW1100, were studied using normal and post-ischemic monkey dentate gyrus (DG) tissue extracts.
Results: Both up-regulation of m-BDNF synthesis in response to two GPR40 agonists; fish oil PUFA and docosahexaenoic acid (DHA) and its down-regulation in response to GW1100, were observed. GPR40 antagonist inhibited m-BDNF synthesis, whereas two GPR40 agonists stimulated m-BDNF synthesis conceivably via furin activation. Cleavage of p-BDNF to m-BDNF by furin as well as syntheses of m-BDNF and furin in the DG tissues, occurred immediately after incubation with fish oil PUFA or DHA. Dynamic changes of GPR40, m-BDNF synthesis, and furin occurred simultaneously.

Conclusion: These data, although correlative, suggested that m-BDNF may be synthesized by the cleavage of pre-stocked pro-BDNF and/or released from the cell store in response to PUFA. By activating GPR40 and furin, PUFA may be related to adult neurogenesis and the concomitant synaptic plasticity for learning and memory.

Title: Exploring occupancy of the histamine H3 receptor by BF2.649 (pitolisant) in humans using PET

Authors: *P. SABIONI[1,2], P. RUSJAN[1,2], P. DI CIANO[1,2], E. MANSOURI[1,2], S. HOULE[1,2], A. WILSON[1,2], I. BOILEAU[1,2], A. LAVEILLE[3], M. CAPET[3], T. DUVAUCHELLE[3], J. C. SCHWARTZ[3], B. LE FOLL[1,2];

Abstract: Rationale: The histamine H3 receptor (H3R) has been investigated as a potential target for the treatment of various CNS disorders. Drugs that selectively block H3 receptors (for example, pitolisant) have been primarily evaluated for the treatment of sleep disorders (narcolepsy and obstructive sleep apnea) because they increase wakefulness. H3R antagonists/ inverse agonists were also suggested to be useful in treatment of psychiatric and substance abuse disorders. Imaging techniques are useful tools to visualize receptors and their occupancy by neurotransmitters or by a selective agonist/ antagonist drug. **Objective:** The aim of this study was to use positron emission tomography (PET) brain imaging and the radioligand H3R antagonist [^{11}C]GSK189254 to investigate occupancy by the novel H3R antagonist/ inverse agonist BF2.649 (pitolisant), a compound recently approved in the treatment of narcolepsy with or without cataplexy. **Methods:** Six healthy adult participants (age: 19-61) were scanned in a High Resolution Research Tomography (HRRT) PET scan for 90 min immediately after receiving an i.v. bolus injection of [^{11}C]GSK189254 (337±51 MBq, 2.7±0.4 μg). Subjects underwent in total two PET scans, in separate days, 3 hours after an oral drug administration. The first PET scan was performed in the placebo condition and the second PET scan, after the H_3

inverse agonist pitolisant (40 mg). Magnetic Resonance Imaging (MRI) was also conducted during the study to provide structural information for PET data analysis. **Results:** Single oral administration of pitolisant 40 mg promoted occupancy of H3R of 82.33% ± 3.55% (Mean ± SEM). The drug was well tolerated and participants experienced no side effects. **Conclusion:** The administration of pitolisant 40 mg produced a good occupancy of H3 receptors.

Title: Activity-dependent polarization of calcium release from intracellular stores

Authors: *N. A. LAMBERT, S. RAJAPAKSHA, Q. WAN;
Dept. of Pharmacol. and Toxicology, Med. Col. of Georgia, Augusta, GA

Abstract: In many neurons activation of G protein-coupled receptors (GPCRs) leads to activation of phospholipase C, hydrolysis of PIP2, production of IP3, and calcium release from intracellular stores. Given the different functional roles of intracellular calcium in postsynaptic and presynaptic processes we were interested in how this mechanism might differ in these compartments. Cultured cerebellar granule neurons expressing the calcium indicator GCaMP6s were stimulated with the muscarinic acetylcholine receptor (mAchR) agonist oxotremorine-M (Oxo-M), which evoked increases in cytosolic calcium in the soma and proximal dendrites but not in axons. This pattern of calcium release was not altered by overexpression of mAchRs, which were present on the surface of axons as well as the soma and dendrites. FRET

measurements using PH-domain indicators showed that activation of native mAchRs led to reversible PIP2 hydrolysis throughout both the somatodendritic and axonal compartments. The ryanodine receptor agonist caffeine and the calcium ionophore ionomycin also released calcium from intracellular stores in the soma and proximal dendrites but not in axons. In the presence of 25 mM K^+, which depolarized neurons and increased cytosolic calcium, Oxo-M, caffeine and ionomycin all produced additional increases in cytosolic calcium due to release from intracellular stores in both cell bodies and axons. Simultaneous imaging of calcium in the cytosol and endoplasmic reticulum suggested that depletion of intracellular calcium stores may contribute to the absence of calcium release in axons under non-depolarizing conditions, but that additional mechanisms are likely to be equally important. These results suggest calcium release mechanisms can be highly polarized in these neurons, and that this polarization can be regulated by neuronal activity.

Title: D_1 receptor activation in the SNr evokes GABA release and increased motor activity and is tonically inhibited by M_4 receptor signaling

Authors: ***M. S. MOEHLE**[1], T. PANCANI[1], N. BYUN[1], Z. XIANG[1], J. WESS[2], J. M. ROOK[1], C. M. NISWENDER[1], C. K. JONES[1], C. M. LINDSLEY[1], P. J. CONN[1];

Abstract: Dysregulation of dopamine (DA) release within the basal ganglia from midbrain dopaminergic neurons of the substantia nigra pars compacta (SNpc) underlie pathological states in a wide variety of central nervous system diseases including psychiatric and movement disorders. Within the basal ganglia, DA plays a critical role in regulating striatal function by actions on two separate non-overlapping pathways, the direct and indirect pathway. Because of the critical modulatory role of DA, a great effort has been placed on understanding both how DA modulates the basal ganglia direct and indirect pathways and how other neurotransmitter systems

regulate DA signaling. Potentially opposing dopamine receptor subtype 1 (D1) signaling, are the muscarinic acetylcholine subtype 4 (M4) receptors. Recently, our lab has reported that the activation of M4 receptors on direct pathway spiny projection neurons (SPNs) can block amphetamine-induced hyperlocomotion by attenuating dopamine release from striato-nigral projections via an endocannabinoid-dependent mechanism, highlighting a previously unreported mechanism by which M4 can inhibit dopamine release and diminish dopaminergic activity in the direct pathway. However, we now report that hyperlocomotion induced by direct-acting D1 agonists can also be blocked by M4 activation, implying that M4 directly opposes D1 signaling in addition to blocking dopamine release. Using a wide range of behavioral, electrophysiological, optogenetic, pharmacological, and functional imaging techniques, we directly tested how D1 agonists induce hyperlocomotion and how M4 activation opposes D1 activation. We found that D1 activation robustly induces gamma-aminobutyric acid (GABA) release from direct pathway SPNs onto cells of the substantia nigra reticulata (SNr) and that this is attenuated by M4 activation at the level of the SNr, likely through a cAMP-dependent mechanism. We also present data to suggest that M4 activity tonically inhibits D1 activity and GABA release in the direct pathway. Additional data suggested that DA release and D1 activation, as well as acetylcholine (ACh) release, in the SNr is equally important to produce and regulate movement as their counterparts in the striatum, extending the current model for how DA regulates basal ganglia processing.

Title: Behavioral consequences of biased D2 dopamine receptor signaling in medium spiny neurons

Authors: *S. J. ROSE[1], T. F. PACK[1], S. M. PETERSON[1], E. BORRELLI[2], M. G. CARON[1]; [1]Dept. of Cell Biol., Duke Univ. Med. Ctr., Durham, NC; [2]UC Irvine, Irvine, CA

Abstract: Dopamine signaling through the D2 dopamine receptor (D2R) in the brain is essential for motor control, reward, and cognition. It is now recognized that G protein-coupled receptors (GPCR), like the D2R, signal through canonical G-protein-mediated pathways as well as through the ability of β-arrestin2 (β-arr2) to scaffold distinct signaling complexes. Previous attempts to understand whether these distinct modes of D2R signaling are important have used cell type specific deletion of β-arr2 but this approach can also influence unrelated GPCRs function. Thus, to more precisely understand the nature of D2R signaling in normal behavior and in pharmacological responses, we used an approach where mutant D2Rs with defined signaling properties were reconstituted in the striatal D2R-positive neurons of the cortico-striato-thalamocortical circuit. D2Rs are expressed in the neuronal population of adenosine 2A receptor (A2AR) positive medium spiny neurons (iMSNs), which are the principal striatal output neurons of the classical "indirect pathway" of the basal ganglia. "Floxed" D2R mice (Anzalone et al., 2012) were crossed with A2ARCre mice, which were then virally reconstituted with four distinct Cre-dependent D2Rs, wild-type (^{WT}D2R), inactive D2R (^{D80A}D2R) and either G-protein (^{Gprot}D2R) or β-arrestin2 ($^{\beta\text{-}arr2}$D2R) selective D2Rs (Peterson et al., 2015). We found that whereas mice rescued with the inactive ^{D80A}D2R showed deficits in several behaviors that could be rescued by the ^{WT}D2R, overall locomotor behavior was rescued most efficiently by the $^{\beta\text{-}arr2}$D2R while both ^{Gprot}D2R and $^{\beta\text{-}arr2}$D2R were required for rearing behavior. Nestlet shredding, on the other hand, a form of repetitive behavior, was solely rescued by the ^{Gprot}D2R. Responses to pharmacological agents like cocaine were rescued by both D2R signaling modes, but $^{\beta\text{-}arr2}$D2R appeared more effective in rescuing amphetamine responses. Interestingly, locomotor responses to morphine could only be rescued partially with the $^{\beta\text{-}arr2}$D2R while the effect of phencyclidine (PCP) was markedly enhanced beyond the ^{WT}D2R rescue by the $^{\beta\text{-}arr2}$D2R. These results illustrate not only the complexity of D2R-signaling in the intact nervous system but argue that D2Rs can activate several distinct patterns of intracellular signals, depending on the context. These findings

should be useful to understand the profile of existing therapies and provide clues to develop more effective and selective approaches.

Title: Evidence for noncanonical adrenergic and dopaminergic activation: dopamine as an adrenergic alpha2 receptor agonist

Authors: *V. CASADÓ ANGUERA[1,2], M. SÁNCHEZ-SOTO[3,2,1], M. ESTEFANIA[1,2], Y. HIDEAKI[3], J. MALLOL[1,2], E. I. CANELA[1,2], A. CORTÉS[1,2], S. FERRÉ[3], V. CASADÓ[1,2]; [1]Departament de Bioquimica i Biomedicina Mol., Univ. of Barcelona, Barcelona, Spain; [2]Ctr. de Investigación Biomédica en Red sobre Enfermedades Neurodegenerativas, Spain, Spain; [3]Integrative Neurobio. Section, Natl. Inst. on Drug Abuse, Intramural Res. Program, Natl. Inst. of Hlth., Baltimore, MD

Abstract: A complex functional connection between the dopaminergic and noradrenergic systems is displayed in the brain and is involved in many brain functions. Dopamine (DA) acts on specific receptors belonging to the G protein-coupled receptor (GPCR) family and are categorized in two main groups including D_1-like and D_2-like receptors. The $G_{\alpha i/o}$-coupled dopamine D_2-like receptor family comprises three subtypes: the D2 receptor (D_2R), D_3 receptor (D_3R), and D_4 receptor (D_4R). The alpha-2 adrenergic receptor (α_2-ADR) is also a GPCR associated with inhibitory G-proteins. It has been classified in mammals into three highly homologous but distinct subtypes including α_{2A}, α_{2B}, and α_{2C}. α_{2A}-ADR is the most common subtype in the prefrontal cortex (PFC) but its expression is low in the striatum. In contrast, α_{2C}-ADR is predominantly expressed in the striatum and hippocampus but its expression is much

lower in the PFC. α_{2B}-ADR plays only a minor role in the brain, it is only weakly expressed in the central nervous system with a limited presence in the thalamus. Previous studies suggested that DA can inhibit adenylyl cyclase trough α_{2C}-ADR activation in mouse striatum and that norepinephrine (NE) can functionally interact with D_4R. Recently, we have reported that NE is a potent agonist for all D_2-like receptors. To our knowledge, inhibitory G_α subunits implicated in interactions between DA and α_2-ADR have not been determined. By using radioligand binding in brain membranes and by functional bioluminescent resonance energy transfer (BRET) assays in transfected HEK cells, the present study attempted a comparison between DA, NE and several synthetic dopaminergic ligands in their possible activation of α_{2A}- and α_{2C}-ADR. Using the non-selective α_2-ADR radioligand [^{3}H]RX821002 we determined the affinities of several DR ligands in sheep brain cortical and striatal membranes. Surprisingly, DA showed only ten-fold lower affinity than NE for α_2-ADR and the selective D_4R ligand Ro10-5824 was in the same range of NE affinity. Other assayed selective DR ligands had low to negligible ADR affinity. Functional BRET assays showed the activation of all inhibitory G_α subunits ($G_{\alpha i1}$, $G_{\alpha i2}$ $G_{\alpha i3}$, $G_{\alpha oA}$, $G_{\alpha oB}$) coupled to α_{2A} or to α_{2C}-ADR by DA and NE proving that D_2-like receptor ligands may act as potent agonists of these ADRs. Remarkably, DA binding to α_{2A} or to α_{2C}-ADR was only 2 to 25-fold less effective than NE in the activation of all inhibitory G_α subunits. Other DR ligands, such as the D_3R selective 7-OH-PIPAT, were also significantly effective. In conclusion, if α_2-ADRs promiscuously bind dopaminergic ligands in some brain regions, they should also be considered as functional dopaminergic receptors.

Title: Dopamine via dopamine receptor 4 alters GnRH neuron activity

Authors: ***L. DAIRAGHI**, S. CONSTANTIN, S. WRAY;
NIH, Bethesda, MD

Abstract: Gonadotropin-releasing hormone (GnRH) secreting neurons control fertility. The release of GnRH regulates the synthesis and release of both LH and FSH from the anterior pituitary. While it has been shown that dopamine is involved in the regulation of LH secretion, the mechanisms through which it does so remains unclear. Previous studies in adult rodents have reported juxtaposition of GnRH cells with fibers containing tyrosine hydroxylase, a marker of dopaminergic cells, and that application of exogenous dopamine inhibits GnRH neurons postsynaptically through D1- and/or D2-like dopamine receptors. Microchip data obtained from single GnRH neurons maintained in nasal explants indicated a high level of transcript for dopamine receptor 4 (Drd4). The present study examines the effect of Drd4 activation on GnRH neurons. Single cell RT-PCR and immunocytochemistry show a subpopulation of GnRH cells express the Drd4 transcript and receptor, respectively. Because intracellular calcium oscillations correlate with electrical activity, and many cells can be monitored simultaneously, calcium imaging was used to assess GnRH neuronal activity. Application of both apomorphine, a general dopamine receptor agonist, and PD168077, a Drd4-specific agonist, inhibited calcium oscillations in a subset of cells. Elimination of GABAergic and glutamatergic inputs to GnRH cells did not block the PD168077-mediated inhibition of GnRH neuronal activity. Together, these results indicate that dopamine directly inhibits GnRH neurons, through Drd4. Further experiments will determine the signaling pathway downstream of Drd4 activation and whether the Drd4 is the receptor subtype involved in inhibition in adult mice.

Title: Structure of LSD in complex with a human serotonin receptor

Authors: *B. L. ROTH, D. WACKER;
Pharmacol., Univ. of North Carolina At Chapel Hill, Chapel Hill, NC

Abstract: LSD is an extraordinarily potent and long-lasting psychedelic that apparently manifests its hallucinogenic effects in humans through serotonin (5-HT) G protein-coupled serotonin receptors. To gain structural insights into LSD's actions we elucidated the structure of LSD bound to a prototypical human serotonin receptor—5-HT_{2B}. The structure reveals a distinct

binding mode for LSD, along with striking conformational rearrangements required to accommodate LSD. Kinetic studies revealed that LSD has an exceptionally slow off-rate from both 5-HT_{2A} and 5-HT_{2B} receptors. We found that mutating a leucine in EL2 predicted to retain LSD in the binding pocket greatly accelerates LSD's binding kinetics, and significantly dampens LSD-mediated β-arrestin recruitment without affecting G protein signaling. These findings explain how LSD's binding mode may specify its unique kinetic and signaling properties and thereby provide an initial molecular explanation for LSD's actions at human serotonin receptors.

Title: Polychlorinated biphenyl 19 blocks G-protein coupled receptor-mediated Ca^{2+} signaling by blocking store-operated Ca^{2+} entry

Authors: *S.-H. LEE[1], K. LEE[1], S.-H. JO[2], K.-T. KIM[3], S.-Y. CHOI[1];
[1]Dent. Res. Institute, Seoul Natl. Univ., Seoul, Korea, Republic of; [2]Kangwon Natl. Univ. Sch. of Med., Chuncheon, Korea, Republic of; [3]Div. of Integrative Biosci. and Biotechnology, Pohang Univ. of Sci. and Technol., Pohang, Korea, Republic of

Abstract: PCB19 is one of non-dioxin-like polychlorinated biphenyls (NDL-PCBs) which are a component of Arochlor1260, ubiquitous pollutants. Especially NDL-PCBs affect cytosolic Ca^{2+} signaling via promoting Ca2+ release (from ryanodine receptor-sensitive Ca2+ pools) and inhibiting the store-operated Ca2+ entry from the extracellular space. However, the clue for NDL-PCB-mediated SOCE inhibition had accomplished with PC12 cells, of which SOCE is mainly mediated by TrpC family channels. Thus it is still unclear whether NDL-PCBs affect Orai-dependent SOCE as well. Here, we investigated the effects of PCB19 (*ortho*-substituted 2,2',6-trichlorinated biphenyl), one of NDL-PCBs on Orai-mediated SOCE in HEK293 cells, of which SOCE is solely mediated by intrinsic Orai channels. We found that PCB19 caused a rapid decline in the Ca^{2+} signaling of carbachol, a typical G_q- and phospholipase Cβ-coupled GPCR in HEK293 cells. PCB19 reduced thapsigargin-induced Ca^{2+} influx after Ca^{2+} pool depletion, suggesting that PCB19 inhibits Orai-mediated SOCE. PCB19-mediated SOCE inhibition was confirmed by demonstrating the ability of PCB19 to inhibit the SOCE current but not the TRPM7 current. These results imply that NDL-PCBs might inhibit not only TrpC-mediated SOCE as in PC12 cells, but also Orai-mediated SOCE as in many other cells including HEK293

cells, thereby interfering with GPCR signaling. **(Key words**: Polychlorinated biphenyl, PCB19, Ca^{2+} signaling, Orai, store-operated Ca^{2+} entry)

Title: Peripheral or central administration of GPR4 blocker NE 52-0057 does not affect central chemosensitivity or cardio-vascular homeostasis

Authors: ***S. KASPAROV**[1], P. S. HOSFORD[2], V. MOSIENKO[1], K. KISHI[1], G. JURISIC[3], K. SEUWEN[3], B. KINZEL[3], M.-G. LUDWIG[3], J. A. WELLS[2], I. N. CHRISTIE[2], A. V. GOURINE[2], A. G. TESCHEMACHER[1];

Abstract: G-protein coupled receptor 4 (GPR4) together with GPR65 and GPR68, comprises a family of proton-sensing receptors (http://www.guidetopharmacology.org). GPR4 is Gs coupled and drives production of cAMP. Our original study (Ludwig et al., 2003) demonstrated that it is inactive at pH >8 and essentially fully activated at neutral to slightly acidic pH. A recent publication (Kumar et al., 2015) suggested that in the mouse GPR4 is essential for central respiratory sensitivity to CO_2 and that GPR4 is selectively expressed by neurones of the retro-trapezoid nucleus (RTN) which has been extensively implicated in this phenomenon. To characterise expression of GPR4 in the brain we used a knock-in mouse where CRE is expressed from the genomic locus of GPR4. It was crossed with an EGFP-reporter mouse allowing lineage tracing of cells expressing GPR4. Consistent with Zhang et al. (2014), EGFP expression was particularly strong in endothelium throughout the CNS. Abundant expression of GPR4 was also detected in neurones of dorsal raphe and in lateral septum. Some, mainly non-noradrenergic neurones, in the locus coeruleus were also positive. Weak GPR4 expression was detected in some neurones of the RTN.

In transiently transfected HEK cells in the present series of experiments, the operational range of GPR4 was between pH~8.0 and 7.4, and at neutral pH (7.4) GPR4 was essentially fully activated. Novartis have developed a small molecule antagonist of GPR4, NE 52-0057. NE 52-0057 was highly effective in blocking GPR4-mediated cAMP accumulation with IC_{50} at pH 7.4 of 14.3 nM. We investigated whether this potent GPR4 blocker has any acute effects on cardio-vascular or respiratory activity in an anaesthetised rat model. At doses of up to 20 mg/kg (i.p.) NE 52-0057 did not affect major hemodynamic variables, cerebral blood flow and BOLD responses in somatosensory cortex to sensory stimulation. Systemic (up to 20 mg/kg i.p.) or direct central administration (1 mM onto the ventral surface of the medulla directly above RTN) of NE 52-0057 had no effect on resting respiratory activity or respiratory responses induced by increases in the level of inspired CO_2 (10%) under conditions of peripheral chemo-denervation. Thus, in the brain GPR4 is mainly expressed by endothelium but there are a few clusters of neurons which also express it. Current results argue against an essential role of GPR4 in central chemosensitivity in the rat. They also demonstrate that NE 52-0057 has no acute detrimental cardio-vascular or respiratory effects and lay the ground for further investigations of its possible uses in areas such as cancer therapy or other diseases where vascular proliferation plays an important role.

Title: Differential expression of the cannabinoid receptor 1 (CB1) as a function of the homozygous genotypes of the single nucleotide polymorphism rs2180619

Authors: **M. A. BARRERA-TLAPA**[1], G. BENÍTEZ-KING[2], S. ALARCÓN[2], U. CABALLERO-SÁNCHEZ[1], M. VÁLDES-TOVAR[2], M. MÉNDEZ-DÍAZ[3], O. PROSPÉRO-

Abstract: The single nucleotide polymorphism rs2180619 consists of a G/A change located in the 5´ regulatory region of the CNR1 gene, which codes for the cannabinoid receptor 1 (CB1). Recently, our research group has identified an association of the homozygous G genotype with a lower efficiency in the resolution of working memory tasks, as compared to homozygous A genotype healthy young Mexican subjects. Another research group, performing an *in silico* analysis, have shown that there are allele-specific differences in the affinity to transcription factors in rs2180619. Nonetheless, the physiological effect of rs2180619 has not been elucidated. In the present work, the difference in the expression of CB1 as a function of rs2180619 in the model of neuronal precursors isolated from olfactory epithelium of living subjects was evaluated. Samples from the olfactory neuroepithelium were taken by exfoliation from four homozygous A and four homozygous G subjects. Cells were cultivated and propagated up to passage 5-9. Western blot was made with the polyclonal anti CB1 antibody made in goat H-150, 1:1,500 (Santa Cruz, Biotechnology Inc, Dallas Tx, U.S.A). GAPDH protein was used as load control and was detected by the anti-GAPDH antibody made in mouse Millipore Mab. 374, 1:20,000 (Millipore, Darmstadt, Germany). Optic densities (OD) of the bands corresponding to the glycated form of CB1 (± 63 KDa) were determined by densitometry. AA subjects showed less relative quantity (OD/mm^2) of CB1 with respect to homozygous G. This result suggest a specific-allele effect of rs2180619 in the expression of CB1 in young healthy subjects and add up to the knowledge of physiology of individual variations associated to cognitive function.

Title: The putative cannabinoid receptor gpr55: expression, modulation of hippocampal plasticity and behavior

Authors: *K. M. HURST, C. BADGLEY, J. EDWARDS;
BYU, Provo, UT

Abstract: Memory occurs due to experience-dependent changes in the brain. These changes are mediated by synaptic plasticity, particularly in the hippocampus. Plasticity can either strengthen or weaken synapses, the former is known as long-term potentiation (LTP). While many forms of plasticity are NMDA-dependent, endocannabinoids mediate several forms of plasticity. Endocannabinoids bind to receptors such as cannabinoid receptor 1 (CB1) and transient receptor potential vanilloid 1 (TRPV1) in various brain areas including the hippocampus. Research has demonstrates a hippocampal non-CB1/TRPV1-dependent endocannabinoid synaptic plasticity. While the receptor(s) involved is unknown, potential candidate receptors that bind the endocannabinoid anandamide have been identified, including orphan G-protein coupled receptors (GPRs) whose distribution and/or function are not well known. GPR55 is of interest as its activation enhances IP3-mediated increases in intracellular calcium. Using quantitative RT-PCR, electrophysiology and memory tasks, we examined hippocampal GPR55 expression and function. GPR55 is expressed in hippocampus of both rats and mice. Application of the GPR55 agonist LPI (2 μM) to wild-type (WT) mice significantly enhanced CA1 hippocampal LTP. This effect was absent in GPR55 knock-out (KO) mice, which exhibit significantly ($p < 0.05$) smaller LTP (146%) than WT (181%). However, LTP in WT and KO mice in the absence of LPI are not significantly different. The GPR55 antagonist CID 16020046 (10 μM) also blocked LPI enhancements in WT mice. GPR55 also appears to increase release probability (Sylantyev et al., PNAS, 2013), denoting a presynaptic role. We examined paired-pulse ratios (PPR) of KO and WT mice with or without LPI. While there is only a slight difference between KO and WT PPRs, after application of LPI there is a significant increase in PPR of WT mice not noted in KO mice, suggesting increased transmitter release but not increased probability. Whole cell patching on interneurons shows no effect on baseline when LPI is applied to the bath (n=3). IHC demonstrated GPR55 in Pyramidal cells in CA1 and CA3 layers of the hippocampus. Behaviorally, KO and WT mice did not differ in the novel object recognition test, and in the radial arm maze task examining spatial memory, KO and WT littermates performed similarly, however KO mice have a higher frequency of anxiety behavior during the task. These data suggest GPR55 is expressed and physiologically relevant in the hippocampus. Because enhanced LTP is often associated with better memory performance, this provides a potential target to enhance the cellular mechanism associated with memory formation.

Title: Sgip1 alters internalization and modulates signaling of activated cannabinoid receptor 1 in biased manner

Authors: *J. BLAHOS[1], A. HÁJKOVÁ[2], M. DVOřÁKOVÁ[2], L. PREZEAU[3], S. RADENKOVIč[4];

Abstract: Many diseases of the nervous system are accompanied by alterations in synaptic functions. Synaptic plasticity mediated by the endogenous cannabinoid system involves the activation of the cannabinoid receptor 1 (CB1R). The principles of CB1R signaling must be understood in detail for its therapeutic exploration. We detected the Src homology 3-domain growth factor receptor-bound 2-like (endophilin) interacting protein 1 (SGIP1) as a novel CB1R partner. SGIP1 is functionally linked to clathrin-mediated endocytosis and its overexpression in animals leads to an energy regulation imbalance resulting in obesity. We report that SGIP1 prevents the endocytosis of the activated CB1R and that it alters signaling via the CB1R in a biased manner. The CB1R mediated G-protein activation is selectively influenced by SGIP1, the β-arrestin associated signaling is changed profoundly, most likely as a consequence of the prevention of the receptor's internalization elicited by SGIP1.

Abstract: Recent studies suggest that cannabinoids may produce different pharmacological actions in experimental species, suggesting that cannabinoid effects in one species cannot be directly extrapolated to another species. We hypothesize that species differences in CB_1R and CB_2R expression, protein structure and function may contribute to different pharmacological actions produced by cannabinoids in different species. Using quantitative RT-PCR, we found species-specific differential expression of CB_1R and CB_2R isoforms in brain regions and peripheral tissues. Human *CNR1* gene may transcribe six different isoforms, and three of them encode CB_1Rs with three different N-terminal amino acid alterations - CB_1R_{472}, CB_1R_{439} and CB_1R_{411}. In contrast, rhesus monkey and rodent *Cnr1* gene transcribes isoforms encoding 472 and 473 amino acids, respectively, without N-terminal variants. Regarding CB_2 receptors, human, rhesus monkey and rat *Cnr2* genes encode 360 amino acids while mouse *Cnr2* gene encodes 347 amino acids with a premature stop codon at its C-terminus. Based on these findings, we predict that different promoters, epigenetic signatures, exons and/or different sequences in 5'-UTR and 3'-UTR of different isoforms may alter CB_1/CB_2 receptor expression in different tissues, brain regions and/or different cellular types, and therefore, contribute to different CB_1/CB_2 receptor responses in different species. Computer modeling of the 3-D structures found significant species differences in receptor structures such as opposite charged amino acid residues located in the vicinities of putative ligand binding sites. Different species also display different pharmacological responses to the same ligands. Systemic administration of ACEA (a selective CB_1R agonist) significantly inhibited spontaneous wheel running activity in rats, but it

was less effective in C57 mice, and not effective in BTBR mice. Conversely, systemic administration of WIN55212-2 (a dual CB_1/CB_2 receptor agonist) significantly reduced spontaneous wheel running activity in BTBR mice, but it was less effective in C57 mice, and not effective in rats. Similarly, systemic administration of JWH133 (a selective CB_2R agonist) significantly inhibited intravenous cocaine self-administration in mice, but not in rats. Taken together, all these findings suggest significant species differences in cannabinoid receptor structures and functions. We propose rhesus monkey (www.rhesusbase.org/) with similar CB_1R and CB_2R structure and function to Homo sapiens as a potential animal model for cannabis-based medication development for human diseases. Title: Synaptic actions of isoflurane on hippocampal and cortical connections

Authors: *B. MACIVER;
Anesthesia, Stanford Univ., Stanford, CA

Abstract: Background/Introduction: Anesthetics are known to depress synaptic transmission, and this effect is thought to underlie the uncoupling of brain regions seen with cortical EEG recordings. We tested the hypothesis that anesthetic-induced depression of synapses leads to uncoupling of electrical activity between frontal cortex and hippocampus. Methods: The present study used electrophysiologically-guided electrode implants to record Schaffer-collateral to CA1 neuron mono-synaptic responses, as well as frontal cortical micro-EEG signals, using a IRB approved protocol. Rats were allowed to recover from surgery and then isoflurane effects were characterized after several days (>7) to several months (<7) later. Simultaneous recordings of cortical and hippocampal micro-EEG signals, evoked synaptic responses, anesthetic concentration, vital signs and behavior were made. Results: Loss of consciousness, measured as righting reflex, was consistently associated with increased synchronized delta activity, in hippocampus and cortex, as well as a novel ~15 Hz rhythmic oscillation produced by isoflurane

in hippocampal micro-EEG recordings. Surgical anesthesia, measured as loss of tail-clamp reflex, was observed on the transition to burst-suppression activity in both hippocampal and cortical micro-EEG signals. Isoflurane produced a concentration-dependent depression of mono-synaptic responses: at surgical anesthetic depths, excitatory postsynaptic potentials were depressed by 26.6 ± 4.2 % (n=5; $p<0.001$) of control amplitudes, but surprisingly, coupling between cortex and hippocampus was further enhanced. Conclusion: Clearly, our hypothesis was wrong, since increased coupling between brain regions was observed at the same time that mono-synaptic responses were depressed. We demonstrate for the first time that cortical-hippocampal coupling is increased at both low (loss of consciousness) and at high surgical concentrations of isoflurane. Title: The effect of Ferrostatin-1 on intrinsic and synaptic properties of hippocampal neurons

Authors: *V. I. NAVARRO[1], L. P. MONTES[2], C. D. LOYOLA BALTAZAR[2], R. SKOUTA[2], K. FENELON[2];
[1]Biol. Sci., Univ. of Texas At El Paso, El Paso, TX; [2]Biol. Sci., Univ. of Texas at El Paso, El Paso, TX

Abstract: Synaptic transmission and cellular excitability is fundamental for the normal function of brain circuits and neuronal systems. Loss or dysfunction of such neuronal communication is associated with many psychiatric and neurodegenerative disorders affecting populations worldwide. In patients suffering from these disorders, both genetic and non-genetic factors can increase cellular levels of reactive oxygen species (ROS) beyond physiological levels. Generated in excess, reactive species can damage cellular lipid membranes, proteins and DNA, leading to abnormal neural growth, differentiation and function. At the neuronal level, elevated ROS levels

have been associated with an increased synaptic transmission and excitability that could lead to cell death in *in vitro* and *in vivo* assays. Therefore, novel small antioxidant molecules able to decrease synaptic transmission and neuronal excitability would represent a promising treatment for disorders associated with increased reactive species. Ferrostatin-1 (Fer-1) is a small antioxidant molecule that can prevent the death of hippocampal neurons exposed to neurotoxic glutamate levels (Dixon et al., 2012). Fer-1 also decreases neuronal death in various disease models including Huntington's disease (HD) brain slices (Skouta R. et al., 2014). Neurons exposed to such assays are normally hyperexcitable. However, the effects of Fer-1 on synaptic transmission and neuronal excitability are unknown even under physiological conditions. The objective was to evaluate the effect of Fer-1 on synaptic and intrinsic properties of healthy hippocampal neurons using mouse brain slices. To do so, extracellular field electrophysiological recordings were performed at the CA1-Schaffer collateral synapses. Synaptic transmission, synaptic plasticity and axonal excitability were assessed in the absence (control) and in the presence of 100 μM Fer-1 (N=7). Our preliminary results suggest that Fer-1 tended to reduce synaptic transmission and axonal excitability of hippocampal neurons. We conclude that in addition to its previously described neuroprotective effects, Fer-1 might also decrease synaptic transmission and cellular excitability in diseases with an excess of ROS.

Title: Effects of early lead exposure on synaptic transmission and plasticity in mouse hippocampal neurons

Authors: *L. E. MARTINETTI, A. TENA, E. PERU, K. FÉNELON;
Dept. of Biol. Sci., The Univ. of Texas At El Paso, El Paso, TX

Abstract: Lead (Pb) is a ubiquitous environmental neurotoxicant that causes behavioral and cognitive deficits. Low-level Pb exposure induces learning and memory deficits in children from low socioeconomic neighborhoods found across the United States. Previous studies reported that high-levels of Pb exposure alter the function of the hippocampus, a key brain region for learning and memory. However, the neuronal mechanisms by which lowest-level chronic Pb exposure affects hippocampal function are still ill defined, due to the lack of animal models. Moreover, the long-term effects of Pb on hippocampal neurons of males and females long after exposure has ceased is unknown. Therefore, we compared control adult mice to mice exposed from birth to post-natal day 28 to either high Pb levels (330 ppm) or low Pb levels (30 ppm). Mice exposed to such low-level Pb were previously shown to exhibit poorer exploratory ambulation (Flores-Montoya and Sobin, 2014) and impaired novel odor discrimination (Flores-Montoya et al, 2015), which are hippocampus-dependent behaviors. Using both high and low Pb exposed male and female mice, extracellular field electrophysiological recordings were performed in the CA1 region of acute hippocampal slices. Our results show that synaptic transmission is decreased in low Pb-exposed mice (Control: N=17 animals; n=24 slices; High Pb: N=13 animals; n=22 slices; Low Pb: N=12 animals; n=19 slices). Interestingly, Pb-exposure had different effects when males and females were compared. In males (Control: N=10 animals; n=16 slices; High Pb: N=10 animals; n= 16 slices; Low Pb: N=4 animals; n=8 slices), low Pb exposure affected synaptic transmission and neuronal fiber excitability whereas in females (Control: N=7 animals; n=8 slices; High Pb: N=3 animals; n=6 slices; Low Pb: N=8 animals; n=11 slices), high Pb exposure affected these cellular properties. Previously, children exposed to low-level Pb showed working memory deficits (Sobin et al., 2015), suggesting an abnormal functional connection between the hippocampus and the medial prefrontal cortex (mPFC). Therefore, we performed

Optogenetics experiments in acute medial PFC slices using these Pb exposed mice to determine if hippocampus-mPFC synapses were altered. Our results show that low Pb exposure altered synaptic transmission whereas high Pb exposure affected short-term synaptic depression at the hippocampal-PFC synapses (Control: N=5 animals; n=6 slices; High Pb: N=4 animals; n=8 slices; Low Pb: N =2 animals; n=3 slices). Overall, these results contribute to better understand the long-term effects of Pb exposure on learning and memory highly relevant to children exposed to Pb early in life.

Title: Characterization caudal pontine reticular nucleus afferent connections relevant to sensorimotor gating

Authors: J. C. CANO, ***S. A. PACE**, K. FÉNELON;
Univ. of Texas - El Paso, El Paso, TX

Abstract: Sensorimotor gating (SG) is a neural sensory filtering process thought to be governed by central inhibitory mechanisms to help focus attention. SG is impaired in several neuropsychiatric disorders, such as anxiety, autism spectrum disorders, schizophrenia, and post-traumatic stress disorder affecting patients worldwide. Extensive work on the circuitry underlying SG has revealed a key connection between the pedunculopontine tegmental area (PPTg) and the caudal pontine reticular nucleus (PnC), the latter being located at a crucial position between the sensory input and the motor output of the SG circuitry. Furthermore, previous studies where the PPTg-PnC connection was inhibited showed a reduced, but persistent, SG. However, how the PnC is connected to the rest of the brain is unknown. Although, previous studies have identified a few brain circuits contributing to SG, our objective was to further identify neurons directly connected to the PnC since these connected neurons could potentially contribute to SG. Therefore, we hypothesize that other brain areas anatomically connected to the PnC remained to be identified. Our hypothesis was guided by previous *in vivo* lesion studies showing that regions such as the central nucleus of the amygdala (CeA) and the medial prefrontal cortex (mPFC) are important for SG. Here, we first confirmed that the CeA and the mPFC were anatomically connected to the PnC using the retrograde neuronal tracer fluorogold in healthy adult mice (CeA-PnC, n=4; mPFC-PnC, n=2). Second, to further characterize the CeA-PnC and mPFC-PnC connections, Channelrhodopsin-2 was injected in the mouse CeA and mPFC, and extracellular field recordings were performed 6 weeks later in acute PnC slices. Photostimulation of the CeA (n=7) and mPFC (n=2) projection fibers activated PnC neurons confirming that these connections are excitatory, monosynaptic and exhibit short-term synaptic plasticity. Better understanding the CeA-PnC and mPFC-PnC connections might reveal potential therapeutic targets for future medical interventions in diseases associated with SG deficits.

Title: Endocannabinoid control of NMDAR-dependent supra-linear dendritic integration via co-agonist supply

Authors: *K. BOHMBACH[1], E. M. SCHÖNHENSE[1], D. MINGE[1], A. ZIMMER[3], H. BECK[2], C. HENNEBERGER[1,4,5];
[1]Inst. of Cell. Neurosciences, [2]Dept. of Epileptology, Univ. of Bonn Med. Sch., Bonn, Germany; [3]Inst. of Mol. Psychiatry, Univ. of Bonn, Bonn, Germany; [4]German Ctr. of Neurodegenerative Dis. (DZNE), Bonn, Germany; [5]Inst. of Neurol., Univ. Col. London, London, United Kingdom

Abstract: Individual dendrites of hippocampal CA1 pyramidal cells integrate local synaptic input. Supra-linear integration of spatially clustered CA3-CA1 input depends on amplification of synaptic input by voltage-gated sodium channels and N-methyl-D-aspartate receptors (NMDARs). Our previous work demonstrated that NMDAR function at these synapses depends on astrocyte supply of the NMDAR co-agonist D-serine (Henneberger *et al.* 2010). This observation implies that also NMDAR-dependent supra-linear integration is controlled by NMDAR co-agonist supply. We used whole-cell patch clamp combined with micro-iontophoretic glutamate application and two-photon excitation fluorescence microscopy to test this hypothesis in acute hippocampal slices from Wistar rats and C57BL/6 mice. We find that, indeed, application of exogenous D-serine reduces the threshold of dendritic spikes, a hallmark of supra-linear dendritic integration, and increases their amplitude. Endogenous D-serine supply depends on astrocyte Ca^{2+} signaling and activation of astrocyte endocannabinoid receptors (CB1R) potently triggers astrocyte Ca^{2+} transients. As expected, application of the CB1R agonist WIN55-212,2 induced prominent Ca^{2+} transients in astrocytes but also boosted supra-linear integration. The latter was not observed in the presence of D-serine at a concentration that saturates the NMDAR co-agonist binding site. Thus, pharmacological CB1R activation increases NMDAR co-agonists supply, likely via astrocyte Ca^{2+} signaling, thereby lowering the threshold of dendritic spikes and increasing their amplitude. Endogenous activation of CB1R occurs when

CA1 pyramidal cells depolarize. Therefore, increasing CA1 pyramidal cell activity should activate the CB1R-dependent boost of supra-linear dendritic integration. We tested this by antidromic activation of CA1 pyramidal cells using electrical stimulation of alvear axons. Activating about 40 percent of CA1 pyramidal cells, revealed by GCaMP5G imaging, was sufficient to decrease the dendritic spike threshold and to increase their amplitudes. Again, this effect was not seen in the presence of saturating concentrations of exogenous D-serine. Importantly, blockade of CB1Rs using AM251 also prevented this effect on dendritic integration. Similarly, alveus stimulation evoked astrocyte Ca^{2+} transients that were sensitive to CB1R inhibition by AM251. In summary, we reveal a novel signaling pathway that creates a positive feedback of CA1 pyramidal cell population activity on their supra-linear dendritic integration involving CB1R-dependent NMDAR co-agonist supply.

Title: Excitatory synaptic signaling in parvalbumin positive interneurons in mouse primary visual cortex

Authors: *L. SANCHO[1], B. L. BLOODGOOD[2];
[1]Neurosciences Grad. Program, UC San Diego, La Jolla, CA; [2]UC San Diego, LA Jolla, CA

Abstract: Dendritic spines are small, membranous protrusions that enclose excitatory synapses and function as specialized biochemical and electrical signaling compartments. On densely spiny neurons, such as pyramidal cells, spines enhance the signaling repertoire of the enclosed synapse and support synapse-specific plasticity. On sparsely spiny interneurons such as parvalbumin basket cells (PVBCs), the majority of synapses are made directly onto the dendritic shaft. We find that in primary visual cortex of juvenile mice, layer 2/3 PVBCs have approximately 1 spine per 10 microns. Using extracellular stimulation of presynaptic terminals, whole-cell electrophysiology, pharmacology, and two-photon glutamate uncaging and calcium (Ca^{2+})

imaging we demonstrate that these spines enclose functional excitatory synapses with heterogeneous glutamate receptors and ion channels. Moreover, the complement of receptors at spine synapses is distinct from what is present at nearby dendritic synapses. Consequently, we hypothesize that spine and dendritic synapses will implement different plasticity rules to modulate synaptic Ca^{2+} signaling and to detect the co-incident activation of neighboring synapses.

Title: Synaptic connections between hippocampal CA2 pyramidal cells

Authors: *K. OKAMOTO[1], Y. IKEGAYA[2];
[1]The Univ. of Tokyo, Bunkyo-Ku, Japan; [2]The Univ. of Tokyo, Tokyo, Japan

Abstract: Among hippocampal subregions, the CA2 region is unique. CA2 neurons receive strong extrahippocampal input from the subcortical area, including the hypothalamus (Chevaleyre *et al.*, 2010), and alter their firing patterns sensitively to subtle environmental changes (Mankin *et al*., 2015) and to the current location during immobility and sleep (Kei *et a*l., 2016). Moreover, the CA2 region is associated with social recognition (Hitti *et al*., 2014). Although recent studies have increasingly focused on the function of the CA2 region, its local circuit structure remains to be elucidated. It is assumed that CA2 pyramidal neurons have many recurrent connections, based on their dense neurite arborizations (Dudek *et al*., 2016), but there is little electrophysiological evidence. Here, we used multiple whole-cell patch-clamp recordings from CA2 pyramidal cells and computed their connection probability.

Title: Abundance of recurrent and lateral inhibition in the dentate gyrus of the hippocampus

Authors: C. ESPINOZA, *S. J. GUZMAN, P. JONAS;
Inst. of Sci. and Technol. (IST) Austria, Klosterneuburg, Austria

Abstract: The dentate gyrus, the input region of the hippocampus, is thought to play a key role in several higher brain functions, such as grid-to-place code conversion and pattern separation. For these computations, the granule cell-GABAergic interneuron microcircuit plays a critical role. However, the connectivity of this important region of the brain is largely unknown. To determine the functional connectivity rules in the dentate gyrus, we made simultaneous octuple patch-clamp recordings from synaptically connected granule cells and interneurons in acute hippocampal slices. Parvalbumin (PV)-expressing interneurons were identified by epifluorescence or confocal microscopy in a parvalbumin-Cre x Ai14 mouse line before the experiment, and their identity was confirmed by the fast-spiking action potential phenotype in subsequent whole-cell recording. This allowed us to obtain an unbiased estimate of connectivity, examine the abundance of connectivity motifs, and determine the summation rules for converging excitatory inputs. In total, we found 24 synaptic connections in 15 octuples of neurons. The average probability of excitatory synaptic connections was 0.167, and the probability of inhibitory synaptic connections was 0.30. Excitatory synaptic connectivity between granule cells and PV+ interneurons declined for an inter-somatic distance of >150 μm, whereas inhibitory synaptic connectivity between PV+ interneurons and granule cells remained relatively constant. In granule cell-PV+ interneuron pairs in which the PV+ interneuron received excitation from the granule cell, the inhibitory connection probability was 0.13. However, in granule cell-PV+ interneuron pairs in which the PV+ interneuron lacked excitation from the granule cell, the inhibitory connection probability was 0.30. Thus, within dentate gyrus inhibitory microcircuits, lateral inhibition is more abundant than recurrent inhibition. In cases where multiple granule cells were connected to a given PV+ interneuron, summation of EPSPs was approximately linear. Plots of EPSP amplitude against number of stimulated inputs suggested that ~5 unitary excitatory inputs have to be synchronously activated to evoke action potentials in a postsynaptic PV+ interneuron. In conclusion, PV+ interneurons operate as coincidence detectors of local excitatory synaptic activity. Furthermore, PV+ interneurons

distribute an inhibitory output signal to a large number of granule cells by lateral inhibition. These results indicate that lateral inhibition is a major factor shaping pattern separation in the principal neuron-interneuron microcircuits of the dentate gyrus.

Title: Properties and detailed temporal dynamics of inhibitory synaptic communication between perisomatic-region targeting inhibitory neurons and pyramidal cells in mouse hippocampal CA3 region.

Authors: *D. SCHLINGLOFF, Z. KOHUS, S. KÁLI, L. ROVIRA-ESTEBAN, O. PAPP, T. F. FREUND, N. HÁJOS, A. I. GULYÁS;
Inst. of Exptl. Medicine, HAS, Budapest, Hungary

Abstract: The CA3 region of the hippocampus is able to generate synchronous network activities intrinsically, and it is crucial for cognitive functions like spatial navigation and long-term memory consolidation. Pyramidal cells and their perisomatic region-targeting interneurons, including parvalbumin (PV)-expressing basket cells, axo-axonic cells and cholecystokinin (CCK)-containing basket cells are the critical elements of the CA3 networks in the generation and control of physiological (sharp wave-ripples, gamma oscillation) and pathological (epileptic) activity patterns. Synaptic interactions among these cell types are thought to be critical for

current and rhythmogenesis. Using paired recordings in the CA3 area of mouse hippocampal slices, we determined the detailed properties and dynamics of inhibitory synaptic communication between morphologically identified inhibitory cells and their pyramidal cell and interneuron targets using action potential patterns recorded during physiological and pathological network states. PV+ and CCK+ interneurons had distinct intrinsic physiological features. Interneurons of the same type, except axo-axonic cells, formed reciprocally connected subnetworks, while the connectivity between the interneuron classes was rather sparse. The characteristics of unitary interactions depended on the identity of both pre- and postsynaptic partners, while the short-term plasticity of synaptic transmission depended mainly on the presynaptic cell type. PV+ interneuron output showed frequency-dependent depression, while more complex dynamics involving facilitation, depression, and asynchronous release characterized the output of CCK+ interneurons. We captured the dynamics of transmission at these different types of connection with simple mathematical models, and described quantitatively the response to physiological and pathological discharge patterns. Our findings support the view that intrinsic and synaptic features of PV+ cells make them ideally suited for the generation of physiological network oscillations, while the continuum of CCK+ cells implement more subtle, graded control.

Title: Afferent synaptic connectivity of the medial septum

Authors: ***F. FUHRMANN**[1], D. JUSTUS[1], D. FRIEDRICHS[1], M. K. SCHWARZ[2], S. REMY[1,3];
[1]German Ctr. For Neurodegenerative Dis. DZNE, Bonn, Germany; [2]Dept. of Epileptology, Functional Neuroconnectonics Group, [3]Dept. of Epileptology, Univ. of Bonn Med. Ctr., Bonn, Germany

Abstract: The medial septum and the diagonal band of Broca (MSDB) modulate the activity of memory circuits in the hippocampal formation (Winson, 1978; Oddie et al., 1996). In addition to the role of MSDB parvalbuminergic neurons (PV^+) as pacemakers for hippocampal rhythmic

oscillations (Hangya et al., 2009), we have shown that MSDB glutamatergic neurons ($VGluT2^+$) mediate a hippocampal state-transition associated with locomotion (Fuhrmann et al., 2015). The activity of MSDB $VGluT2^+$ neurons underlies the speed-modulation of theta oscillations and the speed-modulation of the firing of pyramidal neurons in the hippocampus and entorhinal cortex. Since MSDB activity may contributes to a dynamic representation of self-location during navigation at different speed, it is important to understand the afferent connectivity to the MSDB. Using cre-dependent mono-transsynaptic retrograde tracing we localized specific synaptic input regions onto MSDB $VGluT2^+$ neurons. We found monosynaptic input neurons in several hypothalamic subregions and the median raphe nuclei. We identified the medial preoptic area (MPO), the median preoptic nucleus (MEPO), the periventricular hypothalamic nucleus (PVpo), the arcuate hypothalamic nucleus (ARH) , the lateral hypothalamic area (LHA), the posterior hypothalamic nucleus (PH) and the supramammillary nucleus (SUM) as specific input regions onto MSDB $VGluT2^+$ neurons.
Consistent with excitatory input from PH electrical stimulation of this area reliably evoked locomotor behavior and theta oscillations. We now combine electrical stimulation with cell-type specific silencers in the MSDB and use mono-transsynaptic retrograde tracing to understand the integration and the role of specific afferent input onto MSDB glutamatergic, parvalbuminergic and cholinergic neurons during theta oscillations and locomotor behavior.

Title: Modulation of neuronal excitation/inhibition balance by the light/dark cycle

Authors: ***K. HE**[1], M. D. BRIDI[2], A. KIRKWOOD[2];
[1]IRCBC, Chinese Acad. of Sci., Shanghai, China; [2]Mind/Brain institute, Johns Hopkins Univ., Baltimore, MD

Abstract: It is widely accepted that neural processing depends critically on the balanced interplay of excitation and inhibition, a balance that is dynamically maintained within permissive limits. Dysregulation of neuronal excitation/inhibition (E/I) balance has been implicated in several disorders including schizophrenia, autism, and Alzheimer's disease. Much research has focused on plastic mechanisms responsible for maintaining the E/I balance and much less is

known about how it might naturally change. Here we focused on investigating the contribution of light/dark cycle, which is correlated with the sleep/wake cycle in mouse, to the E/I regulation of the pyramidal neurons in both neocortices and hippocampus. Our results indicate that the measures of strength for excitatory and inhibitory synaptic transmission are modulated by the light/dark cycle, and surprisingly, in the opposite manner: excitation is high when inhibition is low. This leads to large fluctuations in E/I balance during the light/dark cycle. This rhythmic modulation is reflected in both single cell and network levels, and is consistent across different neocortical regions and hippocampus, suggesting that the light/dark modulation of neuronal E/I balance might be generalized to multiple brain structures.

Title: Molecular analysis of Tau in canine brain and csf

Authors: *K. VAN KOLEN[1], D. VAN HAVER[2], D. DHUYVETTER[1], L. DELBROEK[1], I. VERBERNE[1], A. F. MARREIRO[3], M. VANDERMEEREN[1], K. GEVAERT[2], I. PIKE[4], M. WARD[4], D. LATTO[4], H. BORGHYS[1], M. H. MERCKEN[1];
[1]Janssen PRD, Beerse, Belgium; [2]Proteomics expertise center, VIB/UGent, Gent, Belgium; [3]Functional genomics and proteomics, KUL, Leuven, Belgium; [4]Proteome Sci., London, United Kingdom

Abstract: Background: Tau is the main component of neurofibrillary tangles and the current assumption is that neuronal loss results in passive release of this protein in the extracellular space resulting in an increase in both total and phosphorylated Tau in different neurodegenerative diseases. Nevertheless, little is known about the molecular signature of this protein in cerebrospinal fluid (CSF) and how this profile changes in response to Tau-directed therapies. Since CSF collection from mice and rats is not trivial and yields low sample volumes, other preclinical model systems are required. In this respect, studies performed in dog demonstrated spontaneous amyloid plaque formation in function of aging but changes in brain and CSF Tau are poorly documented. The aim of this study is to identify antibody combinations to detect and characterize Tau fragments in canine brain and CSF.

Methods: Pooled dog CSF samples were investigated with sandwich ELISA's and MSD assays using a panel of Tau antibodies directed to a large variety of Tau epitopes. Antibodies giving a positive signal were further validated by immunodepletion experiments combined with mass spectrometry analysis. In parallel a quantitative proteomics analysis (TMTcalibrator™, Proteome Sciences) was performed to estimate the coverage of the Tau protein and other proteins in canine CSF.
Results: Antibodies reacting with Tau in dog CSF samples could be identified. These antibodies are currently used to determine the molecular fingerprint of Tau in dog CSF. Use of the TMT calibrator™ approach showed high coverage of the tau sequence. Although, selective enrichment of phosphopeptides was not employed, it was still possible to detect multiple tau phospho-peptides, likely reflecting the most abundant epitopes in canine CSF. Despite this high coverage, IP/MS experiments showed a differential recovery of Tau peptides depending on the epitope of the antibody used for the pulldown. These data suggest that a substantial fraction of Tau in CSF is fragmented as confirmed by different MSD assays on immunodepleted CSF samples.
Conclusions: This study compared the molecular profile from Tau present in canine CSF to Tau extracted from brain. Although, we provide evidence for the presence of full length Tau, the majority of this protein seems to be fragmented in CSF. Several antibody combinations can be used to quantify those fragments and future studies will shed light on the potential use of those fragments as pharmacodynamic markers for Tau-directed therapies in AD.

Title: Selective regional and neuronal vulnerability in frontotemporal dementia with MAPT mutations

Authors: *L.-C. LIN, J. A. BROWN, L. T. GRINBERG, W. W. SEELEY;
Neurol., Univ. of California, San Francisco, San Francisco, CA

Abstract: Autosomal dominant mutations in the gene encoding microtubule-associated protein tau (*MAPT*) present with behavioral variant frontotemporal dementia (bvFTD) due to tau aggregation and neurodegeneration in anteromedial temporal, amygdala, frontoinsula (FI), and anterior cingulate cortex (ACC). Cell type-specific vulnerability within these regions remains largely unexplored. Patients with sporadic bvFTD show early selective loss of layer 5 von Economo neurons (VENs) in the FI and ACC. Here, we investigated selective regional and neuronal vulnerability in patients with bvFTD due to mutation in *MAPT*. We performed detailed morphological and immunohistochemical analyses of tau pathomorphologies in 54 regions of 5 subjects with FTDP-17 (2 IVS10+16 C>T, 2 P301L, 1 V337M), and compared the findings to 6 patients with bvFTD due to Pick's disease (PiD), a sporadic tauopathy. Nonspecific features of neurodegeneration, including microvacuolation, astrogliosis, and neuronal loss, were semi-quantified based on hematoxylin and eosin stains. Ten tau aggregate types were semi-quantified using an early phosphorylated tau antibody CP13. To assess the overall tau pathomorphologies of each region, we calculated a composite score by adding tau and neurodegeneration scores. The top five most vulnerable regions (highest composite scores) in bvFTD-*MAPT* were entorhinal cortex, locus coeruleus, middle insula, subgenual cingulate cortex, and anterior mid-cingulate cortex. This pattern overlapped with the vulnerability seen in PiD, with 4 of the top 5 regions being identical (except for locus coeruleus). Comparing VENs and neighboring layer 5 neurons bearing tau inclusions in bvFTD-*MAPT*, our preliminary data suggested that VENs were more prone to pathological tau inclusions than neighboring layer 5 neurons in the FI and ACC. Our results indicate a common, early, regional and neuronal vulnerability in the FI and ACC to pathological tau inclusions across bvFTD due to mutations in *MAPT* and PiD. These findings begin to provide neuroanatomical grounding for further investigation of selective vulnerability in sporadic and familial tauopathies.

Title: Loss of SFPQ, an intra-nuclear counterpart of FUS causes FTLD-like phenotypes

Authors: *Y. FUJIOKA[1], S. ISHIGAKI[1], S. YOKOI[1], D. HONDA[1], H. OKADO[2], H. WATANABE[1], M. KATSUNO[1], G. SOBUE[3];
[1]Neurol., Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan; [2]Dept. of Brain Develop. and Neural Regeneration, Tokyo Metropolitan Inst. of Med. Sci., Tokyo, Japan; [3]Res. Div. of Dementia and Neurodegenerative Disease, Nagoya Univ. Grad. Sch. of Med., Nagoya, Japan

Abstract: [Objective]We identified splicing factor, proline- and glutamine rich (SFPQ) as a counterpart of FUS in the nucleus. SFPQ regulates alternative splicing of the Mapt gene at Exon 10 as FUS does. Because the disease mutations in FUS affect the interaction between FUS and SFPQ, we speculated that the interaction is critical for the function of FUS, especially for maintaining the balance of Mapt isoforms. Therefore, we investigate the phenotypes of SFPQ-silenced animals. [Methods]We injected AAV encoding shRNA against SFPQ (shSFPQ) and control to the bilateral hippocampus of C57/BL6J. Next, we performed co-injection of AAV encoding shRNA against Mapt Exon10+ isoform (4-repeat tau:4R-T). These mice were subjected to various behavioral analysis. Sequentially, MRI and immunohistological analysis were performed. [Results]Silencing of SFPQ resulted in an increased ratio of 4R-T/3R-T and exhibited FTLD-like behavioral impairments as well as reduced adult neurogenesis as seen in shFUS mice. Long-term observation revealed phosphorylated tau accumulation and drastic neuronal loss in shSFPQ mice. Co-silencing of 4R-T ameliorated the behavioral phenotypes and reduced neurogenesis; however, it could not rescue neuronal loss in shSFPQ mice. [Conclusions]Loss of SFPQ caused FTLD-like phenotypes, including aberrant behaviors, reduced adult neurogenesis, and phosphorylated tau accumulation mediated by alteration of tau isoforms. These findings are similar with those in FUS-silenced mice, suggesting that SFPQ is essential for the pathogenesis of FTLD/ALS in which quality loss of FUS is associated.

Title: Optogenetic based regulation of autophagy against tauopathies

Authors: *J. BINDER[1], J. WEICK[2], V. DERETIC[1], K. BHASKAR[1];
[1]MGM, [2]Neurosciences, Univ. of New Mexico, Albuquerque, NM

Abstract: Filamentous aggregation of microtubule associated protein tau, as neurofibrillary tangles (NFTs), is a major pathological hallmark of tauopathies including Alzheimer's disease (AD). This pathological tau (p-Tau) impairs microtubule function, axonal transport and synaptic function, which in turn strongly correlate with cognitive decline. Multiple reports have suggested impaired autophagic clearance of p-Tau within neurons leads to NFT pathology and neurodegeneration. Transcription factor EB (TFEB), which is a master regulator of autophagy flux, has recently been shown to clear p-Tau, prevent synaptic and behavioral defects in a mouse model of tauopathy. Futhermore, our group has recently demonstrated that induction of autophagy either via FDA approved drugs (Bromhexine/Flubendazole) or by overexpressed TFEB can clear inflammation-induced p-Tau in neuronal cells. However, sustained activation of TFEB and autophagy may pose the risk of burdening cellular bioenergetics and be deleterious during conditions such as ischemic stroke, which is more prevalent in aged individuals. Here we have tested a light-based gene expression system developed by Gardner et al. (Nat Chem Biol. 2014 March ; 10(3): 196–202) to encode TFEB, with a goal to achieve precise spatio-temporal control over TFEB expression and thus regulatable autophagy flux in neuronal cells. This technology utilizes an engineered version of EL222, a bacterial transcription factor that contains a Light-Oxygen-Voltage protein, which binds DNA when illuminated with blue light (465nm). First, HEK293T cells transiently transfected with EL222 and TFEB-Flag plasmids, displayed robust TFEB-Flag expression when exposed to 465nm light (~2W/m^2) for 9 -12 hours compared to no-light condition. Second, transfection of HEK293Ts with human tau carrying T231D/S235D mutations and light-responsive TFEB-Flag followed by light induction resulted in significant increase in Flag-TFEB expression and reduction of p-Tau (transfected), but not normal tau (endogenous). Third, light-based induction of TFEB also resulted in increased expression of autophagy markers such as p62 and LC3B-II in the HEK293Ts compared to no-light condition. Finally, as a first step in testing this approach in neuronal system, we tested inducible pluripotent stem cell derived neurons (iPSNs) from Down's syndrome patient and observed significantly elevated tau oligomers, tau hyperphosphorylated at AT180 and AT8 sites. In the ongoing studies,

we are engineering lenti-viral expression system that encodes EL222 and TFEB-Flag to induce autophagy in primary neurons, iPSNs and in rTg4510 mouse model of tauopathy.

Title: Survival in 4-repeat tauopathies is associated with cerebrospinal fluid phosphorylated tau

Authors: *K. A. FIRN[1], L. M. SHAW[2], D. J. IRWIN[1], M. GROSSMAN[1], C. T. MCMILLAN[1]; [1]Neurol., [2]Pathology and Lab. Med., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Progressive Supranuclear Palsy (PSP), Corticobasal Degeneration (CBD), and Parkinson's Disease (PD), including PD with mild cognitive impairment (MCI) and dementia, are all characterized by parkinsonian motor features that may additionally include cognitive impairments. However, there are distinct sources of pathology in PSP and CBD (misfolded four-repeat protein tau, 4Rtau) compared to PD (alpha-synuclein). Both sources of pathology are associated with heterogeneous rates of survival, with a median of 5 years in PSP and 9 years in PD. Thus objective prognostic markers are essential to improve management of patient care and to stratify clinical trials. Cerebrospinal fluid (CSF) phosphorylated tau (ptau) is associated with tau pathological inclusions, and thus we hypothesize it will have specificity for 4Rtau survival, but not for PD survival. CSF total tau (ttau), in contrast, is a marker of neuronal degeneration and thus is hypothesized to lack specificity. We evaluated survival in 33 4Rtau patients and 42 age-

matched PD patients. All patients participated in a CSF lumbar puncture <3 years from disease onset, and exclusion criteria included CSF evidence of amyloid pathology (amyloid-beta<192) to exclude co-morbid AD pathology. Survival was calculated from reported age at onset to age at death, or patients were censored using reported year of last clinical visit. Cox regression models covaried gender, disease duration at CSF collection, and age at CSF collection. Ptau was associated with reduced survival in the 4Rtau cohort (β=-0.535; $p<0.005$). Ptau was not associated with survival in PD, and ttau was not associated with survival in 4Rtau or PD (all $p>0.1$). Together, these findings suggest that CSF ptau may provide a specific prognostic marker of survival in 4Rtau and should be considered as covariate in tau-targeted clinical trials.

Title: Amyloid induced axonal degeneration in p301L tau mice

Authors: *C. A. NISHIOKA[1,2], H.-F. LIANG[1], S.-W. SUN[1];
[1]Loma Linda Univ., Loma Linda, CA; [2]Neurosci., UC Riverside, Riverside, CA

Abstract: Evidence from post-mortem histology and in vivo diffusion tensor imaging (DTI) suggest that white matter tract damage is widespread in Alzheimer's Disease (AD). Cohort studies have revealed this damage potentially begins very early in the disease process, in patients with mild cognitive impairment. However, it remains unclear if this damage results purely from general cell loss, or from a selective axonal pathology. To study this phenomena, we attempted to induce early white matter damage in p301L tau transgenic mice using a targeted injection of Aβ into the lateral geniculate nucleus. After injections, we specifically examined retinal ganglion cells and their projections, which form the optic nerve (ON) and tract (OT). Using a combination of modalities, including DTI, optical coherence tomography (OCT) and histology, we could longitudinally tract and disentangle axonal degeneration from cell body loss. We demonstrate that early white matter damage results from selective axonal loss, and suggest that axons follow a 'dying-back' pattern of degeneration. Furthermore, our results indicate that axon loss resulting from amyloid pathology may be dependent upon tau aggregation. These results implicate axon-

specific mechanisms in the development of white matter damage and neurodegeneration during the early stages of AD.

Title: Biochemical characterization of novel transgenic mouse tauopathy models carrying a variant of the human triple-repeat tau gene and/or the hAPP gene.

Authors: ***A. ARNER**[1], A. ADAME[2], E. ROCKENSTEIN[2], M. MANTE[2], D. MASLIAH[2], E. MASLIAH[2], R. A. RISSMAN[2];
[1]Biol., [2]UCSD, San Diego, CA

Abstract: Tauopathies encompass several of the most prevalent neurodegenerative diseases that consistently progress to severe dementia and motor impairments. They involve tau hyperphosphorylation, which leads to the proteins detachment from associated microtubules, and a decline in the structural integrity of the cytoskeleton. This disassociation is followed by intracellular tau aggregation that causes impairment of axonal function. The mortality rate of the most common tauopathy, Alzheimer disease (AD), has increased dramatically in the last decade. Due to a lack of understanding of the pathogenic mechanisms involved in AD, treatment is currently limited to minimizing symptoms, without the ability to slow the rate of neurodegeneration. Another component of AD is that it is uniquely associated with extracellular accumulation of amyloid beta plaques, which appear to disrupt synaptic function, as well as induce inflammation. Developing and researching a variety of transgenic animals meant to model these diseases is critical to advancing the efficacy of their treatment and prevention. We generated a novel transgenic mouse line carrying the human amyloid precursor protein gene (hAPP) and crossed it to our recently generated line of mice that overexpress a variant of the human triple repeat tau gene (3R Tau), to create a novel bigenic mouse AD model. We characterized the pathological and cognitive changes associated with this model, both in young and aged mice. Our results demonstrate higher levels of phosphorylated tau in the mice carrying the 3R Tau gene. Interestingly, bigenic mice had higher levels of phosphorylated tau than all other groups. Increased levels of tau kinases were observed in the 3R Tau mice, with levels in bigenic mice exceeding these levels. Our immunohistochemical data suggest increased levels of

glial scarring and neuronal loss in 3R Tau mice, and this finding was exacerbated in bigenic mice. Beta-amyloid was only detected in the particulate fraction of the hAPP mice.

Title: Role of the microglial TREM2 receptor in a model of tauopathy induced by gene transfer in mice

Authors: *A.-P. BEMELMANS, A. VAUTHENY, G. AUREGAN, C. JOSÉPHINE, M.-C. GAILLARD, K. CAMBON, P. HANTRAYE;
CEA, Fontenay Aux Roses, France

Abstract: Recent genomic studies have shown the correlation between neuroinflammation and Alzheimer's disease (AD) and involved notably the R47H polymorphism of TREM2, a cell-surface receptor of microglia. Subsequently, several studies have shown that microglial activation is altered in mouse models of amyloidosis deficient in TREM2. However the role of TREM2 on the tauopathy component of AD is much less studied. To fill this gap, we have applied our recently developed rodent model of tauopathy in *Trem2* knockout mice. We overexpressed different forms of the human tau protein in CA1 neurons of the hippocampus by intracerebral injection of adeno-associated virus vectors (AAV-Tau). In wild type mice, the transduced cells then gradually develop over several weeks a profile of tauopathy, including Tau hyperphosphorylation and Tau aggregation, evidenced respectively by AT8 and AT100 immunolabeling, and cell death. Based on the 1N4R form, we developed several Tau transgenes that showed different profiles of aggregation and toxicity, and we analyzed tauopathy progression one and three months after AAV administration. Wild-type Tau produced few aggregates but led to an important degeneration of CA1 pyramidal neurons. Tau-P301L, a mutant form found in familial cases of fronto-temporal dementia with Parkinsonian syndrome

linked to chromosome 17, led to significant aggregation and toxicity. We also co-expressed the wild-type form with a peptide seed which promotes its aggregation while markedly reducing its toxicity for CA1 neurons. In *Trem2* knockout mice, the different Tau vectors led to the same pattern of tauopathy as in wild type mice at one month and three months post vector administration. In addition to the tauopathy, AAV-Tau elicited a microglial activation which was more pronounced in wild-type Tau-treated animals than in mice treated with Tau-P301L or Tau co-expressed with the peptide seed. However, in Trem2 knockout mice, microglial activation was significantly reduced following wild type Tau gene transfer. This suggests that, as in amyloidosis models, TREM2 deficiency inhibits microglial activation during tauopathy. However, this does not seem to impact the progression of this cardinal feature of AD.

Title: Altered tau phosphorylation in neurons cultured from a new tau transgenic mouse model of human tauopathy

Authors: *N. YANKOVA[1], M. BONDULICH[2], W. NOBLE[2], D. HANGER[2];
[1]King's Col. London, London, United Kingdom; [2]King's Col. London, Inst. of Psychiatry, Psychology & Neuroscience, Dept. of Basic and Clin. Neurosci., London, United Kingdom

Abstract: Tauopathies comprise a broad group of neurodegenerative diseases that are characterised by the deposition of tau in the brain. It is likely that a combination of a toxic gain-of-function acquired by tau aggregates, together with a loss of normal function of tau, may be responsible for the clinical presentation in these disorders. Diseases in which 4R tau isoforms are overrepresented such as progressive supranuclear palsy, exhibit a truncated form of tau (Tau35) that is absent from age-matched controls. We have generated a new mouse model of tauopathy in which Tau35 is expressed in the absence of any mutation and under the control of the human tau promoter. Unlike most existing tau transgenic mice, expression of Tau35 in these mice is less

than 10% of that of endogenous mouse tau and comparable with tau expression in human neurodegenerative disease. Tau35 mice demonstrate key features of human tauopathy, including aggregated and abnormally phosphorylated tau, progressive cognitive and motor deficits, loss of synaptic protein, and reduced life-span. To determine the influence of a disease-relevant fragment of tau on mechanisms involved in maintaining neuronal viability, we have examined tau phosphorylation and mitochondria in primary cortical neurons derived from Tau35 mice. Many neurodegenerative diseases demonstrate abnormal mitochondrial morphology, biochemical dysfunction and mobility. Therefore, defective mitochondrial function may be critically involved in neurodegeneration cascades and may be of significance for the pathogenesis of tauopathies. This emulation of disease progression in a novel mouse model will enable identification of the molecular changes that lead to a neurodegenerative phenotype in human tauopathies.

Title: Disease-related MAPT mutations alter steady-state levels of tau protein

Authors: ***J. GAMACHE**[1], K. ASHE[2], M. KOOB[3];
[2]Neurol., [3]Lab. Med. and Pathology, [1]Univ. of Minnesota, Minneapolis, MN

Abstract: Alzheimer’s disease is one of 20 tauopathies, diseases in which the microtubule-associated protein tau becomes abnormally regulated and aggregates into neurofibrillary tangles, a hallmark of Alzheimer’s. It is not well understood how mutations in the tau gene (*MAPT)* contribute to the deleterious effects of the mutated protein in the brain. To study this, I am using a novel mouse model that harbors a regulatable human tau transgene in a targeted genomic locus. Genome editing with the CRISPR/Cas system will allow for the generation of multiple lines of mice equivalent in every way except for single mutations in the tau transgene. Preliminary work has shown that a mutation underlying a related tauopathy, Frontotemporal dementia, increased steady-state levels of human tau protein relative to wild-type tau without the mutation. This

observation led to the hypothesis that mutations increase steady-state tau levels by hindering protein degradation, possibly increasing the propensity of tau to mislocalize and aggregate within neurons. Upcoming studies will measure the half-life of this form of mutated tau to clarify whether a slower rate of degradation underlies the observed elevated levels. To determine whether other disease-related *MAPT* mutations may share a common mechanism, I will use CRISPR/Cas to introduce different classes of mutations into the transgene including those affecting the amino acid sequence, alternative splicing, or both. In the resulting mouse lines, I will measure steady-state human tau protein levels associated with each mutation. This work may show that different classes of mutations in *MAPT* have a common effect of prolonging the half-life of tau, which may underlie neurotoxicity in tauopathies.

Abstract: The pathological accumulation of tau is associated with a number of diseases including Alzheimer's Disease (AD). Tau is known as a microtubule stabilizing protein, enabling the replenishment and regulation of the key transport route for axonal cargoes. Tau is hyperphosphorylated, becoming aggregative, and spreads throughout the cell and brain forming intracellular neurofibrillary tangles. The small soluble aggregations of tau are linked to dysfunction within neurons. Uncovering the leading functional elements that could underpin the gross synapse loss and cell death observed in AD is crucial in slowing down or reversing this disease. Mitochondria are crucial neuronal well-being and maintenance of synaptic function. Mitochondrial malfunction is linked to degenerative pathology in dementia. Mitochondrial dysfunction can lead to decreases in ATP production, increases in damaging Reactive Oxygen Species, disruption in calcium buffering and apoptosis control. These dysfunctional and

damaging pathways can lead to synaptic damage and cell death. The changes and the time course of mitochondrial function and its relationship to synapse loss in AD patients and animal models, is unknown. It is thought mitochondria could have upstream effects related to hyperphosphorylated tau, and could also be affected by any downstream microtubule transport impairments. Here, the rTg4510 mouse, which expresses a repressible form of human tau containing the P301L mutation linked to human frontotemporal dementia with parkinsonism-17 (FTDP-17), is used to assess mitochondrial changes associated with onset of neurodegenerative pathology. Longitudinal *in vivo* two-photon microscopy is used to investigate structural and functional changes in mitochondria within cortical neurons along the time course of pathological progression. rTg4510 mice and control littermates were transduced with an AAV driving expression of mitochondrial-targeted fluorescent protein in a subset of excitatory cortical neurons. The distribution and motility of axonal mitochondria was imaged in head-fixed, anaesthetized subjects. Mitochondrial location, morphology and speed of movement were measured semi-manually using ImageJ. Repeated imaging of the same axons over the course of the disease reveals the relationship between development of tauopathy and defects in mitochondrial localization and transport. These insights will define when and how the axonal mitochondria, which are crucial for presynaptic function, are affected by pathological malfunction of tau.

Title: Roles of Aβ plaques on the dynamics of soluble Aβ in the brains of APP transgenic mice

Authors: *Y. NAKA, T. WAKABAYASHI, T. HASHIMOTO, T. IWATSUBO;
Dept. of Neuropathology, The Univ. of Tokyo, Tokyo, Japan

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disease and the most frequent cause of dementia in the elderly. Massive deposition of senile plaques (SPs) in the cerebral cortex is a pathological hallmark of AD brains. Amyloid imaging techniques revealed that SPs are present >10 years before the symptomatic onset, although the roles of SPs in the dynamic aspects of AD pathology are unclear. Based on the understanding that the imbalance between production and clearance of amyloid β peptide (Aβ), a major component of SP amyloid,

leads to AD pathology, we hypothesized that SPs influence the dynamics of soluble Aβ in the brain. To test this theory, we first quantified the level of Tris-buffered saline (TBS)-soluble Aβ and the percentage area of Aβ plaques (Aβ burden) in the hippocampus of 18-month-old APP transgenic (tg) mice (A7 line), and found a positive correlation between the levels of TBS-soluble Aβ and Aβ burden. Next, we quantified the levels of interstitial fluid (ISF) Aβ by *in vivo* microdialysis using 1,000-kDa molecular weight cut-off microprobe in the hippocampus of 18-month-old APP tg mice, and found a negative correlation between ISF Aβ and Aβ burden. These data suggest that, under the presence of Aβ plaques, brain ISF Aβ may be exchangeable with the TBS-soluble Aβ, and that a fraction of TBS-soluble Aβ represents species captured by Aβ plaques from the ISF. To determine the molecular size of TBS-soluble Aβ in APP tg mice, we separated TBS-soluble fraction from the brains of 18-month-old APP tg mice by size exclusion chromatography with tandem Superdex75 columns, and found that TBS-soluble Aβ was separated into three peaks, i.e., at ~200-300 kDa (peak 1), ~50-80 kDa (peak 2), and 10-20 kDa (peak 3). In 5~7-month-old younger APP tg mice bearing no plaques, TBS-soluble Aβ was separated into a single peak eluting at ~50-80 kDa (peak 2). The levels of Aβ in peak1 were positively correlated with the Aβ burden in the hippocampus of 18-months-old Tg mice, whereas no correlation was found between the Aβ levels in peaks 2 or peak 3 and the Aβ burden. These date suggest that Aβ separated as a ~200-300 kDa complex inTBS-soluble fraction may be the species captured by Aβ plaques. Taken together, we postulate that Aβ plaques may have a role as the pool of soluble high-molecular-weight Aβ species, thereby affecting the dynamics of soluble Aβ in the brain.

Title: Antibodies targeting the N-terminal part of the amyloid β-peptide can impair the lateral assembly of filaments and the intrinsic stability of amyloid fibrils

Authors: *A. PAMRÉN, I. IAKOVLEVA, T. ISLAM, K. BRÄNNSTRÖM, L. SANDBLAD, A. OLOFSSON;
Umeå Univ., Umeaa, Sweden

Abstract: The self-assembly of the amyloid β-peptide (Aβ) into amyloid fibrils is linked to Alzheimer's disease and factors affecting its assembly are consequently of interest to elucidate. It has recently been suggested that antibodies targeting the N-terminal part of the Aβ peptide could dissociate amyloid formations into monomers and low molecular weight oligomers. We can here present an alternative explanation suggesting that the Aβ amyloid assembly in presence of antibodies affect the lateral assembly of filaments which result in thinner fibrillar structures with a lower ability to bind thioflavine T. A full effect is already seen at an Aβ: antibody ratio corresponding to around 150:1. Both IgM and IgG isotype antibodies can mediate the response which also render the fibrillar structure less stable. The location of the epitope strongly determines the strength of the effect. Antibodies targeting the N-terminal part of Aβ show a strong effect while antibodies targeting the middle region of the peptide show no effect. Interestingly, autoantibodies of the IgM isotype targeting Aβ is almost invariable present in all humans. Through mapping of the binding pattern from a few healthy individuals, we show that the intrinsic repertoire of anti-Aβ IgM antibodies may target several different Aβ epitopes on the peptide, including the N-terminal part. The specific spectra of clonal B-cell expansion may consequently be an important modulating factor of the fibrillary architecture and the pathology.

Title: The architecture of the amyloid fibrils controls the ability to induce fibril-catalyzed secondary nucleation

Authors: *M. ISLAM, K. BRÄNNSTRÖM, A. OLOFSSON;
Umeå Univ., Umeå, Sweden

Abstract: Self-assembly of the amyloid-beta peptide (Abeta) into amyloid fibrils is associated with the development of Alzheimer's disease. In vivo Abeta1-40 and Abeta1-42 are the dominant forms. The architectures of Abeta1-40 and Abeta1-42 fibrils differ, and Abeta1-42

assemblies generally have higher cytotoxicity. Abeta fibril formation follow a nucleation dependent polymerization process and it is known that new initiation sites, from which the incorporation of monomers can propagate into a fibril, can be generated through at least three different routes, these include; primary nucleation where nuclei spontaneously form in solution, the breaking of fibrils to form new fibrillar ends, and fibril-catalyzed secondary nucleation where formation of new nuclei is catalyzed laterally along already formed fibrils .The overall rate of conversion into amyloid is consequently dependent on the number of initiation sites from which the template-dependent polymerization can start. Under stagnant conditions fibril-catalyzed secondary nucleation dominates. We have performed cross-seeding studies and show that fibrils of Abeta1-42 are impaired to induce fibril-catalyzed secondary nucleation of Abeta1-40 while the elongation process is unaffected. Intriguingly the formed Abeta fibril acquire the same properties as the Abeta1-42 and is, in contrast to spontaneously formed fibrils of Abeta1-40, impaired to induce fibril-catalyzed secondary nucleation of monomeric Abeta1-40. The results suggest that the incorporated Abeta1-40 acquired the structure of Abeta1-42 fibrils and that the architecture of the Abeta fibrils rather than the sequence controls the ability to induce fibril-catalyzed secondary nucleation.

Abstract: The cellular location of the amyloid precursor protein (APP) influences its processing; on the cell surface APP is cleaved by α-secretase to produce non-amyloidogenic fragments, or APP is endocytosed and cleaved by β- and γ-secretase to generate Aβ. Little is known about the subcellular site of interaction between the amyloidogenic secretases and APP and ultimately the site of Aβ generation due to the lack of probes that can interrogate the *de novo* cleavage of Aβ from APP. Using unnatural amino acids and fluorogenic click chemistry, we have site-specifically labeled Aβ within APP with a small fluorophore and fused mClover to the C-terminus of APP to distinguish full-length APP and its β-C-terminal fragment (βCTF) from Aβ. We sought to use this bifluorescent APP construct to detect intracellular Aβ generation by monitoring the separation of click-labeled Aβ from the mClover-tagged APP intracellular domain (AICD-mClover). However, visualization of cleavage events in some intracellular organelles are diffraction limited. We have circumvented this limitation by using super-resolution microscopy. Live mouse neuroblastoma cells were incubated with a cell-impermeable red tetrazine-fluorophore to click-label cell surface APP-mClover within the Aβ segment. This resulted in endocytosis and trafficking of the bifluorescent APP construct. Super-resolution structured illumination microscopy distinguished uncleaved APP or βCTF from Aβ and the AICD providing a subcellular readout of Aβ production (A-D). Following γ-secretase cleavage of APP to generate Aβ, AICD-mClover was localized to the limiting membrane of vesicles while the click-labeled Aβ signal was localized to the lumen of the vesicle (B-D, E shows intensity profile through B). Uncleaved APP resulted in colocalization of the bifluorescent APP probes on the limiting membrane of vesicles (F-I, J shows intensity profile through G). Using this method, we have directly monitored *de novo* Aβ generation at the subcellular level for the first time. This will enable the delineation of intracellular pathways critical for Aβ production.

Title: The effects of apoe genotype on aβ levels in human liver

Authors: *G. E. SERRANO[1], C. MAAROUF[2], J. WALKER[2], A. GARCIA[2], L. SUE[2], T. G. BEACH[2];
[1]Brain and Body Donation Program, [2]Banner Sun Hlth. Res. Inst., Sun City, AZ

Abstract: It is well known that Apolipoprotein E (APOE) genotype alters the risk of developing Alzheimer's disease (AD), but the molecular mechanism of this effect is still unknown. The most accepted general hypothesis is that the E4 allele-coded form of APOE influences the metabolism of amyloid precursor protein and/or its critical cleavage product, amyloid-β (Aβ), resulting in brain accumulation of Aβ as senile plaques. It has also been assumed that the critical molecular events all take place in the brain, but as the liver is a major site for both the synthesis of APOE as well as the metabolism of circulating Aβ, it is possible that alterations of liver function could affect brain Aβ levels through changes in blood Aβ concentration. In this study we hypothesized that APOE genotype may affect the rate of Aβ degradation in the liver. An Aβ degradation assay was developed using fluorescein-labeled Aβ40 and 42 spiked into liver homogenates. Our preliminary data suggest that Aβ degradation rates in the liver do not vary between subjects with different APOE alleles. However, Aβ40 appears to degrade three times faster in non-demented control subjects (ND) than in individuals with AD. The expression of potential Aβ-degrading enzymes presenilin, β-site APP-cleaving enzyme (BACE), and neprilysin were not different in liver samples from AD, while cathepsin D and Insulin-degrading enzyme are significantly affected in AD subjects. The protein Levels in the Liver of both Aβ degrading enzymes significantly correlates with the pathological aggregation of Aβ in the brain. This suggests that inefficient degradation of Aβ in the liver could results in abnormal levels of Aβ in the brain.

Abstract: The brain of Alzheimer's disease (AD) patients is characterised by the deposition of amyloid β (Aβ) peptide and tau phosphorylation, and also shows extensive glial activation and neuronal loss. Apart from secreting pro-inflammatory mediators, activated microglia can also have neuroprotective effects by reducing Aβ accumulation through increasing its clearance, as well as through the release of anti-inflammatory molecules including certain cytokines, growth factors, and the inflammation-resolving molecule annexin A1 (ANXA1). The aim of this study was to determine the effect of ANXA1 on the generation and clearance of Aβ, as well as on microglial activation and phagocytosis. Our data show that ANXA1 is increased in the brains of AD patients and animal models of AD at early stages of the disease. ANXA1 was able to reduce the levels of Aβ in N2a neuroblastoma cells by increasing its enzymatic degradation by neprilysin, and to stimulate Aβ phagocytosis by microglia. In addition, ANXA1 inhibited the microglial secretion of inflammatory mediators induced by Aβ. Our data suggest that ANXA1 plays a key role in the clearance of Aβ and supports the use of ANXA1 as potential therapeutic tool for AD.

Title: The redox state of methionine 35 in amyloid-beta (1-42) peptide (A-betaP) determines the amplitude of prostaglandin E_2 (PGE_2) release from rat microglia *In vitro*.

Authors: *G. POZZOLI[1], F. MISITI[2], E. CLEMENTI[3], G. TRINGALI[1], C. DELLO RUSSO[1], L. LISI[1], P. NAVARRA[1];
[1]Catholic Univ. Sch. Med., 00168 Rome, Italy; [2]Dept. of Hlth. and Motor Sci., Univ. of Cassino, Cassino, Italy; [3]Inst. of "Chimica del Riconoscimento Molecolare", Natl. Council of Res., Rome, Italy

Abstract: Alzheimer's disease (AD) is a brain pathology characterized by the presence of senile plaques in several regions of the central nervous system. A major protein component of the plaques is the amyloid-beta peptide (A-betaP), which possesses direct neurotoxic activity; such neurotoxicity has been associated to the *redox* state of methionine residue in position 35 (Met-35) of A-betaP. The plaques are also the foci of local inflammatory responses, as shown by the activation of surrounding microglia, with increased synthesis and release of several pro-inflammatory mediators; the latter may account for indirect toxic effects of A-betaP. In the present study, we used 3 variants of A-betaP, namely, A-betaP(1-42), where the Met-35 is present in the reduced state, a modified peptide with oxidized Met-35 and an A-betaP derivative in which Met-35 is substituted with norleucine, to investigate the relationship between Met-35 *redox* state and the ability of A-betaP to induce a pro-inflammatory activation in glial cells. The latter was assessed by measuring the levels of prostaglandin E_2 (PGE_2) released after 24-h exposure to test peptides in primary cultures of rat cortical microglia or astrocytes. Under basal conditions, microglia produced and released significant amounts of PGE_2 (100 - 150 pg/ml after 24 h of incubation). 5 microM A-betaP(1-42) induced a 4-fold increase in PGE_2 secretion compared to controls, whereas A-betaP(1-42)Met-35^{Ox} and A-betaP(1-42)Nle35, both at the concentration of 5 microM, had no effect on PGE_2 release. Under basal conditions, astrocytes produced and released tiny amounts of PGE_2, roughly 4 - 6 pg/ml after 24-h incubation, and none of A-beta peptides tested produced significant changes on PGE_2 levels. Moreover, A-betaP(1-42) strongly increased interleukin-1 beta (IL-1beta) mRNA accumulation in microglial cells, whereas A-betaP(1-42)Met-35^{Ox} effect was significantly smaller, and A-betaP(1-42)Nle-35 had no effect. No toxic effects were observed in microglia or astrocytes after treatment with the different peptides. The results of the present study are consistent with previous reports showing that A-betaP increases PGE_2 secretion in activated microglia; in addition, our findings suggest that the reduced state of Met-35 in A-betaP is necessary to induce a pro-inflammatory activation in microglial cells.

Title: Probing amyloid beta-induced cell death using a fluorescence-peptide conjugate in Alzheimer's disease mouse

Authors: *J.-S. BAE[1,2], H. JIN[3];
[1]Sch. of Med., Kyungpook Natl. Univ., Daegu, Korea, Republic of; [2]Cell Matrix Res. Institute, Kyungpook Natl. Univ., Daegu, Korea, Republic of; [3]Col. of Vet. Medicine, Kyungpook Natl. Univ., Daegu, Korea, Republic of

Abstract: With the increasing worldwide incidence of Alzheimer's disease (AD), there is a critical need for the discovery of more effective diagnostic methods. However, development of diagnostic tools in AD has been hindered by obstacles such as the absence of exact biomarkers. Apoptosis caused by amyloid-**β (Aβ)** plays an important role in AD pathology; therefore, provides an attractive biological target for the diagnosis of AD. The present study aimed to evaluate the potential of small peptide, named ApoPep-1 (Apoptosis-targeting peptide-1) as a new apoptosis imaging agent in AD. The fluorescein-conjugated ApoPep-1, but not the control peptide, targeted apoptotic cells in the brain of **amyloid precursor protein (APP)/presenilin 1 (PS1)** mice. We also observed fluorescence signals during *in vivo* imaging of apoptotic cells using ApoPep-1, and fluorescence levels increased in an age-dependent manner in APP/PS1 mice. *Ex vivo* imaging of isolated brains in APP/PS1 mice further confirmed the targeting of ApoPep-1 to apoptotic cells. The fluorescein-labeled ApoPep-1 co-localized with brain cells such as neurons, astrocytes, and microglia, all of which undergo apoptosis in the APP/PS1 mice brain. These findings demonstrate that ApoPep-1 can target apoptotic brain cells, and be used for experimental investigations relevant to apoptosis in AD.

Title: The determinants of amyloid-β fibril formation

Authors: *K. K. BRÄNNSTRÖM[1], T. ISLAM[2], L. SANDBLAD[4], A. OLOFSSON[3];
[1]Med. chemistry, Umeå Univ., Umea, Sweden; [2]Med. chemistry, Umea, Sweden; [3]Med. chemistry, umea, Sweden; [4]Dept. of Mol. Biol., Umea, Sweden

Abstract: Self-assembly of the amyloid-β peptide (Aβ) into amyloid fibrils is associated with the development of Alzheimer's disease. Several different lengths of Aβ are found *in vivo*, but $A\beta_{1-40}$, $A\beta_{1-42}$, and N-terminally truncated variants thereof, are the dominant forms. The architectures of $A\beta_{1-40}$ and $A\beta_{1-42}$ fibrils differ, and $A\beta_{1-42}$ assemblies generally have higher cytotoxicity. We performed cross-templating experiments using surface plasmon resonance and discovered that monomeric $A\beta_{1-42}$ can be readily incorporated onto the ends of immobilized $A\beta_{1-40}$ fibrils, but that monomeric $A\beta_{1-40}$ is poorly incorporated onto immobilized $A\beta_{1-42}$ fibrils. Intriguingly, the most N-terminal residue, Asp1, controls this barrier. We further showed that the monomers that are incorporated onto the fibrillar ends also adopt the properties of the templating fibril. This consequently implies an important role in the mechanism behind the formation and architecture of nuclei from which a fibril subsequently propagates. These results demonstrate a complicated interplay between different Aβ variants where the ability to incorporate monomers control the properties and formation of the amyloid fibrils. We describe a possible pathological mechanism for the N-terminally truncated Aβ variants, and thus expose a novel avenue for intervention.

Title: Picalm mediates autophagic abeta clearance and toxicity mitigation in pericytes

Authors: *E. LAWSON, B. V. ZLOKOVIC, Z. ZHAO;
Dept. of Physiol. and Biophysics, USC, Los Angeles, CA

Abstract: Background: Alzheimer's disease (AD) is the most common form of dementia in the elderly, manifesting the occurrence of amyloid plaques, neurofibrillary tangles and the destruction of the neurovascular unit. Vascular factors are considered as a major risk factor for dementia due to AD. Recent studies have demonstrated pericytes degenerate in AD and potentially play a key role in pathogenesis. However the cellular and molecular mechanisms underlying pericyte degeneration during AD pathogenesis remain elusive. Methods: We examined: i) Abeta accumulation and pericyte degeneration during AD pathogenesis in post mortem AD brain tissues using immunohistochemistry; ii) internalization of soluble Abeta and

clearance of aggregated Amyloid oligomers via autophagy in primary brain pericytes using in vitro culture models; iii) the role of PICALM in mediating the clearance of oligomeric Abeta via autophagy in pericytes in vitro. Results: Our study showed that: a) pericytes internalize soluble Abeta species via LRP1 mediated endocytosis with the assistance of PICALM; b) pericytes clear aggregated Abeta oligomers via PICALM dependent autophagic pathway; c) PICALM-mediated autophagic clearance of intracellular Abeta protects pericytes from Abeta toxicity and cell death. Conclusions: The data suggest that PICALM-mediated autophagy of Abeta regulates its clearance and is a protective mechanism in pericytes in AD.

Title: Justicidin A decreases amyloid β peptide via inhibiting endocytosis of amyloid β precursor protein

Authors: *Y. CHUN[1,2], S. CHUNG[2], G. FOUCHE[3], V. MAHARAJ[4], H. YANG[1];
[1]Natural Products Res. Ctr., Korea Inst. of Sci. and Technol., Gangneung, Korea, Republic of; [2]Dept. of Physiol., Sungkyunkwan Univ., Suwon, Korea, Republic of; [3]Council for Scientific and Industrial Res., Pretoria, South Africa; [4]Univ. of Pretoria, Pretoria, South Africa

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder that is characterized by the accumulation of neurotoxic amyloid β (Aβ) peptides, with eventual cognitive decline and memory impairment. Therapeutic drug for the AD is still unavailable. *Monsonia angustifolia* (coded as BP21) is used for food as indigenous vegetables consumed in Tanzania. In this study, we tested the effect of BP21 on Aβ production and spatial learning ability to investigate its protection against AD. BP21 extract is effective in memory function recovery as well as reduction of Aβ secretion. We next identified its active compounds, Justicidin A. It was known that amyloid β precursor protein (APP) is transported to the plasma membrane, where it is sequentially cleaved by α-secretase and γ-secretase (non-amyloidogenic pathway). Alternatively, once APP undergoes clathrin-dependent endocytosis, it can be sequentially cleaved by β-secretase and γ-secretase at endosomes, producing Aβ (amyloidogenic pathway). O-GlcNAcylation is a novel type of O-linked glycosylation attaching the monosaccharide β-N-acetylglucosamine (GlcNAc) to serine and threonine residues. Recently, we found that O-GlcNAcylation of APP increases the non-amyloidogenic processing of APP and

decreases the production of Aβ. Here, we confirmed specific increase of O-GlcNAcylation of APP by Justicidin A, which is one of lignin derivatives. Justicidin A increased the level of APP in the plasma membrane. We also found that Justicidin A selectively attenuated the endocytosis of APP, but not that of transferrin receptor. The level of sAPPα increased, while the level of sAPPβ and Aβ was concomitantly decreased by Justicidin A. Blocking the clathrin-dependent endocytosis by inhibitor prevented the effect of Justicidin A, suggesting that the effect of Justicidin A on Aβ production was mainly mediated through the decrease of APP endocytosis. These results strongly indicate that O-GlcNAcylation by Justicidin A selectively decreases endocytosis rate of APP, thereby enhancing non-amyloidogenic processing of APP. Thus, O-GlcNAcylation of APP could be a new novel therapeutic target for AD.

Title: Apolipoprotein E isoforms impact pericyte-mediated Aβ metabolism.

Authors: *M. TACHIBANA, Y. YAMAZAKI, G. BU, T. KANEKIYO;
Mayo Clin., Jacksonville, FL

Abstract: Pericytes are an important component of the neurovascular unit. While pericytes regulate cerebral blood flow, angiogenesis and the integrity of the blood-brain barrier (BBB), these cells also play a critical role in brain metabolism of amyloid-β (Aβ). The ε4 allele of the *APOE* gene encoding apolipoprotein E (apoE) is the strongest genetic risk factor for late-onset Alzheimer's disease (AD) among the three human *APOE* alleles (ε2, ε3, ε4). ApoE4 not only exacerbates Aβ accumulation in the brain but also triggers a cascade of events that causes vascular dysfunction including BBB breakdown. Although pericytes and astrocytes are the major cell types producing apoE in the brain, how apoE isoforms influence pericyte-mediated Aβ clearance remains unclear. We isolated primary pericytes from the brains of apoE3 targeted-replacement (TR) mice, apoE4-TR mice or *Apoe*$^{-/-}$ mice at the age of 3-8 weeks. These cells were cultured and incubated with 500 nM of Aβ40 or Aβ42 in the presence or absence of lysosomal inhibitors, and cellular Aβ binding, uptake and degradation were analyzed by FACS,

ELISA and immunocytochemistry. As an alternative approach, apoE particles were purified from conditioned medium of pericytes from apoE3-TR or apoE4-TR mice and their effects on Aβ metabolism was similarly assessed in pericytes from *Apoe*$^{-/-}$ mice. FACS demonstrated that binding of both FAM-labelled Aβ40 and Aβ42 to pericytes from apoE4-TR mice were significantly less than those of pericytes from apoE3-TR mice. The amounts of cell-associated Aβ following uptake were also reduced in apoE4-pericytes compared to apoE3-pericytes. Similar results were obtained by ELISA. However, these apoE isoform-dependent effects on Aβ binding and uptake were not seen using exogenous apoE3 and apoE4 particles in pericytes from *Apoe*$^{-/-}$ mice. Furthermore, when lysosomal inhibitors were used to assess the capacity of lysosomal mediated Aβ degradation, we found that apoE3-pericytes have a greater capacity to degrade Aβ than apoE4-pericytes. Taken together, our results support a superior role of pericytes expressing apoE3 than apoE4 in mediating Aβ cellular metabolism and suggest that the apoE isoform-dependent effects on brain Aβ pathology likely involve both parachyma and vasculature.

Title: Reciprocal crosstalk between amyloid beta and presenilin 1

Authors: ***K. M. ZOLTOWSKA**, M. MAESAKO, O. BEREZOVSKA;
Neurol., Mass Gen. Hospital/Harvard Med. Sch., Charlestown, MA

Abstract: Extracellular amyloid plaques composed of fibrillogenic amyloid β (Aβ) are well-established pathological hallmark of Alzheimer's disease (AD). The potential spreading of the amyloid pathology within the brain from region to region has recently gained widespread interest but the concept raises several controversies and the mechanisms are unclear. The amyloid fibril formation is determined by a relative ratio of longer (i.e., Aβ42/Aβ43) to shorter (i.e. Aβ40) species, which are yielded by the intramembranous cut of amyloid precursor protein (APP) C-terminal stub by the γ-secretase complex, the catalytic component of which is presenilin 1 (PS1). The latter exists in equilibrium of the dynamic conformational states characterized by varied

proximity between PS1 N-terminus and loop/C-terminus, as monitored by the FRET assay in live cells. The close proximity between PS1 domains shifts the γ-secretase cleavage towards the production of longer Aβ species.
Using fluorescence lifetime imaging microscopy, calcium imaging and cytotoxicity assays, we explored mechanistic link between Aβ42 and Aβ40 peptides present at various ratios, and PS1 conformation in primary neurons. Pathogenic conformational changes within the PS1 subdomain architecture were triggered in neurons exposed to Aβ peptides at a relatively high ratio of Aβ42/40. This effect was mediated by increased intracellular calcium load. The pathogenic rearrangement within PS1 shifts further the equilibrium of Aβ peptides towards the longer, aggregation prone species.
Our findings link elevated calcium, Aβ42 and PS1/γ-secretase conformation, provide novel cell- and non-cell autonomous mechanisms of Aβ action, and offer possible mechanistic explanation of the impending spread of the amyloid pathology.

Abstract: Amyloid-β (Aβ) produces neurotoxicity in the brain and causes neuronal death. But the endogenous defense mechanism that is activated on Aβ insult is less well understood. Here we found that acute Aβ increases the expression of protein inhibitor of activated STAT1 (PIAS1) and Mcl-1 *via* activation of MAPK/ERK. Aβ increases the association between PIAS1 and HDAC1 and Aβ induction of PIAS1 enhances the SUMOylation of HDAC1 at Lys-444 and Lys-476 in rat hippocampus. Knockdown of PIAS1 decreases endogenous HDAC1 SUMOylation. It

also blocks the effect of Aβ on Mcl-1 expression. HDAC1 SUMOylation is induced by BDNF, IGF-1 and CRF in the rat brain. Sumoylated HDAC1 reduces it association with CREB, increases CREB binding to the *Mcl-1* promoter and mediates Aβ induction of Mcl-1 expression. Transduction of SUMO-modified lenti-HDAC1 vector to the hippocampus of APP/PS1 mice rescues deficits of spatial learning and memory, contextual fear memory and LTP observed in APP/PS1 mice. It also reduces amyloid plaque in APP/PS1 mice. These results together reveal an important role of HDAC1 SUMOylation as an endogenous protection mechanism against Aβ toxicity.

Title: Genome wide screening of molecules involved in Aβ uptake by CRIPSR/Cas9 system

Authors: *I. EBINUMA, Y. HORI, T. TOMITA;
Lab. of Neuropathology and Neurosci., The Univ. of Tokyo, Tokyo, Japan

Abstract: Amyloid-β protein (Aβ) is one of the pathologically important molecules in the etiology of Alzheimer's disease (AD). Recent studies suggest that impaired clearance of Aβ from the central nervous system is involved in the development of late-onset AD (LOAD). To date, several mechanisms have been implicated in the Aβ clearance; phagocytosis, proteolytic degradation, transport across the blood-brain barrier, or transport via cerebrospinal fluid. Intriguingly, recent genome wide association studies identified molecules related to phagocytic uptake of Aβ (e.g., CD33 or TREM2) as genetic risk factors for LOAD. However, a detailed mechanism of Aβ uptake has not been well characterized. To elucidate molecular mechanism of Aβ uptake in detail, we carried out genome-wide screening of Aβ uptake using CRISPR/Cas9 system-mediated genome editing. We first transduced Cas9-expressing murine neuroblastoma N2a cells with whole genome targeting gRNA lentiviral library to obtain cell population in which each genome was edited at single locus. To screen cells with altered ability in Aβ uptake, fluorescent-labeled Aβ was treated to the genome-edited cell population, and the cells with abnormal fluorescent intensity were collected using FACS. gRNA-target sequences transduced by recombinant lentiviruses in the sorted cells were amplified and analyzed by deep sequencing. In combination with over-representation analysis, we found that genes involved in endocytic machinery and immune response pathway affected the Aβ uptake. In addition, interactome

analysis revealed that INPP5D and CD2AP, which are known as genetic LOAD risk factors, were mapped in same protein-protein interaction network with genes identified by the screening. These results suggest that these risk factors play a role in Aβ clearance in the pathogenesis of LOAD.

Title: Oligomeric amyloid β 1-42 induces a reversible loss of catecholaminergic afferents in the rat insular cortex.

Authors: *R. PEREZ ORTEGA, P. MORENO-CASTILLA, O. URREGO MORALES, F. BERMÚDEZ-RATTONI;
Dept. de Neurociencia Cognitiva, Inst. de Fisiología Celular, Univ. Nacional Autónoma De México, Ciudad de México, Mexico

Abstract: Alzheimer's Disease (AD) is the most common form of dementia in the elderly and is characterized by a progressive neurodegeneration and an overall time-dependent cognitive decline. One of the first symptoms of AD is episodic memory loss. In recent years, the role of catecholaminergic (predominantly dopamine and noradrenaline) systems in AD memory loss and pathology has become increasingly significant. Catecholaminergic systems are important for memory encoding in the hippocampus and cortex and its AD-related dysfunction accounts for behavioral and functional plasticity impairments. Amyloid beta (Aβ) is considered a hallmark in AD pathology and the soluble, oligomeric form of 42 residues long ($A\beta_{42}$) is the most toxic form of Aβ. In this study, we aimed to determine the effect of $A\beta_{42}$ on catecholaminergic afferents in the insular cortex (IC), an area where dopamine (DA) is important for the encoding of recognition and taste memories. We injected $A\beta_{42}$ or a control peptide in the rat insular cortex and analyzed catecholaminergic afferents density by means of tyrosine hydroxylase (TH) immunosignal 2 h, 24 h, 7 days, 15 days, and 30 days after injection. We found that TH afferents density decreased at 24 hours, but was surprisingly restored at 7 days. Furthermore, retrograde

tracer analysis showed that $A\beta_{42}$ impairs the ventral tegmental area (VTA)-IC dopaminergic pathway 24 h after peptide injection. We set to determine if an astroglial response was responsible for afferents density restoration at 7 days. GFAP immunosignal showed that astrocytes were mostly activated at 7 days but not 24 hours after peptide injection. Together, these results suggest that $A\beta_{42}$ has a detrimental effect on catecholaminergic afferents in the insular cortex at immediate times, and that astrocyte activation might be involved in axonal regeneration in subsequent days.

Title: Large soluble oligomers of amyloid β-protein from Alzheimer brain are far less bioactive than the smaller oligomers to which they dissociate

Authors: *T. YANG, S. LI, H. XU, D. WALSH, D. SELKOE;
Ann Romney Ctr. for Neurologic Dis., Brigham and Women's Hosp., Boston, MA

Abstract: Soluble oligomers of amyloid β-protein (Aβ) isolated from brains of Alzheimer's disease (AD) patients have been shown experimentally (in the absence of amyloid plaques) to impair hippocampal synaptic plasticity, decrease synapses, induce tau hyperphosphorylation and neuritic dystrophy, activate microglial inflammation, and impair memory in normal adult rodents. Nevertheless, there has been confusion and controversy about what types of oligomers actually confer these AD-like phenotypes. Here, we show that the vast majority of soluble Aβ species obtained from typical AD brains elute at high MW on non-denaturing size-exclusion chromatography. These species have little or no cytotoxic activity in several bioassays. However, incubation of this HMW oAβ in mildly alkaline buffer led to their quantitative dissociation into low MW oligomers (~8-70 kDa), and these were now highly bioactive: they impaired hippocampal LTP, decreased neuronal levels of β_2-adrenergic receptors, and activated microglia *in vivo*. We conclude that most Aβ assemblies in AD cortex are large and inactive but under certain circumstances can dissociate into smaller but highly bioactive species. Amyloid plaques likely sequester HMW oligomers, limiting their potential to dissociate. Conditions which de-

stabilize HMW oligomers or retard the incorporation of their smaller more bioactive components may be important drivers of Aβ toxicity. Consequently, targeting these small, cytotoxic forms should be therapeutically beneficial.

Abstract: Alzheimer's disease (AD) is the leading cause of dementia and mitigating amyloid-β (Aβ) levels may serve as a rational therapeutic avenue to slow AD progression. Pharmacologic inhibition of the Rho-associated protein kinases (ROCK1 and ROCK2) is proposed to curb Aβ levels, and mechanisms that underlie ROCK2's effects on Aβ production are defined. How ROCK1 affects Aβ generation remains a critical barrier. Here, we report that ROCK1 protein levels were elevated in mild cognitive impairment due to AD (MCI) and AD brains compared to controls. Aβ42 oligomers marginally increased ROCK1 and ROCK2 protein levels in neurons but strongly induced phosphorylation of Lim kinase 1 (LIMK1), suggesting that Aβ42 activates ROCKs. RNAi depletion of ROCK1 or ROCK2 suppressed endogenous Aβ40 production in neurons, and Aβ40 levels were reduced in brains of ROCK1 heterozygous knock-out mice compared to wild-type littermate controls. ROCK1 knockdown decreased amyloid precursor protein (APP) in neurons, and treatment with bafilomycin accumulated APP levels in neurons depleted of ROCK1. These observations suggest that reduction of ROCK1 diminishes Aβ levels

by enhancing APP protein degradation. Collectively, these findings support the hypothesis that both ROCK1 and ROCK2 are therapeutic targets to combat Aβ production in AD.

Title: Alzheimer-associated Aβ oligomers impact the central nervous system to induce peripheral metabolic deregulation

Authors: *J. R. CLARKE[1], N. M. LYRA E SILVA[2], C. P. FIGUEIREDO[1], W. L. KLEIN[3], D. P. MUÑOZ[4], L. A. VELLOSO[5], S. T. FERREIRA[2], F. G. DE FELICE[2];

Abstract: Alzheimer's disease (AD) is associated with peripheral metabolic disorders. Clinical/epidemiological data indicate increased risk of diabetes in AD patients. Here, we show that intracerebroventricular infusion of AD-associated Aβ oligomers (AβOs) in mice triggered peripheral glucose intolerance, a phenomenon further verified in two transgenic mouse models of AD. Systemically injected AβOs failed to induce glucose intolerance, suggesting AβOs target brain regions involved in peripheral metabolic control. Accordingly, we show that AβOs affected hypothalamic neurons in culture, inducing eukaryotic translation initiation factor 2α phosphorylation (eIF2α-P). AβOs further induced eIF2α-P and activated pro-inflammatory IKKβ/NF-κB signaling in the hypothalamus of mice and macaques. AβOs failed to trigger peripheral glucose intolerance in tumor necrosis factor-α (TNF-α) receptor 1 knockout mice. Pharmacological inhibition of brain inflammation and endoplasmic reticulum stress prevented glucose intolerance in mice, indicating that AβOs act via a central route to affect peripheral

glucose homeostasis. While the hypothalamus has been largely ignored in the AD field, our findings indicate that AβOs affect this brain region and reveal novel shared molecular mechanisms between hypothalamic dysfunction in metabolic disorders and AD.

Title: Spatial distribution of Raman shifts within amyloid beta aggregates *In vitro*

Authors: *Y. NAGASHIMA, A. IWATA;
Dept. of Neurology, The Univ. of Tokyo, Tokyo, Japan

Abstract: Amyloid beta (Aβ) plays an important role in pathogenesis of Alzheimer's disease. This protein is prone to aggregate and is known to form senile plaques in brains of patients with Alzheimer's disease. In the present study, we were interested in investigating molecular vibrational spectra of Aβ aggregates in *vitro*. Raman scattering provides vibrational information intrinsic to and characteristic of chemical species without any extrinsic labeling procedures. Therefore Raman spectroscopy enables us to observe somewhat small peptides, such as Aβ, aggregating in physiological condition without involvement of labeling molecules of a size relatively larger. Recombinant human Aβ1-42, pretreated with TFIP (1,1,1,3,3,3-hexafluroro-2-propanol) to dissolve fibrous state in advance, were incubated for 24 hours at 37°C to form protein aggregates in *vitro*. Two dimensional spontaneous Raman spectral images of the aggregates were obtained using laser confocal Raman microspectroscopy. We found that several vibrational modes such as 1003cm^{-1}, 1162cm^{-1}, 1417cm^{-1}, 1449cm^{-1}, 1520cm^{-1}, 1612cm^{-1} and 1656cm^{-1} were prominently observed within the aggregates. Previous studies of molecular vibrations showed that the mode of 1003cm^{-1} originates from phenylalanine residue, and the mode of 1449cm^{-1} originates from CH_2 bond. The modes 1612cm^{-1} and 1656cm^{-1} are reported to originate from Amide I bond and are related to beta-sheet structure of protein, explaining insoluble feature of Aβ aggregates. As for the other modes (1162cm^{-1}, 1417cm^{-1} and 1520cm^{-1}), we currently do not know the origin, but we found some of these Raman shifts were

heterogeneously distributed in the 2D spectral images of aggregates. It is interesting that some of them seemed to form core-like structures around the center of aggregates purely made of Aβ. This indicates that Aβ aggregates are not homogeneous structure in terms of chemical bonds or groups corresponding to these observed vibrational modes of Aβ molecules.
This is the first attempt to reveal spatial distribution of chemical Raman shifts within Aβ aggregates. These results provide a clue about generation and growth mechanism of Aβ aggregation.

Title: Biologically produced Abeta species induce pathological endosomal phenotypes *In vitro*

Authors: ***M. SAWA**, X. CHEN, O. NATERA, M. PEARN, W. MOBLEY;
UCSD, La Jolla, CA

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder that is growing in prevalence. The molecular pathogenesis of AD starts decades prior to clinical diagnosis; so early detection and intervention is critical to halting it’s progression; perhaps even abating symptoms altogether. An early and critical neuronal phenotype of AD is accumulation and enlargement of early endosomes (EE) and increased activation of Rab5. EE enlargement contributes to neurodegeneration by impairing axonal transport of trophic factors necessary for neuronal survival. To better understand the molecular mechanisms underlying the abnormalities, we employed the conditioned medium (CM) of a CHO cell line (7PA2) which expresses the human Indiana mutation of APP (APP V717F); CM7 is used to designate this CM. Wild type CHO cells are used as a control; CMC is used to refer to this CM. CM7 contains biologically relevant amyloid beta (Abeta) species. We assessed the effects of CM7 in PC12 cells and rat primary neurons. We observed that 2hr-treatement of CM7 induced abnormalities in; endosomal pathways, neurotrophin signaling, axonal trafficking and synaptic structures. Immunodepletion analysis showed that Abeta is responsible for these phenotypes. We conclude that CM7 recapitulates AD conditions in vitro. We will discuss the molecular linkages between Abeta species and the AD-related pathologies.

Title: Circadian alterations impact the regulation of insulin degrading enzyme in the brain of Alzheimer patients.

Authors: T. KIM[1], J. MOTT[1], I. TRINH[1], B. SPENCER[1], *P. A. DESPLATS[2];
[1]Neurosciences, Univ. California San Diego, La Jolla, CA; [2]Neurosciences and Pathology, UCSD, LA Jolla, CA

Abstract: Alzheimer disease (AD) is the most prevalent neurodegenerative disorder of the elderly, manifested by progressive memory loss and decline in cognitive functions, with underlying accumulation of amyloid-β (Aβ) and phosphorylated Tau in the neocortex and the hippocampus. Disturbance of circadian rhythmicity is a common ailment for more than 80% of AD patients, evidenced by altered sleep/wake cycles and exacerbated cognitive impairment during the evening (sundowning).
Circadian rhythms coordinate physiology with the environment. About 15% of expressed genes are controlled by the circadian clock, including those involved in insulin metabolism. Disruption of core clock genes Per2 and Bmal1 leads to insulin resistance and diabetes in mice. Normal functioning of the insulin-signaling pathway is important for the maintenance of cognitive performance during aging and hyperinsulinemia, insulin resistance and diabetes increase the risk for AD. Still, the role of circadian deregulation in insulin balance and its contribution to AD pathology is underexplored.
We investigated the role of the circadian protein BMAL1 in the regulation of the insulin-degrading enzyme (*IDE*), which participates in the clearance of both, insulin and Aβ. We hypothesized that alterations in *BMAL1* transcription associated with AD may impair brain insulin metabolism via deregulation of IDE, aggravating neurodegeneration.

We profiled frontal cortex samples from mild cognitively impaired (MCI) and severe AD patients in comparison to age and gender-matched healthy control subjects (N=66), evaluating IDE transcript and protein abundance as a function of the time of death. We detected significant alterations in BMAL1 expression in MCI and AD cases, with reduced amplitude of oscillation and advanced phase of expression. In addition, we observed circadian-like oscillation of *IDE* transcripts in control brains, but the rhythmic patterns of expression were significantly altered in MCI and AD cases for both transcription and protein levels, with changes in amplitude and peak expression time. Moreover, IDE alterations associated with aberrant insulin signaling, including increased IRS-1 phosphorylation in AD brains, and also correlated with cognitive decline. Lastly, *in silico* analysis of the *IDE* proximal promoter identified multiple canonical E-boxes, for the binding of *BMAL1* to the DNA, supporting the role of this clock factor on the regulation of IDE. We conclude that alteration of brain circadian rhythms impact insulin metabolism and potentially Aβ deposition by deregulation of IDE expression, a pathway mediated by *BMAL1*.

Title: p53 dependent SIRT6 expression protects Aβ induced DNA damage

Authors: *H. CHOI[1], E. JUNG[1], H. SONG[1], A. KIM[1], Y. HWANG[2], H. RYU[2], I. MOOK-JUNG[1];

Abstract: Alzheimer's disease (AD) is the most common type of dementia and age-related neurodegenerative disease. Elucidating the cellular changes that occur during ageing is an important step towards understanding the pathogenesis and progression of neurodegenerative disorders. *SIRT6* is a member of the mammalian sirtuin family of anti-aging genes. However, the relationship between SIRT6 and AD has not yet been elucidated. Here, we report that SIRT6 protein expression levels are reduced in the brains of both the 5XFAD AD mouse model and AD patients. Aβ42, a major component of senile plaques, decreases SIRT6 expression, and Aβ42-induced DNA damage is prevented by the overexpression of SIRT6 in HT22 mouse hippocampal neurons. Also, there is a strong negative correlation between Aβ42-induced DNA damage and

p53 levels, a protein involved in DNA repair and apoptosis. In addition, upregulation of p53 protein by Nutlin-3 prevents SIRT6 reduction and DNA damage induced by Aβ42. Taken together, this study reveals that p53-dependent SIRT6 expression protects cells from Aβ42-induced DNA damage, making SIRT6 a promising new therapeutic target for the treatment of AD.

Title: Mechanisms of suppression of Kv1.1 channel activity by Aβ(1-42)

Authors: *K. DEBOEUF[1,2], M. ISLAM[2], J. FARLEY[1,2];
[1]Psychology, [2]Neurosci., Indiana Univ. Bloomington, Bloomington, IN

Abstract: Many studies have found that Aβ-peptides participate in the pathogenesis of Alzheimer's disease (AD), leading to disruption of Ca^{2+} homeostasis and eventual cell death. The mechanisms underlying these effects remain unclear. Our work suggests that Aβ-inhibition of voltage-dependent K^+ channel (e.g., Kv1.1) activity is among the earliest steps. Using murine Kv1.1 expressed in *Xenopus* oocytes, we previously elucidated a pathway in which Ca^{2+}-dependent activation of protein phosphatase 2B (PP2B), PKC, PTKs, and RhoA all participated to produce rapid strong suppression of Kv1.1 activity (Hallahan et al., 2016, under revision). This pathway is recruited by a variety of stimuli that increase $[Ca^{2+}]_i$, including GPCRs that couple to $G_{q/11}$ -PLC, Ca^{2+} ionophore (A23187), and LGICs that flux Ca^{2+}. Because Kv1.1 and related channels are activated during an action potential, regulate depolarization Ca^{2+} influx, and inhibition of Kv1 channels can be neurotoxic, we speculate that Aβ-suppression of Kv1 channels could lead to hyperexcitability, altered synaptic transmission, disrupted Ca^{2+} homeostasis, and neurotoxicity. We assessed the effects of Aβ(1-42) peptide (Anaspec, monomers and low-*n* oligomers) on Kv1.1 channels in oocytes. Aβ(1-42) [10 nM -1 uM] produced dose-dependent inhibition of macroscopic Kv1.1 current: ~50% reductions within 30 m for 1 uM. Reverse sequence (40-1) peptide and other controls failed to suppress Kv1.1. Aβ suppression of Kv1.1 was partially Ca^{2+}- and PP2B-dependent, being reduced by ~50% when cells were loaded with BAPTA-AM, or exposed to the PP2B-inhibitor cyclosporine A. Patch-clamp results suggest that Aβ-suppression of Kv1.1 involves both PP2B-dephosphorylation and direct protein-protein

interaction of Aβ with Kv1.1 channel subunits. Exposure of inside-out single Kv1.1 in ripped-off oocyte patches to application of purified, catalytically-active PP2B produced gradual reductions in *p*(open), followed by abrupt disappearance of Kv1.1 activity. Heat-inactivated PP2B had no effect. Application of Aβ to the intracellular face of Kv1.1 channels under conditions where little enzymatic activity could occur (zero Ca^{2+}, absence of Mg^{2+}/ATP) also produced dramatic reductions in *p*(open).

Title: Suppression of Adiponectin receptor 1 exacerbates $A\beta_{1-42}$ -induced memory impairment and neurodegeneration via down-regulating insulin signaling

Authors: *M. KIM, S. U. REHMAN, N. B. ABID, M. KIM;
Gyeongsang Natl. Univ., Jinju-Si, Gyeongsangnam-Do, Korea, Republic of

Abstract: Illuminating metabolic dysfunction in brain have elaborated a new paradigm in Alzheimer's disease (AD) research. Adiponectin a fat derived hormone binds to Adiponectin receptor 1 (AdipoR1) a major switch to activate metabolic pathway encompasses various organs including brain, liver, heart, pancreas, kidney etc. A Role of AdipoR1 has not established so far and need to be explored. We previously reported the role of Osmotin- a homolog of mammalian adiponectin, in mitigating AD pathology via AdipoR1-AMPK-SREBP2 pathway. To further elucidate osmotin mode of action to ameliorate AD pathology, role of AdipoR1 needs to be elaborated. Present study elucidates relationship between AdipoR1 and $A\beta_{1-42}$ -induced neurodegeneration. For this purpose PEI-based AdipoR1 shRNA-mediated knockdown mice with intravenous injection and induced AD pathology with intracerebral injection of $A\beta_{1-42}$ peptide were generated. Results shows that AdipoR1 knockdown mice showed decreasing pattern of spontaneous alternation behavior as well as long-term spatial learning memory. Evidences from both *in vitro* and *in vivo* models highlighted AdipoR1 deficiency induced activation of apoptotic cascades including caspase3/7 activity, cleaved caspase3, PARP1. Furthermore, insulin signaling correlation to AdipoR1-neuronal cell death have been addressed.

Present study is a first report of AdipoR1 role in neurodegenerative disease and illuminating new therapeutic paradigm of AD.

Title: Oxidative damage impairs cholinergic function in cultured neurons exposed to Alzheimer's-linked Aβ-oligomers

Authors: ***L. E. SANTOS**, C. FIGUEIREDO-FREITAS, N. NUNES-TAVARES, S. T. FERREIRA, F. G. DE MELLO;
UFRJ, Rio De Janeiro, Brazil

Abstract: Acetylcholine is a major neurotransmitter in both central and peripheral nervous systems, usually synthesized near pre-synaptic terminals, in a reaction involving the transfer of an acetyl group from acetyl-coenzyme A to choline. This reaction is carried out by an enzyme known as choline acetyltransferase (ChAT, EC 2.3.1.6), also regarded as a marker of cholinergic neurons. Disturbances of cholinergic neurotransmission have long been implicated in the development of several central nervous system (CNS) pathologies. Among them, Alzheimer's disease (AD) - an alarmingly prevalent form of dementia - stands out for having one of the most well established cholinergic hypotheses, first presented formally in the 1980s. Early work by our group, using chick retina as a CNS model, showed that ChAT activity in cultured or *ex vivo* neurons can be markedly and quite specifically down-regulated by excitotoxic stimuli, such as excitatory amino-acid (EAA) treatments, long before any significant changes in cell viability or enzyme levels occur. This effect was shown to be dependent on calcium influx and at least partially on nitric oxide (NO) production [J Neurochem. 2001; 77:1136-1144]. Recently, we observed similar results in a more specific context. After treating cultured cholinergic neurons

with oligomeric forms of the amyloid-β peptide (AβOs), we found that ChAT activity was significantly down-regulated, without any concurrent loss of neuron viability or enzyme expression. AβOs are diffusible synaptic toxins found in AD brains, which are currently regarded as possible culprits of the disease. Notably, we also showed that this effect of AβOs on ChAT activity is linked to excitotoxicity and the production of reactive oxygen species (ROS), being likely mediated by oxidative damage to the enzyme [JBC 2012; 287:19377-19385]. In the current work, we expand these observations to cultured neurons of the rat septal region, and identify oxidative modifications involved in the loss of cholinergic activity associated with AβOs. Using S-nitrosothiol resin-assisted capture (SNO-RAC) and 4-acetamido-4'-maleimidylstilbene-2,2'- disulfonic acid (AMS) labeling of reduced thiols we show that cysteine modifications are apparently unrelated to this inactivation of the enzyme. Tyrosine nitration, in the other hand, is shown by immunoassay to be induced in the enzyme by treatments with EAAs, AβOs or NO donors, and to correlate well with the loss of ChAT activity. These results suggest a novel mechanism for cholinergic dysfunction, which precedes neuronal death, and may be relevant in early-stage AD pathology.

Title: Modification of aggregation kinetics and cytotoxicity of amyloid beta peptide through insertion of aminoacid point mutations

Authors: A. ESTRADA-RODRIGUEZ[1], J. TREVIÑO-GARZA[2], H. MARTINEZ-RODRIGUEZ[2], R. VIDALTAMAYO[4], *V. ZOMOSA[3];
[1]Bioquimica y Medicina Mol., [2]BIOQUIMICA Y MEDICINA MOLECULAR, [3]UANL, Monterrey, Mexico; [4]Dept. de Ciencias Basicas, Univ. de Monterrey, Monterrey, Mexico

Abstract: Alzheimer´s Disease (AD) is the most common type of senile dementia. Deposition of Amyloid beta (Aβ) peptide in the brain is one of the most important events in AD progression. Current evidence implicates soluble oligomers as primary toxic agents in amyloid diseases. Preventing formation of these soluble oligomers could stop amyloid β-sheet self-assembly. For that reason, formation of Aβ oligomers is being considered a target for therapeutic strategies for AD. It is well known that the amino acid sequence of Aβ peptide is essential for its aggregation and amyloid plaque formation. In this work, we used two variants of Aβ peptide: One containing amino acids 1-40 and other restricted to amino acids 25-35. We inserted point mutations at positions: A30W, K28A and M35C to assess the role of the amino acids in these positions in Aβ-peptide aggregation kinetics and to evaluate if changes in aggregation kinetics correlate with changes in cytotoxicity of the peptides. We used thioflavin S (ThS) as a fluorescent probe to determine amyloid-like structure formation and 8-anilinonaphthalene-1-sulfonic acid (ANS) as a fluorescence probe to determine formation of unstructured hydrophobic aggregates. Our results show that Aβ(25-35), Aβ(25-35)-K28A and Aβ(1-40)-K28A formed more amyloid aggregates, while Aβ(25-35)-A30W did not aggregate at all. We evaluated whether the mutants could modulate aggregation of the wild-type sequence Aβ peptide. We observed that Aβ(25-35)-A30W, Aβ(25-35)-K28A and Aβ(1-40)-A30W acted as inhibitors of amyloid formation, while Aβ(25-35)-M35C, Aβ(1-40)-K28A and Aβ(1-40)-M35C acted as enhancers of amyloid aggregation. We tested the effects of the mutant peptides on cell viability using the rat C6 glioma cell line. Wild-type sequence Aβ-(25-35) and all its mutants decreased cell viability to 45%. In contrast, wild-type Aβ(1-40) decreased cell viability to 55%, while the Aβ(1-40)-A30W mutant increased cell viability to 65%. Remarkably, Aβ(1-40)-K28A and Aβ(1-40)-M35C did not decrease cell viability with respect to control conditions. Our result demonstrate that point mutations change the aggregation kinetics and cytotoxicity of the Aβ peptide, and the strategy of introducing these point mutations could be used to design new therapeutic agents for Alzheimer's disease.

Title: Aggregation dependent effects of Aβ1-40 on human brain pericyte

Authors: *N. SCHULTZ[1], K. BRÄNNSTRÖM[2], A. OLOFSSON[2], M. WENNSTRÖM[1]; [1]Dept. of Clin. Sci., Lund Univ., Malmoe, Sweden; [2]Dept. of Med. Biochem. and Biophysics, Umeå, Sweden

Abstract: The amyloid beta (Aβ)1-40 peptide is known to form depositions, so called cerebral amyloid angiopathy (CAA) in the vessel walls. These depositions are suggested to cause vascular changes such as impaired blood circulation, decreased angiogenesis, dysfunctional and leaking vessels as well as blood brain barrier (BBB) damage. Since Aβ1-40 is toxic for pericytes, a cell type important for vessel function and BBB maintenance, it can be hypothesized that Aβ1-40 induced pericyte loss underlies the vascular changes linked to CAA. Pericytes are recognized by their expression of NG2, a transmembrane glycoprotein important for proliferation, migration and survival. Although the impact of Aβ1-40 on pericyte viability has been shown before, there are few studies examining whether these effects are aggregation dependent. In the current study we use lactate dehydrogenase assay to analyze cell death and immunoassays to analyze caspase 3/7 activity, proliferation and NG2 shedding in primary fetal human brain pericytes (HBVP) after exposure to fibril, oligomer or monomer Aβ1-40. Our study shows that exposure to fibril Aβ1-40 increase cell death. In contrast, monomer Aβ1-40 decreased cell death while unaltered cell viability was found after oligomer Aβ1-40. Further, fibril Aβ1-40 induced an increased shedding of NG2 whereas neither monomer nor oligomer Aβ1-40 affected shedding of this pericyte protective proteoglycan. Moreover, fibril Aβ1-40 induced cell death was ablated when HBVPs were incubated together with either anti-NG2 or anti-low density lipoprotein (LRP)-1 antibodies. Interestingly, monomer Aβ1-40 dramatically increased proliferation of pericytes and co-incubation with anti-NG2 antibody ablated this effect. Fibril Aβ1-40 on the other hand decreased proliferation and oligomer Aβ1-40 had no effect on this event. These results demonstrate that the aggregation form of Aβ1-40 determines the impact of Aβ1-40, as fibril and monomer had quite the opposite effect on pericytes. The results also suggest that LRP-1 and NG2 are involved in the fibril Aβ1-40 toxicity and that the mitogenic effect of monomer Aβ1-40 is mediated via NG2. The findings add knowledge on how Aβ1-40 affects the microvascularity and contribute thereby to a further understanding of the role of CAA in brain vascular pathology.

Title: Possible role of membrane fluidity in the modulation of neurotoxicity of Alzheimer's amyloid beta peptide

Authors: *E. J. FERNANDEZ, F. J. SEPULVEDA, N. RIFFO, D. BASCUÑAN, S. A. SANCHEZ, L. G. AGUAYO;
Univ. De Concepcion, Concepcion, Chile

Abstract: The beta-amyloid peptide (Aβ), crucially involved in Alzheimer's Disease (AD), has been described to have the ability to associate and aggregate on the cell surface, disrupting the plasma membrane through the formation of pores and membrane breakage. However, the molecular determinants involved in this interaction, as well as the role played by the physicochemical properties of the cell membrane, are largely unknown. Since cholesterol is an important molecule for membrane integrity and fluidity, we examined the effect of varying cholesterol content with the association and subsequent perforation of the plasma membrane by Aβ in hippocampal neurons.
Using cultured rat hippocampal neurons and methyl-β-cyclodextrin (MβCD) as a tool to increase or decrease the levels of cholesterol in the cellular membrane, we analyzed if membrane fluidity affected membrane association and perforation using confocal/spectral microscopy, generalized polarization (GP), and electrophysiologal techniques. The results showed that cholesterol removal produced an increase in membrane fluidity (30% decrease in GP value compared to control cells) and facilitated membrane perforation by Aβ with respect to control cells (time to establish perforated configuration (TEPC): control=8±2 vs. MβCD=2.3±0.5 min, $p<0.01$). Interestingly, under this condition, a decrease in the association of Aβ to neuronal membranes was observed (fluorescent-punctas/20µm: control=18±2 vs. MβCD=10±1, $p<0.05$). On the contrary, increasing cholesterol levels by 25%, which is known to increase membrane rigidity (40% increase in GP value compared to control cells) enhanced the association and clustering of the peptide with the membrane (fluorescent-punctas/20µm: control=18±2 vs. MβCD=10±1, $p<0.01$), but inhibited membrane disruption.
In conclusion, our results strongly suggest the importance of plasma membrane organization in the toxic effects of Aβ in hippocampal neurons, since fluidity can regulate the distribution and insertion of the Aβ peptide in the neuronal membrane.

Title: The distribution of neuronal pserstat3 is affected by a mediator released by astrocytes in response to AβOs

Authors: ***Y. A. MUÑOZ**[1], A. PAULA-LIMA[2], M. T. NUÑEZ[1];
[1]Dept. of Biol., [2]Inst. for Res. in Dent. Sci., Univ. of Chile, Santiago, Chile

Abstract: Astrocytes are essential for neuronal survival; however, under pathological conditions astrocytes participate in the degeneration of adjacent neurons. Amyloid-beta oligomers (AβOs) have been found in Alzheimer's disease (AD) brains and astrocytes respond to AβOs through a process called reactive astrogliosis, which generates reactive oxygen/nitrogen species (ROS/RNS) and inflammatory cytokines that affect surrounding neurons. Stat3 is a crucial transcription factor involved in maintenance and function of nervous system and its deregulation has been implicated in AD. Growth factors induce serine-727 phosphorylation and this modification is associated with modulation of transcriptional activity of Stat3. The main goal in this work is determine if hippocampal neuronal Stat3 is affected by reactive astrocytes. **Methods**: Primary hippocampal neuron and astrocytes cultures were used. Changes in pSerStat3 distribution were detected by immunocytochemistry. The oxidative tone and ROS production were evaluated by microscopy and fluorimetry. Protein and mRNA levels were determined by Western blotting and PCR, respectively. **Results:** Here, we show that AβOs does not induce changes in protein neither mRNA Stat3 levels in neurons but it produces pSerstat3 redistribution in mixed neuron-astrocytes cultures. The mediator released by astrocytes-stimulated by AβOs in the media increase neuronal oxidative tone. **Conclusion:** We propose that in hippocampal neurons, pSerStat3 is a sensor for stressor astrocyte-produced induced by AβOs activation.

Title: Identification of short brain penetrant amylin receptor based peptides as potential therapeutic agents for Alzheimer's disease

Authors: *R. N. SOUDY[1], W. FU[1], K. KAUR[2], J. JHAMANDAS[1];
[1]Dept. of Med., Univ. of Alberta, Edmonton, AB, Canada; [2]Chapman Univ. Sch. of Pharm. (CUSP), Chapman Univ., Irvine, CA

Abstract: Aggregation and deposition of β-amyloid (Aβ) peptides in brain play a pivotal role in Alzheimer's disease (AD) pathogenesis. We have identified the amylin receptor as a putative target for the deleterious effects of Aβ in the brain, and chronic administration of AC253 (a 24-amino acid peptide), an amylin receptor antagonist, improves age-dependent deficits in spatial memory and learning in transgenic mouse model of AD. Identification of shorter amylin receptor antagonist peptides, that are proteolytically stable and brain penetrant when administered systemically could provide novel therapies for AD. An AC253 based peptide library of 14 peptide fragments was synthesized on cellulose membrane and screened for binding to amylin receptor using transfected HEK-293 that express the amylin 3 (AMY3) receptor subtype (AMY3). Promising sequences were synthesized using Fmoc synthesis, and labeled with Cy5.5 dye for further studies. *In vitro* cell uptake was evaluated in AMY3 cells using flow cytometry and fluorescence microscopy. *Ex-vivo* brain uptake was done using near infrared imaging, and fluorescence microscopy. Peptides R5 (12 aa), and R14 (14 aa) showed significant binding to HEK293-AMY3 cells compared to other library fragments. *In vitro* studies showed that both peptides blocked human amylin cellular responses in HEK293-AMY3 cells with equal the potency as full length AC253. Flow cytometry and fluorescence microscopy cell uptake studies demonstrated that R5, and R14 peptides have selective and significant specific binding to HEK293-AMY3 cells similar to AC253. *Ex vivo* brain imaging in wild type mice after intra-peritoneal administration of Cy5.5 labelled peptides revealed that both R5, and R14 peptides can cross the Blood Brain Barrier, and peptide R5 showed superior brain penetration to that observed in AC253. Microscopy studies showed that labeled peptides were mainly distributed in the hippocampal and cortical regions, which coincides with the amylin receptor localization in the

brain. Our data identify novel promising peptides amylin receptor antagonists for future pre-clinical and clinical studies in AD.

Title: Effects of amylin receptor antagonist AC253 fragments on beta amyloid (Aβ) - and human amylin-induced depression of hippocampal long-term potentiation.

Authors: ***R. KIMURA**[1], R. SOUDY[2], W. FU[2], D. WESTAWAY[2,3], J. JHAMANDAS[2]; [1]Ctr. for Liberal Arts and Sci., Tokyo Univ. of Science, Yamaguchi, Sanyo-Onoda, Japan; [2]Medicine. (Neurology) and Inst. of Neurosci. and Mental Hlth., [3]Ctr. for Prions and Protein Folding Dis., Univ. of Alberta, Edmonton, AB, Canada

Abstract: Alzheimer's disease (AD) is characterized by accumulation of amyloid-β peptide (Aβ) in the brain regions that subserve memory and cognition. We have previously demonstrated that effects of $A\beta_{1-42}$ and human amylin on hippocampal long-term potentiation (LTP) are blocked by the amylin receptor antagonists, AC253 and pramlintide. In this study, we examined the effects of several peptidergic fragments, that were derived from AC253, on $A\beta_{1-42}$ and human amylin-evoked depression of LTP at Schaeffer collateral-CA1 hippocampal synapses. In mouse hippocampal brain slices, field excitatory postsynaptic potentials (fEPSPs) were recorded from the stratum radiatum layer of the CA1 area in response to electrical stimulation of Schaeffer collateral afferents. LTP was induced by either high frequency (HFS) or 3-theta burst stimulation (TBS) protocols. $A\beta_{1-42}$ (50 nM) and human amylin (50 nM) depressed LTP evoked using both stimulation protocols. Pre-application of fragment #5 (R5, 250 nM) and #14 (R14, 250 nM), but not #11 (R11, 250 nM), blocked both Aβ- and human amylin-induced reduction of LTP without affecting baseline transmission or LTP on their own. We also examined the effects of these fragments on LTP in Aβ-over-expressing transgenic mice (TgCRND8). In contrast to wild-type age matched control mice, 6-12-month old TgCRND8 mice show blunted LTP. In TgCRND8

mice, basal depression of LTP is enhanced by application of R5 and R14 but not R11 fragments. Our data show that specific shorter sequence peptides derived from AC253, possess amylin receptor antagonist activity to reverse the effects of $A\beta_{1-42}$ and human amylin on LTP, and furthermore, also increase LTP in TgCRND8 mice with increase brain amyloid burden. These peptidergic fragments by virtue of their ability to block the amylin receptor may thus serve as potentially useful therapeutic agents in treatment of AD.

Title: Systemic administration of amylin receptor antagonist, cyclic AC253, improves spatial memory in Aβ over-expressing (TgCRND8) mice

Authors: ***A. N. PATEL**[1,2], R. SOUDY[1], W. FU[1], D. MACTAVISH[1], J. YANG[2], D. WESTAWAY[2], J. JHAMANDAS[1];
[1]Dept. of medicine, Univ. of Alberta, Edmonton, AB, Canada; [2]Ctr. for Prions and Protein Folding Diseases, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Alzheimer's disease (AD) is characterized by accumulation of amyloid-β peptide (Aβ) in the brain regions that subserve memory and cognition. We have previously demonstrated that electrophysiological and neurotoxic effects of Aβ can be blocked by the amylin receptor antagonist, AC253. Furthermore, chronic intracerebroventricular infusions of AC253 restore spatial memory deficits in APP over-expressing transgenic mice (TgCRND8). In this study, we performed systemic administrations of cyclized AC253 (cAC253) that is proteolytically stable

and brain penetrant, to examine the effects of this peptide on memory and learning in TgCRND8 mouse model.
TgCRND8 and wild-type (Wt) littermate control mice (3.5 months of age) received daily intraperitoneal injections for 10 weeks of either cAC253 or saline. Hippocampal-dependent spatial learning and memory was assessed at baseline and 10 weeks after drug administration using standard Morris Water Maze (MWM) and Novel Object Recognition tests. In the acquisition phase (escape latency) in MWM task, TgCRND8 mice had significantly longer escape latencies over the 5-day testing period than Wt littermate controls at 6 months of age. However, TgCRND8 mice receiving cAC253 for showed significant shorter escape latencies in MWM at 6 months of age compared to TgCRND8 treated with saline. Western blot analysis of brains from Tg cAC253 treated group showed increase (15%) in synapsin-1 and synaptophysin compared to Tg saline treated group. Other markers of AD pathology from treatment groups are being evaluated. These studies provide evidence for the utility of systemic administrations of the brain penetrant amylin receptor antagonist, cyclic AC253, in mitigating spatial memory learning deficits in an AD mouse model.

Abstract: Pyroglutamate-3 Aβ (pGlu-3 Aβ) is an N-terminally truncated and modified Aβ species found in plaques and vascular amyloid in Alzheimer's disease (AD) brain (Saido et al., 1995; Lemere et al., 1996). Following truncation of the first 2 Aβ residues, pGlu-3 Aβ is formed by the cyclization of glutamate at residue 3 by glutaminyl cyclase (QC) and is associated with increased aggregation and neurotoxicity (Russo et al., 2002; Schilling et al., 2006; Nussbaum et al., 2012). Previously, we reported that chronic treatment in plaque-rich 12 mo-old APP/PS1dE9 mice with an anti-pGlu-3 Aβ IgG2a mAb (07/2a), demonstrated significant cognitive improvement and plaque reduction compared to PBS-control mice and was more effective than an anti-pGlu-3 Aβ IgG1 mAb (07/1) (SfN 2015). Here, we treated hAPP/hQC double transgenic (Tg) mice, an hAPP mouse model with enhanced pGlu3-Aβ generation due to overexpression of human QC, with: i) 07/2a at two doses (150μg and 500μg); ii) 07/2a-k (500 μg), 07/2a bearing a CDC mutation to avoid complement activation; and iii) PBS. Passive i.p. immunization was performed weekly from 8 to 12 months of age. PyroGlu-3 Aβ immunoreactivity (IR), measured by 07/2b IgG2b (k17) mAb, was significantly reduced in the hippocampus in 07/2a-treated (150μg dose, $p<0.05$; 500μg dose, $p<0.01$), and 07/2a-k-treated ($p<0.05$) compared to PBS-control hAPP/xhQC mice. General Aβ (R1282 IR) was significantly decreased in hippocampus in all three pGlu-3 Aβ vaccinated groups compared with PBS-control hAPP/hQC mice. Although a few hemosiderin-positive microhemorrhages were seen in all groups, no differences were observed immunized vs. PBS-control hAPP/hQC mice. In a separate study, we performed longitudinal ^{18}F-GE180 TSPO microPET imaging of microglial activation at baseline and Days 3 and 30 following a single injection of 07/1, 07/2a and 07/2a-k in young, pre-plaque vs. aged, plaque-rich APP/PS1dE9 mice. Differences were observed in hippocampal and whole brain uptake of ^{18}F-GE180, suggesting that the IgG isotype and CDC mutation of the anti-pyroGlu3 Aβ mAbs, as well as aging and the presence of plaques, differentially affected microglial activation. In summary, we demonstrate that: 1) murine anti-pGlu-3 Aβ IgG2a antibodies with and without a CDC mutation significantly lowered pyroGlu3 and general Aβ plaques without increasing microhemorrhage in a mouse model with enhanced pyroGlu3 Aβ deposition, and 2) microglial activation was differentially altered by a single injection of 07/2a and 07/1 mAbs but unchanged by immunization with 07/2a-k. Further studies are underway to better understand the clearance mechanisms for each of these anti-pyroGlu3 Aβ antibodies.

Title: Tocotrienol-rich fraction inhibits amyloid β fibrillation *In vitro* and in transgenic mouse model of Alzheimer's disease

Authors: *N. F. IBRAHIM[1,2], D. YANAGISAWA[1], L. W. DURANI[1,2], H. S. HAMEZAH[1,2], H. A. DAMANHURI[2], W. Z. WAN NGAH[2], I. TOOYAMA[1];
[1]Mol. Neurosci. Res. Ctr., Shiga Unversity of Med. Sci., Otsu, Japan; [2]Dept. of Biochem., Universiti Kebangsaan Malaysia, Kuala Lumpur, Malaysia

Abstract: Aim and Background
Abnormal aggregation of amyloid β (Aβ) peptides may result in formation of insoluble Aβ fibrils that deposit outside neurons, known as senile plaques in Alzheimer's disease (AD). Therapeutic approaches aimed at modulation of Aβ pathology have been studied, and one such approach involves vitamin E. Tocotrienol-rich fraction, (TRF) an extract of palm oil containing large amounts of vitamin E analogs (mostly tocotrienols) has been shown to reduce Aβ-induced toxicity in cell culture. Therefore, the present study investigated the effects of TRF, in potentially modulating Aβ fibril formation *in vitro* and in APP/PS1 transgenic mice.
Methods
The effect of TRF on Aβ (1-42) fibrillation was investigated with thioflavin T (ThT) assay and SDS-PAGE (sodium dodecyl sulfate electrophoresis on polyacrylamide gel). APP/PS1 mice were daily supplemented with either water (n = 9), or palm oil stripped of vitamin E (PO, n = 10), or TRF (60 mg/kg; n = 11) from ages 5 to 15 months. Meanwhile wild type mice (n = 13) received water. Novel object recognition tests were done at age 14.5 months. After that, Thioflavin S staining and immunohistochemistry using anti-Aβ (N) antibody were performed. Immunoreactive areas were measured using ImageJ software.
Results
Under cell-free conditions, ThT assay fluorescence intensity for Aβ (1-42) incubated alone increased progressively with incubation time. Interestingly, TRF dose-dependently inhibited the formation of Aβ fibrils, as shown by a reduction of fluorescence intensity. In SDS-PAGE, TRF treatment showed relatively more intense bands of low molecular weight Aβ (1-42) aggregates in

a dose-dependent manner.
In animal experiments, APP/PS1 mice supplemented with TRF showed significantly more exploration of the novel object as indicated by recognition index, compared to water-supplemented APP/PS1 mice. This result indicated preservation of cognitive function comparable to wild type mice. Moreover, thioflavin-S-positive fibrillar load was significantly reduced in APP/PS1 mice supplemented with TRF. In addition, Aβ immunoreactivity was decreased in the brains of TRF-supplemented mice. No significant benefit was seen in PO-supplemented mice. These results indicated that TRF reduced Aβ pathology in the brain of APP/PS1 mice.
Conclusion
These findings suggest potential beneficial effect of TRF as a therapeutic agent to reduce amyloid fibrillation *in vitro* and in transgenic mouse model of AD.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder caused by the aggregation of the amyloid-beta peptide (Aβ) in senile plaques and cerebral vasculature. The $A\beta_{25-35}$ fraction

has shown the most toxicity; its neurotoxic mechanisms are associated with the generation of oxidative stress and reactive astrogliosis that induce neuronal death and memory impairment. Studies indicate that pharmacological treatment with flavonoids reduces the rate of AD, in particular, it has been shown that antioxidants are compounds that could interact with this peptide due to their antioxidant properties. In this study, experimental and computational tools were used to calculate the molecular electrostatic potential and the Fukui function with the Gaussian 09 computational program, to predict the most reactive parts of these molecules and make the complex between $A\beta_{25-35}$ and two flavonoids (catechin and epicatechin) in the absolute gas-phase, where a possible interaction between them was observed. This is important for understanding the $A\beta_{25-35}$-Flavonoid (A-F) interaction as a therapeutic strategy to inhibit the neurotoxic effects that this peptide causes in AD, which currently is still considered an ambiguous process.

Abstract: Alzheimer's disease (AD) is the most abundant neurodegenerative disorder and threatens our ageing society. Immunotherapeutic approaches are currently the most advanced therapies for treatment of AD. Antibodies raised to amyloid β-peptide (Aβ) cross the blood-brain-barrier and bind to amyloid plaques in the brain of AD patients. Bound antibodies induce clearance of amyloid plaques by microglia via Fc receptor-mediated phagocytosis. Dysfunctions of microglia may play a pivotal role in AD pathogenesis and could result in reduced efficacy of antibody-mediated Aβ clearance. Recently, heterozygous mutations in the triggering receptor expressed on myeloid cells 2 (*Trem2*), a microglial gene involved in phagocytosis, were genetically linked to late onset AD. Loss of TREM2 has been shown to reduce the ability of microglia to engulf Aβ. We have now investigated if loss of TREM2 affects the efficacy of immunotherapeutic approaches. Using CRISPR/Cas9 modified N9 microglial cell lines as well as bone marrow derived macrophages (BMDM) and primary microglia cells from wild-type (wt) or *Trem2* knockout (ko) mice, we investigated the potential of these cells for antibody-dependent phagocytosis of pre-formed Aβ fibrils or engulfment of antibody covered amyloid plaques from brain slices of APP/PS1 mice. We showed that anti-Aβ antibodies stimulate fibril Aβ uptake and amyloid plaque clearance in a dose-dependent manner in the presence or absence of TREM2. However, TREM2-deficient N9 cells, as well as macrophages and primary microglia derived from *Trem2* ko mice showed significantly reduced uptake of antibody bound Aβ and as a consequence reduced clearance of amyloid plaques. The level of Fcγ-receptors I-IV increased in *Trem2* ko BMDM, indicating a compensatory increase of TREM2 independent antibody/antigen uptake pathways and probably explaining why *Trem2* ko cells still response to increasing concentrations of anti-Aβ antibodies. Antibody titration experiments revealed that reduced efficacy of amyloid plaque clearance and fibril Aβ uptake in *Trem2* ko cells can be compensated by elevating the concentration of therapeutic antibodies. Taken together, our findings suggest that patients with compromised TREM2 function may require a higher dose of the therapeutic antibody to achieve efficient Aβ clearance.

Title: Aβ vaccination with bee venom derived phospholipase A2 (bvPLA2) ameliorates Alzheimer's disease pathology through the induction of Aβ-specific Treg population in 3xTg-AD mice

Authors: *H. BAE, H. BAEK, C. LEE, G. LEE, D. CHOI;
Col. of Korean Med., Seoul, Korea, Republic of

Abstract: Alzheimer's disease (AD) is the most common form of dementia and characterized by an imbalance between the production and clearance of amyloid-beta (Aβ) and tau proteins. Vaccination against Aβ peptide results in dramatic reduction of Aβ pathology in experimental mouse models. Our recent study demonstrated that bvPLA2, the major component of BV, causes immune tolerance by increasing the population of CD4+ CD25+ Foxp3+ Tregs in cisplatin-induced nephrotoxicity, an allergic asthma and Parkinson disease murine model. Here, we investigated that the effect of bvPLA2 to induce antigen-specific Tregs to ameliorate Alzheimer's disease pathology through linked immunosuppression. First, we investigated whether bvPLA2 would improve the cognitive function and the pathological features of AD in Aβ-vaccinated-3xTg-AD mice. bvPLA2 treatment dramatically ameliorated learning and memory deficits in Aβ-vaccinated-AD mice. In addition, bvPLA2 significantly reduced Aβ deposits in the hippocampus and cortex region of AD mice, compared with the Aβ-vaccinated-AD mice group. Next, we systemically administered Aβ-specific Treg populations generated in the absence or presence of bvPLA2 into 3xTg-AD mice. Systemic transplantation of Aβ-specific Tregs into 3xTg-AD mice improved cognitive function and reduced deposition of Aβ plaques. Furthermore, adoptive transfer of Tregs generated in the presence of bvPLA2 showed reduced Aβ plaques and diminished learning and memory ability compared with Tregs generated in the absence of bvPLA2. This opens the possibility of new therapeutic strategy to target Tregs to tissue-specific antigens for the treatment of AD.

Title: Epigenetic modulation of amyloid precursor protein (APP) metabolites and other Alzheimer's disease biomarkers *In vitro* and *In vivo*

Authors: *C.-H. VOLMAR, H. SALAH-UDDIN, P. HALLEY, G. LAMBERT, A. WODRICH, S. MANOAH, N. PATEL, N. MEHTA, G. SARTOR, K. JANCZURA, S. DESSE, D. DORCIUS, C. WAHLESTEDT;

Abstract: Alzheimer's disease (AD) is the most common form of dementia in the elderly. Currently approved treatments are not efficacious and are palliative at best. The "amyloid cascade hypothesis" places beta amyloid (Aβ) at the origin of AD, causing a chain of molecular events leading to neuronal degeneration, memory loss, motor impairment, and eventually death. No FDA-approved treatment presently reduces Aβ accumulation (the main constituent of plaques) in the brain of patients. With the recent clinical trial shortcomings of Alzheimer's immunotherapy and γ-secretase inhibitors, experts in the field agree that "drug cocktails" are desirable but present challenges in terms of clinical and regulatory hurdles. We therefore took an epigenetic approach where a single drug would simultaneously affect the expression of a number of defined AD-related targets.
Screening of our in-house comprehensive library of epigenetic compounds in an AD cell model over-expressing APP with the Swedish mutation resulted in the identification of small molecules that are able to significantly reduce Aβ. Confirmed non-toxic Hits were then tested in RT-QPCR and western blots to hone in on compounds that affect AD-related and neuro-protective genes and proteins. We identified an atypical small molecule histone deacetylase inhibitor (HDACi), CTI-309, that reduces beta amyloid (Aβ), decreases tau gene expression, and increases the expression of the following genes: BDNF, α-secretase (ADAM10), Mint2, Fe65 and REST. This molecule increases the production of sAPPα, the cleavage product of ADAM10, in line with the increased gene expression observed for ADAM10. This molecule also increases levels of immature APP, supporting an effect on APP trafficking, as do the increases in Mint2 and Fe65. Treatment of the triple transgenic (APP/PS1/tau) (3xTg AD) mouse model with CTI-309 resulted in significant increases in spontaneous alternations in the Y-maze compared to controls. We also observed, in these CTI-309 treated mice, significant increases in frequency and time spent with the novel object in the novel object recognition test. Interestingly, no differences were observed in the open field test. Taken together, our data suggest that the newly identified epigenetic molecule CTI-309 is brain penetrant, targets the non-amyloidogenic pathway, affects APP trafficking, increases neuroprotective genes, shows less toxicity than other HDACis tested and increases memory in an AD model. We are currently conducting experiments to decipher the exact mechanism of this molecule.

Title: Lipoprotein receptor related protein 1 as a therapeutic target for alzheimer’s disease

Authors: *A. RAMACHANDRAN[1], S. KUMAR[1], K. V. RUPANAGUDI[1], H. S. ILAMATHI[2], S. S. THAKUR[2], M. CHAND[3], P. KHANNA[3], S. C. JAIN[3], V. RAVINDRANATH[1]; [1]Indian Inst. of Sci., Bangalore, India; [2]Ctr. for Cell. and Mol. Biol., Hyderabad, India; [3]Univ. of Delhi, Delhi, India

Abstract: Alzheimer’s disease (AD), a debilitating neurodegenerative disorder is characterised by progressive loss of memory, cognitive, and executive functions. Accumulation of β-Amyloid 42 (Aβ42) is considered to be the causative factor in Alzheimer’s disease, either due to the over production of Aβ42 (in familial AD) or decreased clearance as seen in sporadic forms of the disease. The drugs currently used for treatment of AD provide symptomatic relief but do not cure or alter the progression of the disease. We have previously shown that partially purified extract of root of *Withania somnifera* (WS) reverses behavioural deficits and pathological hallmarks of AD in middle aged and old APPswe/PS1ΔE9 (APP/PS1) mice via upregulation of liver lipoprotein receptor related protein 1 (LRP1) leading to clearance of Aβ42 from brain (Sehgal *et al*, Proc. Natl. Sci, 2012) to the periphery through the peripheral sink, sLRP in the plasma. In order to identify the active principle(s) in the partially purified extract of WS, we fractionated it into twelve sub-fractions and studied the effect of these sub-fractions on LRP1 expression, *in vitro* using luciferase based reporter system. Different regions of LRP promoter were cloned into pGL3 basic promoterless vector such that the luciferase gene is expressed under LRP promoter. This construct was transfected into H6 cells and the cells were further treated with each sub-fraction followed by luciferase assay. Two sub-fractions showed significant increase in reporter induction as compared to the crude extract. We further studied the effects of these two sub-fractions *in vivo* and found that treatment of 9 month old APP/PS1 mice for 15 days results in a

three fold increase in liver LRP expression. Identification of the active principle(s) in these two sub-fractions will help in generation of a class of drugs that help clearance of Aβ42 from the brain leading to reversal of cognitive deficits.

Title: Inflammation induces natural anti-amyloid beta antibodies in a murine Alzheimer's disease model

Authors: ***M. J. CHUMLEY**[1], M. A. THOMPSON[1], K. C. PAULHUS[1], M. J. EIMERBRINK[2], J. L. PETERMAN[2], J. D. WHITE[2];

Abstract: Alzheimer's disease is the leading cause of dementia, and amyloid beta (Aβ) plaques are one of the main pathologies associated with the disease. Anti-Aβ immunotherapy has been investigated as a means of reducing the Aβ burden seen in Alzheimer's patients. Studies in transgenic mice have shown that immunization with anti-Aβ antibody or with the Aβ protein itself causes a significant decrease in the Aβ burden. Immunohistochemistry of the brains of these mice reveals increased IgG binding to Aβ plaques in the brain, correlating with decreased overall plaque burden (Schenk et al., 1999; Wilcock et al., 2004). Furthermore, recent studies in humans have shown increased levels of naturally produced anti-Aβ antibodies in Alzheimer's patients (Kellner et al. 2009). Previous research from our lab as shown that CD57BL6/J mice given seven daily intraperitoneal injections of lipopolysaccharide exhibit a significant increase of Aβ in the brain. Additionally, when mice were given a two-week recovery period followed by a second bout of LPS injections, there was no additional Aβ production, suggesting a protective effect initiated by the first LPS bout. The objective of the present study was to determine if anti-Aβ immunoglobulin production increases with LPS stimulation, and to investigate whether this IgG crosses the blood brain barrier and aggregates around Aβ plaques. Female Alzheimer's transgenic mice were injected with LPS for one week, followed by a two-week recovery period and a second week of LPS injections. After injections, mice were euthanized in accordance with IACUC-approved methods, immediately after which brains and blood samples were collected.

The blood was analyzed by ELISA to determine antibody concentration, and brains were analyzed by immunohistochemistry to determine IgG presence around Aβ plaques. We found an increase of anti-Aβ IgG in the blood, correlating with an increased amount of IgG around plaques as compared to controls. These results demonstrate that mice can be stimulated to produce natural anti-Aβ antibodies as a response to inflammation and the increased Aβ burden caused by inflammation.

Title: Sigma-2/PGRMC1 antagonist pharmacodynamic target engagement biomarker discovery for Alzheimer's disease

Authors: *C. REHAK, N. IZZO, K. MOZZONI, C. SILKY, R. YURKO, H. SAFFERSTEIN, S. CATALANO;
Cognition Therapeut. Inc., Pittsburgh, PA

Abstract: Cognition Therapeutics Inc. (CogRx) discovered CT1812, a novel Abeta oligomer receptor antagonist which is the only drug candidate demonstrated to prevent and displace Abeta oligomer binding to neuronal receptors. By stopping the initiating event in the Abeta oligomer cascade, this first-in-class drug blocks downstream synaptotoxicity and restores memory to normal in transgenic mouse models of Alzheimer’s disease (AD). CT1812 displaces receptor-bound oligomers by allosterically antagonizing the sigma-2/PGRMC1 receptor (Izzo et al., 2014a, b). CT1812 is the first disease modifying therapeutic that will test the oligomer

hypothesis of AD. Biomarkers in patient biofluids that change following CT1812 engagement with the target receptor enable independent verification of compound activity. Despite prior clinical experience with sigma-2 ligands, biomarkers of sigma-2/PGRMC1 antagonist functional target engagement are not reported in the literature. Sigma-2/PGRMC1 has been demonstrated to regulate expression levels and subcellular localization of several proteins, including EGF receptor (Ahmed et al., 2010), mPRα receptor (Thomas et al., 2014), UNC 40/DCC (Runko et al., 2004), and GLP-1 receptor (Zhang et al 2014). We hypothesize that sigma-2/PGRMC1's role in regulating expression levels and subcellular localization of several proteins may provide an opportunity to measure drug-target engagement, which may manifest as changes in target protein expression or downstream signaling in clinically relevant samples. In 21DIV neurons, sigma-2/PGRMC1 localization was visualized by immunocytochemistry and quantified via image processing. In neurons, GLP-1R was expressed predominantly in the cytoplasm at low levels. Addition of Abeta oligomers caused a significant increase in GLP-1 receptor protein expression in the nucleus. Treatment with sigma-2/PGRMC1 antagonist CT1344 (analog of clinical candidate CT1812) at therapeutic brain concentrations blocked this increase, restoring GLP-1R expression pattern to normal, but did not affect expression in the absence of Abeta oligomers. The magnitude of protein concentration changes associated with the effects of Abeta oligomers on expression levels of GLP-1R was modest (i.e. 20%), but was completely reversed by CogRx sigma-2/PGRMC1 antagonist. Target engagement "fingerprints" (patterns of consistent changes in amounts of several proteins, each modest in magnitude) have been used successfully as pharmacodynamic biomarkers in clinical studies (Paweletz et al. 2009; Tsitoura et al. 2015).

Title: Prevention of Aβ-induced deficits in long term potentiation (LTP) *In vitro* and *In vivo* by MRZ-99030 and MRZ-14042

Authors: *G. RAMMES[1], R. D. JEGGO[2];
[1]Clin. Rechts der Isar, Munich, Germany; [2]Neurodegeneration in vivo, Lundbeck, Valby, Denmark

Abstract: β-Amyloid (Aβ) plays a pivotal role in the aetiology of Alzheimer's disease (AD) and other neurodegenerative, protein aggregation disorders. Recently, increasing evidence indicates that small soluble toxic Aβ species are the more synaptotoxic form. MRZ-99030 and MRZ-14042 are both small dipeptide molecules that interfere with Aβ aggregation. MRZ-14042 was more potent than MRZ 99030 in binding to Aβ as determined by surface plasmin resonance – affinities for monomeric $A\beta_{1-42}$ were 10nM and 30 nM respectively. Atomic force microscopy and diffuse light scattering experiments revealed that both MRZ-99030 and MRZ-14042 prevent the formation of toxic oligomeric species by promoting aggregation into non-toxic, off-pathway MRZ-99030 / Aβ assemblies and thereby suppressing the toxic effect of Aβ oligomers. MRZ-14042 had lower stoichiometric requirements than MRZ 99030 i.e. was also effective at a 1:1 ratio, whereas MRZ-99030 required a 10-20 fold excess over Aβ.
Long term potentiation (LTP) is regarded as an electrophysiological correlate of neuronal synaptic plasticity and is impaired by acute administration of Aβ oligomers. MRZ-99030 fully prevented deficits in LTP *in vitro* induced by $A\beta_{1-42}$ oligomers (10 - 50 nM) when applied at a 10:1 ratio e.g. 100 nM of MRZ-99030 against $A\beta_{1-42}$ 10 nM, whereas at a 1:1 ratio MRZ-99030 was ineffective. Surprisingly, MRZ-14042 (100nM) did not reverse deficit in *in vitro* LTP evoked by $A\beta_{1-42}$ (10nM).
MRZ-99030 50 mg/kg s.c. had little effect *per se* on LTP *in vivo* but almost completely prevented the deficits in synaptic plasticity induced by $A\beta_{1-42}$ oligomers (6μL, 1.8 μM). The dose-dependency of this effect was further investigated with MRZ-14042 which was effective even at doses as low as 0.4mg/kg MRZ-14042 (~10nM brain ECF). The reasons for this apparent discrepancy in *in vitro* and *in vivo* LTP are unclear.
In addition, MRZ-14042 (1μM) almost completely prevented depolarization of retinal ganglion cells and retinal epithelial cells by $A\beta_{1-42}$ oligomers (50nM) *in vitro* whereas MRZ-99030 (1μM) was somewhat less efficacious – around 50% effect size.
These data provide proof of concept for both compounds as potential treatments for Alzheimer´s

disease and retinal pathologies associated with toxic effects of Aβ oligomers e.g. glaucoma and age-related macular degeneration.

Title: Treatment with a Clusterin/ApoJ peptide reduces amyloid pathology in APP/PS1 mice

Authors: *D. A. HOTTMAN[1], D. S. CHERNICK[2], Y. ZHANG[1], A. GRAM[1], R. OMTRI[3], K. KANDIMALLA[3], L. LI[1];

Abstract: Alzheimer’s disease (AD) is a progressive neurodegenerative disorder that poses a growing challenge to health care systems and economies across the globe. Currently there is no cure for AD. Recent genetic studies have identified the clusterin gene (*CLU*, also known as apoJ) as one of the top-ranking loci associated with late-onset AD. Like apoE (a primary genetic risk factor for AD), apoJ is a multifunctional protein; apoJ binds Aβ, inhibits Aβ aggregation, enhances phagocytosis of Aβ aggregates, and facilitates the clearance of Aβ across the blood-brain barrier (BBB) as well as modulates inflammatory and immune functions in the brain. Previous studies have shown that a 10-amino acid peptide derived from an integral sequence of apoJ, apoJ[113-122], recapitulates several beneficial properties of full length apoJ. In preliminary studies, we have found that apoJ[113-122] inhibits Aβ aggregation, protects neuronal cells against Aβ-induced cytotoxicity, enhances hippocampal synaptic plasticity in mouse brain slices, promotes anti-inflammatory activity of plasma HDL, and crosses the blood-brain barrier *in vitro* . Following these findings, an *in vivo* daily injection study of apoJ[113-122] was conducted for 3 months in the APP/PS1 mouse model of AD. The cerebral Aβ load was markedly reduced in apoJ[113-122] treated mice, compared with PBS treated controls.

Intriguingly, there was a corresponding increase in the level of Aβ in the plasma of apoJ[113-122] treated mice, indicating that apoJ[113-122] enhances Aβ efflux from the brain across the BBB. Additional biochemical analysis are underway to further elucidate the mechanisms by which apoJ[113-122] elicits these observed effects. These findings suggest that the apoJ[113-122] peptide could be a potential new therapeutic agent against AD.

Title: Treatment with Aβ oligomer eliminating D-peptide causes uptake of Aβ species by neurons in Tg AD model mice.

Authors: *T. VAN GROEN[1], I. KADISH[1], M. TUSCHE[2], N. JIANG[2], D. WILLBOLD[2]; [1]Cell, Developmental and Integrative Biol., Univ. Alabama-Birmingham, Birmingham, AL; [2]Forschungszentrum Juelich, Juelich, Germany

Abstract: Our two transgenic mouse lines express two AD mutations, i.e., PS1 (ΔE9 mutation) and APPswe or APPswe/dutch/iowa. They develop plaques at about four months of age, and we have described that two types of deposits are present, plaques (with a thioflavine S [and Congo red] positive core) and diffuse deposits. Furthermore, plaques are surrounded by activated glial cells, but diffuse deposits are not. We hypothesized that these distinct amyloid deposits would label differently following intracerebral anti Aβ42 targeted D-peptide injections in these mice. We sacrificed and transcardially perfused the mice at 1, 2 and 4 days following the injections. The brains were cut and immunohistochemically stained for APP and Aβ, and GFAP and Iba-1. Following the 1 and 2 days survival time the AD mice displayed a clear labeling of Aβ in the cortex and hippocampus, after 4 days retrograde transport was seen (related to specific terminal fields, i.e., connected to the injected area), however they do not show a change in the number of plaques. Further, the labeled Aβ is present in lysosomes in neurons near the injection site. Labeled Aβ deposits stay labeled over the researched timeframe, whereas the diffuse labeling (not bound) disappears over 2 days. It should be noted that none of these injections is associated with any glial activation, neither in the cortex nor in the hippocampus, except for the injection

track. Thus, the D-peptides label amyloid deposits that develop in these AD model mice, and the D-peptides are taken up with Aβ by neurons and transported.

Title: Stem cells treatment for alzheimer's disease

Authors: ***T. BOLMONT**[1], A. LUKASHEV[2];
[1]EPFL STI IMT LOB, Lausanne, Switzerland; [2]Stemedica Intl., Lausanne, Switzerland

Abstract: Adult human stem cells constitute a promising therapeutic approach for the treatment of various neurodegenerative disorders including Alzheimer's disease (AD). We have investigated the impact of intravenous human stem cell delivery on cerebral Abeta amyloid pathology in a mouse model of AD. The cells used in the study were human mesenchymal stem cells (hMSC), bone marrow derived, ischemia-tolerant, cultured under a controlled, low physiological level of oxygen, manufactured under cGMP conditions and currently used in FDA-approved clinical trials in the US. Importantly, these hMSC express negligible levels of human leukocyte antigen-D related (HLA-DR) cell surface receptor. Both young pre-depositing APPPS1 mice as well as aged APPPS1 mice were used in experiments with either single or repeated intravenous delivery of hMSC or control Lactated Ringers Solution (LRS). Intravenous delivery of hMSC safely reduced cerebral Abeta pathology in both aged and young APPPS1 mice. Concomitantly, microglial activation was diminished in hMSC-treated APPPS1 mice, with no increase of vascular amyloid or manifestation of microhemorrhages. Quantitative RT-PCR biodistribution analysis revealed that intravenously delivered hMSC migrate to the brain and could be detected in this organ with the highest value at 1 hour post-delivery. These preclinical results were used to substantiate an IND application with placebo-controlled, crossover study to assess the safety, tolerability, and preliminary efficacy of a single intravenous dose of allogeneic human mesenchymal stem cells to subjects with mild to moderate dementia due to AD. Although all the details of the action of hMSC on AD are not yet fully understood, solid clinical safety

profile and preclinical efficacy of hMSC may open a new area of their application for this devastating disease.

Title: Mesenchymal stem cells protect hippocampal neurons from oxidative stress and synapse damage induced by amyloid-β oligomers

Authors: ***M. GODOY**[1], L. SARAIVA[2], L. CARVALHO[2], A. VASCONCELOS-DOS-SANTOS[2], H. BEIRAL[2], L. SINIS[2], N. CUNHA-E-SILVA[2], A. GALINA-FILHO[2], A. VIEYRA[2], F. DE FELICE[2], S. FERREIRA[2], R. MENDEZ-OTERO[2];
[1]Univ. Federal Do Rio De Janeiro, Rio De Janeiro, Brazil; [2]UFRJ, Rio de Janeiro, Brazil

Abstract: Background: Alzheimer's disease (AD) is a neurodegenerative disease with high prevalence and morbidity, for which there are no effective therapies. Soluble oligomers of the amyloid-β peptide (AβOs) are the main neurotoxins involved in the early synaptic dysfunction and oxidative stress associated with the disease. The therapeutic potential of bone marrow mesenchymal stem cells (MSCs) has been investigated in several models of neurological diseases and the main mechanism of action of these cells is based on paracrine signaling, through the release of trophic or neuroprotective factors.The aim of the current study was to evaluate the neuroprotective actions of MSCs against the deleterious effects caused by exposure of hippocampal neurons to AβOs. Methods: For this, we established a model of indirect coculture of neurons and MSCs.Results: Here, we report for the first time that MSCs protect neurons against oxidative stress and synaptic failure through internalization and degradation of the extracellular AβOs, as well as by the release of extracellular vesicles containing the antioxidant enzyme catalase. Conclusions: Taken together, our data suggest that mesenchymal stem cells may represent a promising therapeutic alternative for the treatment of Alzheimer’s disease.

Abstract: The accumulation and deposition of beta amyloid play a major role in the pathogenesis of Alzheimer’s disease. In vivo and in vitro studies suggest that soluble beta-amyloid is the critical toxic component, which significantly induce the dendritic spine loss, synaptic plasticity impairment and memory deficit. We generated a naïve camel heavy-chain variable domain antibody (VHH) phage display library against human amyloid beta 42 (Aβ42) peptide. The 2 clones of VHH anti-Aβ42 VHH effectively inhibited the assembly of monomer Aβ into oligomeric or fibrillary forms. Electrophysiological, biochemical and immunostaining assays showed significant ameliorating effects of anti-Aβ42 VHH on Aβ42-induced impairment of neuronal functions. Memory deficit caused by soluble Aβ42 oligomers is rescued through VHH co-injection. Together, the anti-Aβ42 VHH may be a therapeutic application for treating Alzheimer’s disease.

Abstract: The inhibition of the beta-site amyloid precursor protein-cleaving enzyme 1 (BACE1) is a main therapeutic approach for the treatment of Alzheimer's disease (AD). The characterization of BACE1 inhibitors has largely focused on direct effects, i.e. the reduction of β-amyloid (Aβ) generation and deposition in the brain. We previously reported an age-related increase of tau protein in the cerebrospinal fluid (CSF) of Aβ precursor protein (APP) transgenic mice reminiscent of changes in the CSF of AD patients. Using a novel high-sensitivity tau sandwich immunoassay we now demonstrate that BACE1 inhibition prevents CSF tau increase both in early-depositing APP tg mice and APP tg mice with moderate Aβ pathology. Our results demonstrate that BACE1 inhibition not only reduces Aβ generation but also downstream AD pathophysiology. The tight correlation between Aβ aggregation in brain and tau levels in CSF renders CSF tau a valuable marker to predict the effectiveness of BACE inhibitors in current clinical trials.

Title: Regulation of amyloid-beta precursor protein (APP) and beta-secretase 1 (BACE1) expression by transcription factor modulating compounds mithramycin A and tolfenamic acid in human cells

Authors: *B. L. BAYON[1], K. NHO[2], B. MALONEY[3], N. CHOPRA[3], D. K. LAHIRI[4]; [1]Dept. of Med. & Mol. Genet., [2]Radiology, [3]Psychiatry, [4]Psychiatry, Med. & Mol. Genet., Indiana Univ. Sch. of Med., Indianapolis, IN

Abstract: Transcription factors (TFs) play a role in the survival of neuronal cells and regulate genes associated with Alzheimer's disease (AD). Expression levels of some TFs, such as Sp1, are perturbed in AD. BACE1 is responsible for the rate-limiting cleavage of APP to amyloid-β (Aβ). Sp1 positively regulates APP and induces BACE1. To test the involvement of Sp1 in regulation of APP, we treated human cells with mithramycin A (MTM), an Sp1 inhibitor, and tolfenamic acid (TA), which induces Sp1 degradation. We also transfected a variety of mammalian cell lines, a primary human fetal neuron culture, and mixed brain cultures derived from human fetal neurospheres with siRNAs. Minimal changes in confluence, cytotoxicity, neurite length, and neurite outgrowth were seen after Sp1 knockdown via siRNA or treatment with Sp1 modulating drugs. Treatment with TA did not change Aβ42 levels, or affect APP and BACE1 levels. Treatment with MTM led to a significant decrease in the expression of APP and BACE1, and significantly decreased Aβ42 levels. Neither treatment with Sp1-inhibiting drugs

alone nor transfection with Sp1 siRNA alone affected cell viability of human cells illustrating that Sp1 levels can be safely reduced in cells. However, combination treatments of MTM plus TA or of Sp1 inhibition by siRNA in combination with TA treatment led to high cytotoxicity in human cells. To understand the relationship between genetic variants in Sp1 and AD-related endophenotypes, we performed an association analysis of single nucleotide polymorphisms (SNPs) in Sp1 with an AD imaging biomarker (entorhinal cortex thickness) in the AD Neuroimaging Initiative cohort, and identified a SNP (rs11170553) in Sp1 significantly associated with entorhinal cortex thickness. We found that rs11170553 was also associated with global cortical Aβ load measured by Florbetapir PET, demonstrating a possible correlation with Sp1 and AD pathology. To better understand the activation of multiple TFs and elucidate the status of signaling pathways after MTM or TA treatment, we used a TF luciferease transactivation reporter array. This array revealed decreased activation of several TFs with MTM treatment that correspond with a decrease or no change with TA treatment. These, as well as TFs with binding sites on the BACE1 promoter or those known to be implicated in AD were used as a preliminary screen for future assays targeting these alongside Sp1. Compounds that can modify Sp1 or other TF binding to sites on the BACE1 and APP promoters could provide a means to limit the production of Aβ peptide and may slow the symptoms of AD. These results show that appropriate modulation of a specific TF could potentially be a novel drug target for AD.

Title: Amelioration of abeta (1-42) induced plasticity impairment by inhibition of g9a/glp complex in ca1 hippocampal neurons

Authors: *M. SHARMA[1], T. DIERKES[2], S. SREEDHARAN[1];
[1]Physiology, YLL Sch. of Med., Natl. Univ. of Singapore, Singapore, Singapore; [2]Div. of Cell. Neurobio., Zoological Institute, Tech. Univ. Braunschweig, Braunschweig, Germany

Abstract: Alzheimer’s disease (AD) is the most common form of age-related neurodegenerative disorder and the leading cause of dementia among the elderly. AD is characterised by the

formation of extracellular amyloid plaques and intracellular neurofibrillary tangles (NFTs); and is featured with progressive memory loss. Altered epigenetic mechanisms are implicated in the impairment of memory. G9a/GLP histone methyltransferase complex is an important epigenetic regulator that is reported to regulate gene transcription in the hippocampus during memory consolidation. We hypothesized that modulating G9a/GLP complex could alleviate the effects of A-beta (1-42) on neuronal plasticity. We aim to address the role of epigenetic complex G9a/GLP in A-beta induced plasticity impairments and elucidate the underlying molecular pathway using vitro electrophysiology, neuropharmacology and biochemical analyses. We studied late long-term potentiation (late-LTP), a cellular correlate of memory and its associative mechanisms such as synaptic tagging and capture (STC) in the CA1 area of hippocampal slices from 5-7 week old male Wistar Rats. Our findings demonstrate that A-beta (1-42) impairs the late-LTP as well as STC in the CA1 pyramidal neurons. Inhibition of G9a/GLP complex activity restores the late-LTP and re-establishes the STC. We noticed that the restoration of LTP and STC by G9a/GLP complex inhibition is mediated by BDNF. We provide evidence for the promotion of plasticity in AD like conditions by G9a/GLP complex inhibition and hence propose G9a/GLP complex as the possible target for preventing A-beta induced plasticity deficits in hippocampal neurons.

Title: Characterization of novel, highly stable, and cytotoxic oligomers in the context of transthyretin amyloid disorders

Authors: ***Y. S. EISELE**[1,2], L. PLATE[1,2], G. J. MORGAN[1,2], G. C. LANDER[3], N. REIXACH[1], J. N. BUXBAUM[1], L. R. WISEMAN[1,4], E. T. POWERS[2], J. W. KELLY[2,1,5];
[1]Mol. and Exptl. Med., [2]Chem., [3]Dept. of Integrative Structural and Computat. Biol., [4]Chem. Physiol., [5]The Skaggs Inst. for Chem. Biol., The Scripps Res. Inst., La Jolla, CA

Abstract: Transthyretin (TTR) is one of over 30 amyloidogenic proteins that are known to misfold and form amyloid fibrils in neurodegenerative diseases. In its native form TTR is a well-

folded, homotetrameric protein that is mainly secreted from the liver into the blood, but also from the choroid plexus into the cerebrospinal fluid. TTR-related amyloid disorders present as age-related peripheral neuropathies, cardiomyopathies, or cerebral amyloid angiopathy (CAA). Importantly, TTR amyloidosis is the only amyloid disorder for which a regulatory agency approved disease-modifying treatment is available. Tafamidis, a small molecule, kinetically stabilizes the native TTR tetramer and thereby prevents TTR amyloidogenesis. However, the amyloid load does not appear to change in patients that respond to tafamidis. Thus, smaller, non-native TTR oligomers are hypothesized to be a driver of the degenerative pathology.
Here, we report the time- and concentration-dependent formation of novel TTR oligomers *in vitro* from monomeric TTR as well as from destabilized initially tetrameric TTR variants at near physiological pH at 37°C. Oligomers were biochemically and biophysically characterized in regard to their molecular weight, stability, and ligand binding. TTR oligomer formation requires the dissociation of the native TTR tetramer and likely involves partial misfolding that compromises the small molecule-binding site present in the native TTR tetramer. Interestingly, once formed, the oligomers seem relatively stable and their stability further increases over time, probably owing to conformational annealing. Atomic force microscopy and negative-stain electron microscopy reveal a filamentous, protofibrillar appearance. These TTR oligomers exhibit cytotoxicity in a *C. elegans* pharyngeal pumping assay in contrast to the native TTR tetramer. In addition, our findings suggest that similar TTR oligomers are present in blood samples of patients with TTR amyloidosis. All these traits indicate that the newly characterized, highly stable and cytotoxic non-native TTR oligomers might be highly relevant in the TTR pathogenesis cascade. Ongoing studies focus on deciphering the precise structure of these TTR oligomers and delineating a structure-toxicity relationship.

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disease, marked by extracellular senile plaques and intracellular neurofibrillary tangles (NFT). Amyloid-β peptides (Aβ) has relationship with both two hallmark pathologies. Total flavonoids from *Dracoephalum Mololariea* L (TFDM) is a traditional Chinese medicine, which has been proved to show a significant therapeutic effect on cardiovascular diseases from the epidemiological data. But no available study has reported that whether TFDM has any therapeutic activity on neurological disorders including Alzheimer's disease or not. In this study, we investigated the effects of TFDM on both APP/PS1 double transgenic AD mice and APPsw overexpressing SH-SY5Y cells. The results from our experiments showed that TFDM treatment improved the learning and memory capability of APP/PS1 mice, and increased the cell viability when subjecting to Aβ toxicity. These results demonstrated that TFDM has neuroprotective effects against AD related deficits. Besides, TFDM has anti-amyloidogenic effect, involving decreasing the Aβ burden through APP processing pathway by BACE1 and insoluble Aβ levels. In addition, TFDM exhibited antioxidative effects on both mice and cells through decreasing superoxide anion and improved enzyme activity of superoxide dismutase and glutathione peroxidase. Furthermore, TFDM up-regulated neurotrophic ERK/CREB/BDNF pathway in both cerebral cortex and APPsw over-expressing SH-SY5Y cells, which illustrated its neurotrophic effect. In general, TFDM may lightened the toxicity of Aβ by decreasing Aβ burden, inhibited amyloidogenic pathway, down-regulated oxidative stress, and up-regulated ERK/CREB/BDNF pathway. In one word, TFDM would be an alternative drug on curing or ameliorating AD.

Title: TFEB activation and protective effects by ouabain in Alzheimer's disease models

Authors: *H. SONG, S.-Y. YOON, D.-H. KIM;
Univ. of Ulsan Col. of Med., Seoul, Korea, Republic of

Abstract: Autophagy is impaired in AD and especially the late steps of autophagy, autophagosome-lysosome fusion and degradation, is thought to be impaired in AD, hence resulting in accumulation of autophagosomes and tau aggregates. Several world-wide groups have tried to find novel autophagy-enhancing compounds which inhibit mTOR or increase LC3-II (+) autophagosomes. Transcription factor EB (TFEB) is a recently known mater regulator of autophagy and lysosomal degradation. TFEB is a transcription factor which transcribes lysosomal and autophagy genes. Hence, TFEB activation can enhance not only the initial steps of autophagy but also the late steps of autophagy-lysosomal degradation. Thus, we developed high content screening (HCS) of TFEB activity system and screened with huge compounds library. Several hit compounds were found, and ouabain, one of which, will be discussed about neuroprotective effects in AD models.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder, which is characterized by cognitive impairment and synaptic dysfunction. Adenosine plays an important role in regulating various physiological functions and notably plasticity through four adenosine receptors (i.e., A_1R, $A_{2A}R$, $A_{2B}R$, and A_3R) and several adenosine transporters (e.g., ENT1, ENT2). We developed a group of dual-function adenosine compounds, which exhibit ability, at low affinities, to activate $A_{2A}R$ and inhibit ENT1. Previous studies demonstrated that these adenosine compounds show therapeutic effects on several neurodegenerative diseases, such as Huntington's disease, spinocerebellar ataxia type 3, and amyotrophic lateral sclerosis. Here, we investigated the effect of a dual-function adenosine compound (J4) on the impairment of cognitive functions in a mouse model of AD (APP/PS1dE9). Chronic oral intake of J4 (0.02 g/L in drinking water) from the age of 3 to 10 months significantly enhanced the impaired spatial memory of APP/PS1dE9 mice, and normalized the decremental long-term potentiation (LTP) in the CA1 region of hippocampus as well as the reduced levels of several proteins associated with neuronal plasticity. These findings suggest that modulation of adenosine homeostasis by J4 is beneficial in a mouse model of AD. Our study provides a potential therapeutic approach to delay the progression of AD.

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized by extracellular amyloid-beta deposits and neurofibrillary tangles. Its occurrence depends on different genetic and environmental factors. Epidemiological and experimental studies on Tau and amyloid models have shown that caffeine, a non-selective adenosine receptor antagonist, may be protective in AD, an effect thought to be ascribed to the blockade of adenosine A_{2A} receptors ($A_{2A}R$). Our recent report of a significant protection achieved by $A_{2A}R$ genetic deletion and pharmacological blockade in a Tau transgenic mouse model reinforces this idea. However so far, the outcome of $A_{2A}R$ blockade on amyloïdogenesis and related brain impairments have remained unclear.
The present study was aimed to study the impact of $A_{2A}R$ blockade on memory deficits and pathological development in the APP/S1dE9 transgenic mouse model of AD, using a specific $A_{2A}R$ antagonist, MSX-3. This pro-drug was chronically administered at the dose of 0.3g/L through drinking water to APP/PS1dE9 mice and littermate controls from 3 to 9 months of age. At completion of the treatment, MSX-3 was detectable in plasma and brain of treated mice. MSX-3 treatment improved spatial memory of APP/PS1dE9 mice. This was associated with a reduction of amyloid-beta plaques and a decrease of the levels of $A\beta_{42/40}$ ratio in the cortex, but not with an improvement of neuroinflammation. Furthermore, treatment with MSX3 did not improve microglial phagocytic activity, which additionally argues against immune processes as the main effector mechanism.
These results show that chronic blockade of A_{2A} receptors using MSX-3 is beneficial in a mouse model of amyloïdogenesis, but the underlying mechanisms still remain to be uncovered. Combined with our previous data in a Tau transgenic mouse model, our data suggest that caffeine-analogues specifically targeting $A_{2A}Rs$ constitute important novel therapeutic options in the treatment of AD.

Title: Intranasal orexin A (hypocretin 1) increases neuronal activation in cortical and basal forebrain regions implicated in memory and attention

Authors: C. B. CALVA, *J. R. FADEL;
Univ. of South Carolina Sch. of Med., Columbia, SC

Abstract: Hypothalamic orexin/hypocretin (OX) neurons are implicated as integrators of physiological function and have recently been proposed as a potential therapeutic target in the treatment of age-related cognitive disorders. OX neurons project to the medial prefrontal (mPFC) and agranular insular cortices (AIC), two areas implicated in attention and interoceptive awareness of physiological status, respectively. Additionally, OX neurons send projections directly to all parts of the basal forebrain cholinergic system, including the vertical limb of the diagonal band of Broca (vDBB) and the ventral pallidum/substantia inominata (VP/SI), two areas highly involved in emotional memory formation and attention, respectively. We have previously shown that orexins increase cortical acetylcholine release and that aged rats have reduced numbers of OX neurons, which suggests that orexins play a role in the cognitive and homeostatic dysfunction seen with age. A limited number of human and animal studies have suggested that intranasal OX may enhance cognition and wakefulness, but the brain regions and neurotransmitter systems underlying these effects are unknown. Here, young (3 months) male Fisher344/Brown Norway rats received intranasal administration of either vehicle (0.9% saline) or orexin A (OxA; 25 ul of a 5nM solution) into each nare. At two hours post-treatment, the animals were sacrificed and their brains were processed for immunohistochemical detection of the neuronal activity marker, c-Fos, and phenotypic markers of specific neuronal populations. Intranasal OxA significantly increased c-Fos expression in the prelimbic mPFC and AIC compared to vehicle treatment. Intranasal OxA treated animals also showed greater activation of

cholinergic neurons in the vDBB and VP/SI. Interestingly, c-Fos expression in parvalbumin positive (PV+) interneurons was decreased in the prelimbic mPFC, which could be mediated through inhibition by PV+ GABAergic projection neurons of the basal forebrain. OxA did not alter c-Fos expression in several other rostral cortical areas, including the horizontal DBB and infralimbic cortex, indicating that effects produced by intranasal OxA were not a global phenomenon. Overall, these data demonstrate that intranasal OxA activates brain regions that mediate attention to the external environment as well as attention to internal homeostatic cues, two functions that are dysregulated during age-related cognitive decline. Ongoing studies of neurochemical correlates of intranasal OxA will provide additional insight into the mechanisms underlying the putative cognitive effects of this manipulation.

Title: Compound A, a selective and potent muscarinic acetylcholine M4 receptor positive allosteric modulator (PAM), is active in pre-clinical models sensitive to clinically-active antipsychotic drugs

Authors: *S. M. GRAUER[1], X. ZHOU[1], N. JOCHNOWITZ[1], L. A. HYDE[1], N. HASTINGS[1], G. VARTY[1], R. MAZZOLA[2], J. MORROW[3];
[1]In Vivo Pharmacology-Neuroscience, Merck Res. Labs, Kenilworth, NJ; [2]Chem., Merck Res. Labs, Rahway, NJ; [3]Neurosci., Merck Res. Labs, West Point, PA

Abstract: Current understanding of the pathophysiology of both Alzheimer's disease (AD) and schizophrenia suggests altered muscarinic cholinergic activity. Xanomeline, a M_1/M_4 preferring muscarinic acetylcholine receptor (mAChR) agonist, was evaluated in clinical studies and demonstrated efficacy in alleviating psychosis and behavioral disturbances in AD and schizophrenic patients, with a profile that matched or was superior to that of existing antipsychotics. Despite this, xanomeline's clinical development was halted due to adverse side effects, primarily gastrointestinal (GI) in nature, likely due to inadequate mAChR subtype selectivity. Targeting the less conserved and spatially distinct allosteric binding site was a strategy adopted to overcome selectivity issues with orthosteric agonists such as xanomeline. Arising out of this approach is Compound A, a selective and potent M_4 PAM, which has low nM binding affinity at the M_4 receptor, and exhibits $\geq$1200-fold functional selectivity over other

mAChRs. Compound A was tested in a series of preclinical assays designed to assess antipsychotic-like activity. These models included the attenuation of hyperactivity induced by either the indirect dopamine receptor agonist d-amphetamine or the selective D_1 dopamine receptor agonist SKF 82958 in both rats and mice, and the reversal of deficits in prepulse inhibition (PPI) in mice. Compound A (100 mg/kg PO) significantly attenuated both d-amphetamine and SKF 82958 hyperactivity in CD rats, while doses as low as 30 mg/kg were active in C57Bl/6 mice. On-target activity in the locomotor assay was confirmed by an absence of activity vs. SFK 82958 hyperactivity in M_4 knockout (KO) mice. Compound A (100 mg/kg PO) significantly potentiated PPI when administered alone, and significantly attenuated a d-amphetamine induced PPI deficit. The PPI effects were M_4 mediated, as Compound A (100 mg/kg PO) was without effect against a SKF 82958 induced PPI deficit in M_4 KO mice, but blocked the SKF 82958 gating deficit in wild type littermates. Compound A was also evaluated in a mouse GI transit model where activation or inhibition of M_2 or M_3 mAChRs accelerate or attenuate, respectively, intestinal motility. Compound A was without effect, whereas indirect activation of GI mAChRs by the acetyl cholinesterase inhibitor donepezil significantly increased transit, an effect blocked by a selective M_2 antagonist. The on-target effects of an M_4 PAM, in two well established preclinical assays related to the dopamine hyperfunction hypothesis of psychosis, support the viability of a therapeutic approach which will not be limited by side effects associated with non-selective activation of mAChRs.

Title: Sesamol reverse memory deficit and restore phospho-GSK3beta decreased in hippocampus in intracerebroventricular streptozotocin induced Alzheimers disease model

Authors: *M. GOLECHHA[1,2], J. BHATIA[1], V. PARIHAR[4], D. SAXENA[3], D. ARYA[1]; [1]Pharmacol., All India Inst. of Med. Sci. (AIIMS), New Delhi, India; [2]Hlth. Policy, [3]Epidemiology, Indian Inst. of Publ. Hlth. Gandhinagar, Gandhinagar- Gujarat, India; [4]Dept. of Radiation Oncology, Univ. of California, Irvine, Irvine, CA

Abstract: Intracerebroventricular (ICV) streptozotocin (STZ) treated rat has been described as a suitable model for sporadic Alzheimer's disease (AD). Therefore, the present study was undertaken to investigate the effect of post-training administration of sesamol, a bioflavonoid with potent antioxidant and anti-inflammatory activities on memory functions, brain insulin receptors (IRs), acetylcholinesterase (AChE) activity and oxidative stress in intracerebroventricular (ICV) administered streptozotocin (STZ) induced dementia in rats. In these same animals the phosphorylated GSK3β (p-GSK3β) and total GSK3β levels were determined, and importantly GSK3β regulates the tau phosphorylation responsible for neurofibrillary tangle formation in AD. Wistar rats received ICV STZ application (3mg/kg twice) and 2 weeks later short- (STM) and long-term memories (LTM) were assessed in an autoshaping learning task. Animals were sacrificed immediately following the last autoshaping session, their brains removed and dissected. The enzymes and IR protein levels were measured in the hippocampus and prefrontal cortex (PFC) by western blotting. ICV STZ-treated rats showed a memory deficit and significantly decreased p-GSK3β levels and significant decrease in IR protein level in both hippocampus and PFC, while total GSK3β did not change, in both the hippocampus and PFC. Memory impairment was reversed by sesamol (5 and 10 mg/kg, i.p.). The p-GSK3β and IR protein levels were restored by sesamol in the hippocampus and PFC. Sesamol produced no changes in p-GSK3β levels in neither the hippocampus nor PFC. Total GSK3β levels did not change with either drug. Furthermore, STZ (ICV) resulted into enhanced AChE activity in hippocampus and PFC which was normalized by sesamol. An increase in MDA level and decrease in GSH level were obtained in both hippocampus and PFC in STZ treated group, indicating state of oxidative stress, which was also attenuated by sesamol. Altogether these results show the beneficial effects of sesamol due different mechanisms of actions on memory impairment induced by ICV STZ. The results suggest that besides the anticholinesterase and antioxidant activity, effect on brain IR, p-GSK3β levels, a kinase key of signaling cascade of insulin receptor may also be an important factor for protective effect of sesamol against STZ induced dementia model.

Title: Systemic administration of IGF-II facilitates memory enhancement in rats with decreased TrkB receptor activity in the brain

Authors: *J. H. GRAHAM[1], T. CONNER[2], K. BARANOWSKY[2];
[1]DPT, Emory and Henry Col., Marion, VA; [2]Psychology, Emory and Henry Col., Emory, VA

Abstract: One of the most identifiable symptoms of Alzheimer's disease (AD) and other types of dementia is a decline in cognitive function with memory impairment. Brain derived-neurotropic factor (BDNF) and its receptor, tyrosine kinase B (trkB), have been shown to play a critical role in this process. Animals lacking BDNF show impairment in long term potentiation, learning, and memory formation. BDNF is correlated with synaptic plasticity, as well as cell genesis, growth, and survival, while AD patients have been shown to have a decrease in BDNF levels. Other studies have shown an injection of insulin-like growth factor 2 (IGF-II) into an AD mouse model improved memory and decreased the accumulation of amyloid plaques observed in the hippocampus. In this study, a novel object recognition task was used with female, Sprague-Dawley rats to study episodic memory, which is known to be affected and impaired in AD patients. The rats were tested when they were young (3 months) and older (9 months), at intervals 4-6 hrs. after injection, and 24 hrs. after injection A spontaneous alteration task was also used, to test working memory, which is impaired in AD patients. Again the rats were tested when they were young and older, at intervals 20-30 min. after injection, and 4-6 hrs. after injection. TrkB receptors were blocked with a BDNF-antagonist (ANA-12), and IGF-II was used to overcome the effects of that blockade. IGF-II rescued memory deficits created by lower BDNF levels during the novel object recognition task in young rats. IGF-II enhanced working memory in the spontaneous alternation task in young and middle-aged rats. This study showed that a systemic injection of IGF-II in rats rescues the episodic memory deficit created during a novel object recognition task and significantly enhances working memory in a spontaneous alternation task. Thus, IGF-II does indeed have the potential to be a clinical candidate for AD and dementia patients who have substantial memory decline.

Abstract: Ferulic acid is a compound with potent anti-oxidant and anti-inflammatory activities. We previously reported the protective effects of ferulic acid administration against two animal models of Alzheimer's disease (AD): intracerebroventricular (i.c.v.) injection of Aß1-42 in mice and APP/PS1 mutant transgenic mice. In this study using the same AD animal models, we examined the effect of KMS4001, one of dimeric derivatives of ferulic acid. Intragastric pretreatment of mice with KMS4001 (30mg/kg/day) for 5 days significantly attenuated the Aß1-42 (i.c.v.)-induced memory impairment both in passive avoidance test and in Y-maze test. APP/PS1 mutant transgenic mice at KMS4001 doses of 3 and 30mg/kg/day via drinking water showed the significantly enhanced novel-object recognition memory at both 1.5 and 3 months after the start of KMS4001 treatment. Treatment of APP/PS1 mutant transgenic mice with KMS4001 for 3 months at the doses of 3 and 30mg/kg/day markedly decreased Aβ1-40 and Aβ1-42 levels in the frontal cortex. The KMS4001 dose-response relationships for Aβ decrease and for improvement in novel-object recognition test corresponded to each other. Taken together, these results suggest that KMS4001 could be an effective drug candidate against AD.

Title: Estimating receptor occupancy requirements for positive allosteric modulators of the M1 muscarinic acetylcholine receptor as cognitive enhancers

Authors: *D. BEHER, A. SAND, M. NÉNY, J. HANTSON, S. OUSSON, B. PERMANNE, A. QUATTROPANI, C. WIESSNER;
Asceneuron SA, Lausanne, Switzerland

Abstract: Clinical use of acetylcholinesterase inhibitors (AChEis) has established that the restoration of deficits in cholinergic transmission improves cognitive function in patients with Alzheimer's disease (AD) and Parkinson's disease dementia (PDD). Nonetheless, the use of AChEis is limited due to the dose-limiting side effects since these drugs non-selectively raise acetylcholine (ACh) neurotransmitter levels throughout the body. We have partially optimized novel, potent, and selective positive allosteric modulators (PAMs) of the M1 muscarinic acetylcholine receptor, which increase the affinity of the receptor for its natural ligand. Based on their mechanism of action M1 PAMs have the potential to maintain the cholinergic tone in AD and PDD patients at a physiological level. Since our PAMs do not display any intrinsic agonism, this approach will maintain the spatial and temporal pattern of neurotransmission whilst having a reduced likelihood of receptor desensitisation. Overall, this should lead to a wide therapeutic window with a reduced risk of overdosing. One of the challenges of PAM development is to understand receptor occupancy which is required to achieve a certain potentiation of the endogenous ligand response. To address this question, we have investigated the potentiation of M1 receptor response by M1 PAMs in a cellular assay system. In the absence of a radioligand, which correlates the affinity and cellular response, we have calculated cellular receptor occupancy by the following equation: relative occupancy = [PAM] / ([PAM] + EC_{50}) assuming that PAM binding is independent of acetylcholine binding. The corresponding results using this approximation suggest that a relatively high receptor occupancy (>80%) will be required to achieve a meaningful receptor potentiation in the brain.

Title: The locus coeruleus: a potential link between cerebrovascular and neuronal pathology in Alzheimer’s disease

Authors: *S. C. KELLY[1,2], P. T. NELSON[4,5,5], S. E. COUNTS[1,3,2,6];
[1]Translational Sci. and Mol. Med., [2]Cell and Mol. Biol. Program, [3]Dept. Family Med., Michigan State Univ., Grand Rapids, MI; [4]Dept. Pathology & Lab. Med., [5]Dept. Anat. & Neuobiol, Univ. of Kentucky, Lexington, KY; [6]Hauenstein Neurosci. Ctr., Mercy Hlth. St. Mary’s, Grand Rapids, MI

Abstract: Noradrenergic locus coeruleus (LC) neuron loss is a major feature of Alzheimer’s disease (AD). The LC is the primary source of norepinephrine (NE) in the forebrain, where it modulates attention and memory in vulnerable cognitive regions such as prefrontal cortex and

hippocampus. Furthermore, LC-mediated NE signaling is thought to play a role in blood brain barrier maintenance and neurovascular coupling, suggesting that LC degeneration may impact the high comorbidity of cerebrovascular disease (CVD) and AD. However, the extent to which LC projection system degeneration occurs in the earliest stages of AD is not fully characterized to date. To address these issues, we analyzed LC tissue samples from University of Kentucky AD Center subjects who died with a premortem diagnosis of no cognitive impairment (NCI) and Braak stages 0-II at autopsy, NCI subjects with Braak stages III-V thought to be in a preclinical AD (PCAD) stage, and subjects with mild cognitive impairment (MCI) or mild AD (n = 5-6 cases/group). Paraffin-embedded pontine tissue blocks containing the LC were cut at 20µm, immunostained with tyrosine hydroxylase (TH, a marker for NE synthesis), and analyzed by stereology to estimate total LC neuron number (total number of neuromelanin-containing LC neurons) and the percentage of TH+ LC neurons. Preliminary analysis reveal a ~20% loss of both total and TH+ LC neurons in PCAD ($p = 0.08$), a ~30-35% loss of these neurons in MCI ($p < 0.05$), and a ~45-50% loss of total and TH+ neurons in AD ($p < 0.01$) compared to NCI. Studies were also performed to compare additional LC neuronal pathologies (phospho-tau, TDP-43, and 8dOHG) in the diagnostic groups. A substantial increase in 8dOHG and phospho-tau is observed in PCAD compared to NCI. The morphometric data will be correlated with postmortem neuropathologic and CVD variables (e.g., microinfarcts and cerebral amyloid angiopathy) to gauge the relationship between LC neurodegeneration and cerebral AD and vascular pathology. To model these relationships *in vivo*, we stereotactically lesioned LC projection neurons innervating the PFC, a major LC projection zone, in the TgF344-19 rat model of AD (6 months old) using the noradrenergic immunotoxin, dopamine-β-hydroxylase-saporin, or a control lesion (n = 8/group). Prior to sacrifice at 9 months, immunotoxin- and control-lesioned rats will be tested behaviorally on the Barnes maze task. Postmortem PFC will be analyzed for LC fiber innervation, NE and NE metabolite levels, CVD pathology and AD-like pathology. Taken together, these data will shed light on the multifactorial noradrenergic pathways contributing to neuronal and vascular pathologies during the onset of AD.

Title: Investigating the effects of Chromobacterium violaceum violacein at the human serotonin 2C receptor

Authors: *L. FEARS[1], M. CURTIS[2], T. JOHNSON[2], H. FENTRESS[2];
[1]Biol. Sci., [2]Tennessee State Univ., Nashville, TN

Abstract: The monoamine neurotransmitter serotonin (5-HT) plays a role in many physiological responses by binding to at least 14 receptor subtypes. The 5-HT_{2C} receptor subtype is a 7-transmembrane, G protein-coupled receptor (GPCR) that is involved in neuronal excitability, spatial learning, mood, and appetite. The microorganism *Chromobacterium violaceum* produces a purple pigment, violacein, which can be extracted. Violacein has antibiotic, antileishmanial, antifungal and antitumoral properties in various cancer cell lines. Violacein is derived from the amino acid tryptophan like 5-HT, and therefore they have similar chemical structures, however, no one has reported the activity of violacein at 5-HT receptors. To investigate the effect of violacein on receptor trafficking, Human Embryonic Kidney (HEK) 293 cells expressing fluorescently-tagged 5-HT_{2C}receptor were treated with 5-HT, violacein, water or vehicle then cells were fixed and visualized with fluorescent microscopy. Violacein treatment did not cause receptor internalization. Our recent studies suggest that the 5-HT_{2C} receptor can activate the JAK/STAT pathway. To see if violacein can effect this pathway, HEK 293 cells expressing 5-HT_{2C} receptor were treated with violacein or pretreated with violacein followed by incubation with 5-HT. Phosphorylation states of JAK2 and STAT3 were examined by immunoblotting. Preliminary data suggests that violacein may hinder activation of STAT3 but further study is required. Future studies will examine G protein-coupling by measuring phosphoinositide hydrolysis and affinity for violacein at the 5-HT_{2C}receptor via competition binding.

Title: Cognitive deficits and impaired long-term potentiation in adiponectin knockout mice

Authors: *J. BLOEMER[1], W. SMITH[2], A. ALHOWAIL[2], D. BHATTACHARYA[2], S. BHATTACHARYA[2], P. DAS[2], R. JUDD[2], V. SUPPIRAMANIAM[2];
[1]Drug Discovery and Develop., [2]Auburn Univ., Auburn, AL

Abstract: Adiponectin is a hormone produced by adipocytes which regulates numerous metabolic processes, and it has recently been implicated as a potential player in Alzheimer's Disease and other cognitive disorders. Plasma levels of adiponectin are inversely proportional to body fat percentage, and a number of animal studies show that absence of adiponectin decreases insulin sensitivity and impairs normal glucose metabolism leading to diabetes. Our laboratory has previously demonstrated that central insulin resistance results in hippocampal glutamatergic dysfunction leading to cognitive impairment. In addition, animals lacking adiponectin display higher levels of amyloid beta compared to age matched controls, and amyloid beta is a hallmark of Alzheimer's disease. It is known that adiponectin receptors (AdipoR1 and AdipoR2) are found in the hippocampus of the brain, but the central function of these receptors is unknown. Based on existing literature, adiponectin may play a major role in the shared pathophysiology between diabetes and cognitive impairment. We hypothesize that adiponectin plays a role in hippocampal synaptic plasticity, and lack of adiponectin leads to cognitive deficits. One-year-old Adiponectin KO and C57BL/6J mice were utilized. Behavioral analysis was done using novel-object recognition test. Long-term potentiation (LTP) theta-burst protocol was utilized to measure hippocampal field potentials in Schaffer collateral pathway. Our results indicate that adiponectin KO mice display cognitive deficits in novel-object recognition test. In addition these mice showed a decrease in LTP and decrease in PI3k expression. Our findings demonstrate that adiponectin is necessary for normal cognitive function and hippocampal synaptic plasticity.

Title: Significant and asymmetric depletion of basal forebrain cholinergic system in primary progressive aphasia with Alzheimer pathology

Authors: N. LALEHZARI, *D. T. OHM, G. KIM, S. WEINTRAUB, E. H. BIGIO, M.-M. MESULAM, C. GEULA;
Cognitive Neurol. & Alzheimer's Dis. Ctr., Northwestern Univ., Chicago, IL

Abstract: Primary Progressive Aphasia (PPA) is a disorder that presents with progressive loss of language capabilities. Approximately 30-40% of PPA cases show Alzheimer's disease (PPA-AD) pathology, with asymmetric distribution favoring the cortical language network in the dominant hemisphere. The amnestic variant of AD is characterized by significant loss of basal forebrain cholinergic neurons (BFCN) and their cortical projections. However, the status of BFCN and their axons in PPA is unknown. The purpose of this study was to determine the presence and extent of hemispheric asymmetry of AD pathology, neuronal loss and axonal loss in the BFCN system in PPA-AD. Tissue from four PPA-AD and four normal controls, with frozen or paraffin sections, were used. Thioflavin-S stain, and immunohistochemistry with antibodies to phospho tau (AT8) and amyloid-β, revealed abundance of neurofibrillary tangles (NFT) / pre-NFT in BFCN, and moderate diffuse amyloid plaques (AP) in the BF region in PPA-AD, and sparse NFT / pre-NFT and diffuse AP in the normal controls. Neuritic plaques were rare in the area occupied by the BFCN. Nissl stains demonstrated substantial loss of BFCN in PPA-AD when compared with control brains. In one PPA-AD and one control case, stereological counting was conducted. BFCN in the left hemisphere of the PPA-AD case contained 19% more thioflavin-S-positive NFT when compared with the right. Immunohistochemistry for low affinity neurotrophin receptor, which is enriched in BFCN, revealed 14.1% fewer cholinergic neurons in the left hemisphere than the right. The PPA-AD brain contained 80.8% less cholinergic neurons in the left hemisphere than the control case. Acetylcholinesterase-positive cholinergic axons were also stereologically quantified in three language (superior temporal gyrus, inferior parietal lobule and inferior frontal gyrus) and two non-language (anterior cingulate and entorhinal cortices) cortical areas. Cholinergic axon length was 16.2-58.1% lower in the left hemisphere than the right in the PPA-AD case. The PPA-AD case also displayed 34-98% less cholinergic axon length when compared with the control case. This difference was more pronounced in language areas (92-98%) than in non-language regions (34-56%). These findings indicate that, like typical amnestic AD, PPA-AD is characterized by substantial degeneration of basal forebrain cholinergic system. Furthermore, the cholinergic pathology reveals a leftward asymmetry that has not been described in typical amnestic forms of AD. The results suggest that cholinesterase inhibitors used as therapeutic agents in AD are likely to also be effective in PPA-AD.

Title: Amyloid beta co-localizes with tyrosine hydroxylase in the locus coeruleus and with dopamine beta hydroxylase in the infralimbic medial prefrontal cortex of mice with forebrain specific overexpression of corticotropin releasing factor: anatomical evidence for putative regulated co-secretion

Authors: *J. A. ROSS[1], B. A. S. REYES[1], V. RISBROUGH[2], R. J. VALENTINO[3], E. J. VAN BOCKSTAELE[1];
[1]Pharmacol. and Physiol., Drexel Univ. Col. of Med., Philadelphia, PA; [2]Dept. of Psychiatry, Univ. of California, San Diego, CA; [3]The Div. of Stress Neurobio., The Children's Hosp. of Philadelphia, Philadelphia, PA

Abstract: Over 5 million Americans are currently suffering from Alzheimer’s disease (AD), the most common cause of dementia. AD is a neurodegenerative disorder classically characterized by histological features including amyloid beta (Aβ) peptide aggregates known as senile plaques, and hyper-phosphorylated tau protein aggregates known as neurofibrillary tangles (NFT). One of the earliest regions to become dysregulated in AD is the locus coeruleus (LC), the dorsal pontine nucleus that provides the neurotransmitter norepinephrine (NE) to almost all levels of the neuraxis. In response to stress, the LC releases norepinephrine (NE) throughout the entire neuraxis via its broadly distributed efferent projections. Stress-induced activation of the LC is mediated by corticotropin releasing factor (CRF) and CRF receptors exhibit sex-biased stress signaling. Sex differences have been described in the neurochemical, morphological and molecular regulation of LC neurons by CRF, providing a compelling basis for vulnerability of females to stress-related disorders such as AD. In the present study, we examined the cellular substrates for interactions between Aβ and tyrosine hydroxylase (TH) a marker of noradrenergic somatodendritic processes in the LC in mice conditionally overexpressing CRF in the forebrain (CRF OE) under a Doxycycline (DOX) regulated tetO promoter. Preliminary immunofluorescence data shows co-localization of Aβ and TH in somatodendritic processes of the LC. Using high resolution immunoelectron microscopy semi-quantitative preliminary analysis revealed that 42.9% (51/119) of TH-containing somatodendritic processes also exhibited Aβ-immunogold silver particles in DOX treated males, compared to 32.4% (92/284) in male transgenic littermate untreated controls and 61.6% (151/245) TH-containing somatodendritic processes also exhibited Aβ-immunogold silver particles in DOX treated females compared to

34.4% (21/61) in female transgenic littermate untreated controls. Thus, the preliminary results of immunoelectron microscopy experiments in male and female CRF OE mice indicate a trend towards increased Aβ in TH labeled somatodendritic processes of the LC, and that these increases may be exaggerated in females. Preliminary immunofluorescence also shows Aβ immunoreactivity in noradrenergic terminals of the infralimbic medial prefrontal cortex (ILmPFC) labeled with Dopamine-β-hydroxylase (DβH). An ongoing study seeks to quantify alterations of Aβ levels and subcellular distribution under conditions of CRF overexpression.

Title: Aβ oligomer-induced synapse loss in mature culture hippocampal neurons and brain's macaques: protection by an anti-diabetic agent

Authors: *A. F. BATISTA[1], L. FORNY-GERMANO[1], N. LYRA E SILVA[1], J. BRITO-MOREIRA[1], M. GRALLE[1], S. BOEHNKE[2], B. COE[2], A. LABLANS[2], C. HOLSCHER[3], S. MARQUES[1], A. MARTINEZ[1], W. KLEIN[4], J. HOUZEL[1], S. FERREIRA[1], D. MUNOZ[2], F. DE FELICE[1];

Abstract: Alzheimer's disease (AD) is a debilitating neurodegenerative disorder and a major health problem worldwide. The lack of effective drugs to treat AD stimulates an intense pursuit of disease-modifying therapeutics. However, a major impediment may lie in fundamental

differences between humans and animal models, largely based in rodents. Disruption of insulin signaling has been recently described in the brains of AD patients and animal models, and may further contribute to cognitive impairment in this disease. Therefore, drugs that restore normal insulin function in the central nervous system have been recently suggested as promising novel approaches to treat AD. The aim of this study is to test a possible beneficial effect of Liraglutide, an anti-diabetic agent that activates pathways common to insulin signaling through stimulation of glucagon-like peptide 1 (GLP-1) receptors, on Aβ oligomer-induced synapse loss in the macaque brain. We further investigated the possible protection by Liraglutide on the impact of Aβ oligomers in cultured hippocampal neurons.Nine female cynomolgus macaques (Macaca fascicularis) were used. Three were shamoperated and served as a control group. We performed intracerebroventricular (i.c.v.) injections of Aβ oligomers into six cynomolgus macaques. Two of these monkeys had been pre-treated for one week with daily intraperitoneal injections of Liraglutide. Liraglutide administration continued daily until the last injection of oligomers. Brain sections were used for immunohistochemistry to evaluate the levels of synaptic markers. Our results showed that i.c.v. injections of oligomers trigger loss of synaptic proteins in cynomolgus macaques. Synapse density and levels of NMDA, AMPA and insulin receptors were decreased in the brains of macaques that received i.c.v. injections of AβOs, and these effects were prevented in animals pre-treated with liraglutide. In addition we have shown that synapses and insulin receptors were decreased in hippocampal neurons in vitro and significantly Liraglutide protects against these effects. In conclusion, this study suggests that Aβ oligomers, important synaptotoxins that accumulate AD brains, induce loss of synaptic proteins when injected into the brains of non-human primates. Importantly, treating monkeys with the novel anti-diabetic drug Liraglutide prevented the impact of Aβ oligomers on synapses.

Abstract: Background: The toxicity of amyloid-beta (Aβ) is strongly associated with Alzheimer's disease (AD), which has a high incidence in the elderly worldwide. Recent evidence shows that alteration in N-methyl-D-aspartate receptor (NMDAR) activity plays a key role in Aβ-induced neurotoxicity. NMDARs are glutamate-gated ion channels that require the co-agonists glycine or D-serine. It has been suggested that D-serine is the primary co-agonist at synaptic NMDARs while glycine plays this role at extrasynaptic sites. The activation of synaptic and extrasynaptic NMDARs has distinct consequences for plasticity, gene regulation, neuronal death, and Aβ production. It is also known that synaptic and extrasynaptic receptors are involved in Aβ-mediated effects. Activation of synaptic NMDARs is thought to be neuroprotective. In contrast, extrasynaptic NMDARs are activated under conditions that result in glutamate spillover and are linked to excitoxicity. Previous work suggests that Aβ-induced excitotoxicity is attenuated in serine racemase knockout (SRKO) mice, which have depleted D-serine levels. **Objective:** The main goal of this investigation was to determine the effects of Aβ on synaptic and extrasynaptic NMDAR function and how D-serine alters these Aβ-mediated effects. We used SRKO mice and Aβ secreted from CHO cells containing the V717F mutation in the APP gene. **Preliminary data:** In CA1 pyramidal neurons, Aβ significantly reduced the amplitude of evoked synaptic NMDAR excitatory postsynaptic currents (EPSCs) in wild type (WT) mice. Interestingly, this effect was significantly more pronounced in SRKO mice. A similar effect was observed on isolated evoked extrasynaptic NMDAR currents. In addition, ambient levels of D-serine and glutamate tonically activate extrasynaptic NMDARs in the absence of synaptic stimulation, and changes in this current were observed by monitoring the holding current. During recordings of synaptic NMDAR currents, Aβ potentiated the holding current only in WT mice, suggesting an increase in tonic extrasynaptic NMDAR activation in WT but not in SRKO mice. SRKO mice also showed lower levels of tonic NMDAR activation. Furthermore, these experiments were performed in parallel with behavioral tests. Having lower levels of extrasynaptic NMDAR activation could be a possible mechanism through which SRKO mice attenuate Aβ-induced toxicity. **Conclusion:** These data suggest that low levels of D-serine alter NMDAR function upon application of Aβ and provide insight for future experiments exploring the importance of D-serine in the pathophysiology of AD.

Title: Efr3a regulates oligomeric amyloid-β induced disruption of excitatory transmitter release in hippocampus

Authors: *Y. HE[1], M. WEI[1], F. HUANG[2], Y.-D. ZHOU[1];
[1]Dept. of Neurobio., Zhejiang Univ. Sch. of Med., Zhejiang, China; [2]Ctr. for Stem Cell and NanoMedicine, Chinese Acad. of Sci., Shanghai, China

Abstract: Amyloid-β (Aβ) oligomer-inducedaberrant neurotransmitter release has been proposed to be a crucial early event leading to synapse dysfunctionin Alzheimer's disease (AD).In the present study, we found that knocking outthe membrane protein Efr3a, a key component in thephosphatidylinositol 4-kinase (PI4K) complex, in CA3 region of the hippocampus in mice strongly preventedexogenousoligomeric Aβ-induced suppression of the frequency of miniature excitatory postsynaptic currents (mEPSCs)recorded from CA1 pyramidal neurons.By contrast, overexpression of Efr3aaggravatedoligomeric Aβ-induced impairment in mEPSC frequency.By estimating the release probability at the synapse between the Schaffer collateral (SC) and CA1 pyramidal neurons (PNs), we found that oligomeric Aβ-induced decrease of mEPSC frequency was mainly due to a reduction in thepresynaptic release probability, whereas the readily releasable pool size did not change. Remarkably, knocking out Efr3a in CA3 area of the hippocampus in a mouse model of AD significantly rescued aberrant release probability at the SC-PN synapse in these mice. Our work demonstrates that Efr3a regulates oligomeric Aβ-induced impairment of synaptic transmission via a presynaptic mechanism, and implicates that the level of phosphatidylinositol-4,5-bisphosphate (PtdIns(4,5)P2)in the membrane of the presynaptic terminal, which is related to synaptic vesicle fusion,may be tightly regulated by Aβ-Efr3a interaction. Keywords: Efr3a, release probability, amyloid-β. Support: Major Research Program from the State Ministry of Science and Technology of China (2013CB530902).

Title: UCH-L1 in nigrostriatal dopaminergic neurodegeneration: neurotoxicant exposure and aging

Authors: *B. M. WINNER, M. M. FARTHING, H. ZHANG, K. J. LOOKINGLAND, J. L. GOUDREAU;
Pharmacol. and Toxicology, Michigan State Univ., East Lansing, MI

Abstract: Deficits in protein degradation are a hallmark of neurodegenerative diseases. In Parkinson disease (PD), protein clearance mechanisms such as the ubiquitin proteasome system (UPS) and autophagy lysosome pathway are dysfunctional in post-mortem brain tissue. Not surprisingly, key players in the UPS are mutated in familial forms of PD, such as ubiquitin carboxy-terminal hydrolase L1 (UCH-L1). UCH-L1 is a neuron-specific, highly abundant deubiquitinating enzyme tasked with maintaining pools of monomeric ubiquitin. UCH-L1 function ensures that an adequate supply of monomeric ubiquitin is available so that targeted proteins may be tagged and degraded by the 26S proteasome. UCH-L1 is downregulated and oxidatively modified in post-mortem brain tissue from PD and Alzheimer disease patients, providing a clue that loss of UCH-L1 function could contribute to neurodegeneration. In mice, UCH-L1 and monomeric ubiquitin are decreased in the substantia nigra 24 h after acute neurotoxicant treatment. Similarly, UCH-L1 protein, activity, and monomeric ubiquitin are altered over time in striatal synaptosomes from mice treated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). Decreased UCH-L1 protein was correlated with the decrease in monomeric ubiquitin, suggesting an integral relationship between the abundance of these two key UPS-related proteins. Loss of UCH-L1 and monomeric ubiquitin is hypothesized to contribute to loss of tyrosine hydroxylase (TH) expression in the striatum characteristic of acute neurotoxicant stress and contribute to increased susceptibility of aged mice to MPTP exposure. These experiments will yield insight into the ability of UCH-L1 to preserve TH phenotype by maintaining supply of monomeric ubiquitin and promote UPS-mediated protein degradation.

Title: Matrix metalloproteinase-8 inhibitor ameliorates inflammatory responses and behavioral deficits in LRRK2 G2019S parkinson's disease model mice

Authors: *T. KIM[1], J. JEON[1], J.-S. PARK[2], J. KIM[1], H. NOH[1], H.-S. KIM*[2], H. SEO*[1]; [1]Hayang Univ., Ansan, Gyeonggi, Korea, Republic of; [2]Ewha Womans Univ., Seoul, Korea, Republic of

Abstract: Parkinson's disease (PD) is a neurodegenerative disorder that involves the loss of dopaminergic neurons in the substantia nigra (SN). Matrix metalloproteinases (MMPs) are known to be related to neuroinflammation and neurodegeneration in the nigro-striatal pathway in PD. MMP-8, also known as neutrophil collagenase, is a functional player in the progressive pathology of various inflammatory disorders. In this study, we administered an MMP-8 inhibitor (MMP-8i) in an *in vivo* PD model, LRRK2 G2019S transgenic mice, to determine the effects of MMP-8i on PD pathology. We observed a significant increase in inflammatory markers (CD45, CD11b and SRA) and the number of Iba1-positive activated microglia in the striatum (STR) of LRRK2 G2019S mice, indicating increased neuroinflammation. MMP-8i administration significantly decreased CD45 and SRA levels as well as the number of Iba1-positive activated microglia. In addition, MMP-8i increased the levels of phosphorylated alpha-tubulin, which is a cytoskeletal network protein, and cellular ATP, the product of oxidative phosphorylation from mitochondria. Although MMP-8i did not alter the number of tyrosine hydroxylase (TH)-positive dopaminergic neurons in the SN brain region, MMP-8i significantly increased the cell body area of TH-positive dopaminergic neurons in the SN region of LRRK2 G2019S mice indicating neuroprotective effects on cellular atrophy in PD model mice. Furthermore, MMP-8i markedly improved behavioral abnormalities in LRRK2 G2019S mice, as determined by the rota-rod and open field tests. These data suggest that MMP-8i administration attenuates the pathological symptoms of PD through anti-inflammatory processes in LRRK2 G2019S PD model mice

Title: Regulation and function of the y-chromosome gene sry in acute and chronic animal models of parkinson's disease

Authors: *P. PINARES-GARCIA[1,2], H. LOKE[1], D. THYAGARAJAN[3], V. HARLEY[1,2], J. LEE[1,2];
[1]Brain and Gender, Hudson Inst. of Med. Res., Melbourne, Australia; [2]Dept. of Anat. and Developmental Biol., [3]Dept. of Med., Monash Univ., Melbourne, Australia

Abstract: Whilst the cause of dopamine cell loss in Parkinson's disease (PD) is unknown, it is clear that the male-sex is a strong risk factor. The incidence of PD is 2-fold higher in males, and disease progression more rapid in males than females. Aside from the protective actions of sex hormones, growing evidence suggests that sex-specific genes contribute to this male-bias in PD. We previously showed that the Y-chromosome gene, SRY, co-localises with dopamine neurons, where it regulates dopamine biosynthesis and motor function in males. Here, we investigated the regulation and function of nigral SRY in i) acute toxin-induced hemiparkinsonian and ii) chronic systemic rotenone rat models of PD. We assessed the effect of reducing nigral SRY levels, via repeated infusions of SRY antisense oligonucleotide into the rat substantia nigra (SNc), on motor and dopaminergic function. In normal male rats, reducing SRY expression, via repeated intranigral SRY antisense oligonucleotide (ASO) infusion, transiently reduced motor function in the cylinder and rotarod tests, compared to the sense oligonucleotide (SO) treated control group. In contrast, ASO treatment in female rats did not affect motor function. In the acute 6-hydroxydopamine (6-OHDA) or rotenone-lesioned rat models of PD, nigral *SRY mRNA* was

significantly up-regulated at 7 days post 6-OHDA (+330%) or rotenone (+250%) injection. Remarkably, repeated ASO infusion significantly attenuated motor deficits and nigrostriatal degeneration in both 6-OHDA and rotenone-induced models of PD in male rats. In contrast, female rats showed no differences in 6-OHDA-induced motor deficits or nigrostriatal degeneration between the ASO- and SO-infused groups. In the chronic systemic rotenone rat model of PD (Cannon et al., 2009), we assessed the effect of daily intraperitoneal (IP) injections of rotenone on motor function and nigral gene expression.
Daily IP injections of rotenone (3mg/kg/day) for 14 days led to a time-dependent reduction in rearing behaviour (-59%,-69%,-77%,-79% on days 3, 7, 10 and 14 respectively compared to day 0). Similarly, in the open-field test we showed a time-dependent reduction in distance travelled (-67%, -73%, -75%, -66%), velocity (-68%, -74%, -76%, -67%), and increased duration inactive (+169%, +288%, +279%, +147%). Reduction in motor function was associated with a reduction in nigral *TH* mRNA expression (-55%) and increased nigral *SRY* mRNA expression (+160%) at day 7 compared to day 0. These data indicate that dysregulation of SRY directs a novel genetic mechanism of nigral cell death in males, and that inhibition of nigral SRY may be a novel therapeutic target to slow the progression of PD in males.

Title: Analysis of PKCγ substrates in the nigro-striatum system: The role of CSPα phosphorylation in the neuronal survival

Authors: *T. SHIRAFUJI[1], T. UEYAMA[2], K.-I. YOSHINO[2], N. ADACHI[2], S. TANAKA[1], I. HIDE[1], N. SAITO[2], N. SAKAI[1];
[1]Dept. Mol. and Pharmacol. Neurosci. Hiroshima Univ., Hiroshima-city, Japan; [2]Lab. of Mol. Pharmacology, Bosignal Res. Center, Kobe Univ., Kobe, Japan

Abstract: We found that PKCγ knockout (KO) mice showed Parkinsonian symptoms such as dopaminergic neuronal loss in the substantia nigra and dopamine release impairment in the striatum. However, the PKCγ substrates responsible for the neuronal cell survival *in vivo* have not yet been elucidated. To identify the PKCγ substrates, we employed phospho-proteome analysis. In the striatum of PKCγ KO mice, we found 10 candidate proteins with PKC

phosphorylation motif that exhibited decreased phosphorylation levels. Among them, we focused on csyteine string protein alpha (CSPα), which is a chaperone on the synaptic vesicle, and found that PKCγ directly phosphorylates CSPα at Serine 10 in the cell culture. Classical PKC inhibitors and CSPα knockdown (KD) significantly suppressed the neuronal survival in PC12 cells. The decreased level of neuronal survival in CSPα KD cells was rescued by wild-type CSPα, but not CSPα mutants whose serine 10 was substituted by alanine. These findings indicate that the phosphorylation of CSPα at serine 10 plays pivotal roles in neuronal survival in the substantia nigra. Thus, we propose that PKCγ positively modulates neuronal survival through CSPα phosphorylation. The PKCγ- CSPα phosphorylation axis may provide a new therapeutic target for the treatment of Parkinsonian syndrome.

Title: Nicotine-afforded neuroprotection of dopaminergic neurons is mediated by the alpha 4 subunit of nicotinic acetylcholine receptors

Authors: *E. CUEVAS, S. LANTZ, S. SARKAR, S. ALI, S. ALI, W. SLIKKER, M. G. PAULE, S. IMAM;
NCTR/FDA, Jefferson, AR

Abstract: The cause and mechanisms underlying the loss of dopaminergic (DA) neurons in Parkinson’s disease (PD) are poorly understood. A major barrier to the development of new and effective therapies for PD is the current limitation in our understanding of the molecular and cellular events that lead to degeneration of the nigrostriatal DA system. Currently, there are two clinical trials underway to determine whether nicotine might be a useful therapeutic for the treatment of PD. Here, we evaluated the effect of nicotine pretreatment (0.5 or 1.0 μM 2 h prior to MPP+ exposure) in 1-methyl-4-phenylpyridinium (MPP+)-treated (1.0 mM) SHSY-5Y neuroblastoma cells, as an *in vitro* model of PD-related neuronal damage. Assessments were made 24 h after MPP+ exposure. Treatment with MPP+ significantly reduced the number of active mitochondria in neuronal cells, where pretreatment with nicotine prevented this effect. Additionally, nicotine significantly prevented MPP+ induced loss of cellular proliferation. A significant concentration-dependent neuroprotection afforded by nicotine against MPP+ induced

loss of DA was also observed. In a separate set of experiments, in which SH-SY5Y were transfected with 27-mer primer specific siRNA towards nicotinic acetylcholine receptor (nAChR) α4 subunits prior to MPP+ treatment, nicotine was no longer able to protect cells from the loss of DA caused by treatment with MPP+; this suggests that the neuroprotection afforded by nicotine is likely mediated via nAChRα4 subunits. These data suggest a role for nicotine in protecting mitochondria and facilitating neuronal proliferation via nAChRα4 subunits. Further research of this pathway might lead to critical insight into therapeutic approaches for neuroprotection in PD.

Guadalajara, Mexico

Abstract: URB597 is fatty acid amide hydrolase (FAAH) enzymatic inhibitor; this enzyme is responsible of the degradation of endocannabinoids in special Anandamide or *N*-arachidonoylethanolamine (AEA) mediated by CB1 and CB2 receptor. AEA is involved in biological activities in central nervous system like synaptic communication, neurogenesis and neuroinflammation besides acting in pain perception because of neuroprotective response on demand after damage. The aim of this study was to determine how URB597 molecule is involved in behavior and microglia cells of mice C57BL/6J intraperitoneal injected (I.P) with MPTP (1-methyl-4-phenyl-1, 2, 3, 6-tetrahydropyridine) that has been widely used as a model of PD. So in this work we investigate if prophylactic use URB597 administered 1 month at doses 0.2mg/kg I.P every 48 hours for 30 days before MPTP (30mg/kg/day for 5 days I.P) damage can

modify behavioral test like pole test, gait test and beam test and also if has any change in microglial activation stained with IBA-1 antibody. We use 10 mice for each one group: control, URB597, MPTP and URB597+MPTP. After 3 days of MPTP injection we performance behavioral test in 5 animals and for immunohistochemistry experiments resting mice were submitted to intracardiac perfusion with 4% paraformaldehyde and light immunohistochemistry technique was performed. Statistical analyses of the data were performed using the Kruskas-Wallis non parametric test and pos-hoc Mann-Whitney U test. The level of significance was set at $p<0.05$.Our result suggest that mice treated with URB597 + MPTP were significant different compared to the group with MPTP in pole, gait and beam tests ($p <0.05$). Finally IBA immunohistochemistry shows major microglial activation in MPTP group vs Control and URB597+MPTP groups respectively ($p <0.05$).

Title: Inhibition of PTP1B increases a lysosomal degradation of α-synuclein in SH-SY5Y cells.

Authors: *H. CHOI, J. KIM, K. PARK, H.-H. LIM;
Dept. of Structure and Function of Neural Network, Korea Brain Res. Inst., Daegu, Korea, Republic of

Abstract: The ubiquitin-proteasome system (UPS) and lysosomal degradation pathway (autophagy) are two major pathways to degrade undesired proteins in the cells including α-synuclein. Since that, both systems are often called protein quality control systems in the cell. α-Synuclein can be removed by passing through the autophagy and the proteasomes. The failure in either of those two can lead accumulation of α-synuclein and cause neurodegeneration such as Parkinson’s disease. Previously, we demonstrated that PTP1B inhibitor increases phosphorylation of α-synuclein and the binding of α-synuclein to HSC70 for chaperone mediated autophagy. Also, the treatment of PTP1B inhibitor enhanced neuronal survivability and motor performance in the paraquat-induced PD mouse model. Here, we confirmed that PTP1B inhibitor

can increase the translocation of α-synuclein into lysosome, which results in a protective effect of PTP1B inhibitor against cellular toxicity of α-synuclein accumulation caused by the UPS impairment or other risk factors. Thus, the augmentation of lysosomal degradation pathway by PTP1B inhibitor could be a possible way to decrease α-synuclein aggregates from varied environmental stresses and to protect neuronal cells against cytotoxicity.

Title: Elucidation of extracellular matrix-related gene expression pattern in patients with Parkinson's disease

Authors: *M. KIM[1,2], M.-Y. LEE[1], J. YU[1,2], J.-H. SEO[1,2], Y. SHIN[1,2], S. WI[1,2], S.-R. CHO[1,2]; [1]Dept. & Res. Inst. of Rehabil., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [2]Brain Korea 21 PLUS Project for Med. Science, Yonsei Univ., Seoul, Korea, Republic of

Abstract: Introduction: Parkinson's disease (PD) is common neurodegenerative disorder affecting the motor and cognitive functions. Pathologically, PD patients show a loss of dopaminergic neuron in substantia nigra pars compacta and are frequently present with Lewy bodies, eosinophilic intracellular inclusions composed of amyloid-like fibers and α-synuclein. However, the underlying mechanism causing pathogenesis of PD has not been elucidated so far. To elucidate differential gene expression associated with pathogenesis of PD, this study compared expression levels of genes, especially extracellular matrix (ECM) related genes, via transcriptome analysis in PD and normal control.
Methods: Human lipoaspirate was obtained from a volunteer with informed consent. Fat tissue was treated with 0.075% collagenase. After the isolation, adipose-derived mesenchymal stem cells (MSCs) were seeded in a specific medium. MSCs were subcultured from passage 1 to 8, and when they reached passage 8, transcriptome analysis was conducted. Differentially expressed genes (DEG), the result of transcriptome study, was then analyzed by a program DAVID, which yielded Kyoto Encyclopedia of Genes and Genomes (KEGG) pathway. DEG

was validated by RT-PCR.
Results: KEGG pathway, the result of DAVID program, showed several pathways that explained the role of genes in the pathogenesis of PD. Among DEG, since the 12 down-regulated genes in PD were affected ECM, this study focused on the genes that related to ECM, and compared genes between PD and normal control. The result of RT-PCR showed that, among 12 genes, 6 genes—Collagen 5 alpha 3, Collagen 6 alpha 3, Collagen 6 alpha 2, Dystroglycan 1, Reelin, and Fibronectin 1—represented the same pattern as KEGG pathway.
Conclusion: The expression of collagen group, Dystroglycan 1, Reelin, and Fibronectin 1 showed down-regulated pattern in both KEGG pathway and RT-PCR. We have focused on ECM and suggest that ECM molecules such as Collagen 5 alpha 3, Reelin, and Fibronectin1 have neuroprotective effects in extra synaptic transmission, and might be associated with progression of PD.

Title: The therapeutic potential of alternative respiratory enzymes in neurodegeneration

Authors: *K. M. HOLMSTROEM, P. K. DHANDAPANI, M. SZIBOR, H. T. JACOBS; Inst. of Biotech., Univ. of Helsinki, Helsinki, Finland

Abstract: Neurodegenerative disorders encompass a large number of diseases that all stem from the progressive loss of brain cells. The two most common outcomes of aging associated neurodegenerative diseases are either dementia such as Alzheimer’s disease (AD) or a movement disorder such as Parkinson’s disease (PD). Despite intensive efforts, no cure exists for most neurodegenerative diseases, however, with an aging population the number of people suffering from the condition is growing. Mitochondrial dysfunction is a well-known characteristic of neurodegeneration, often due to failing oxidative phosphorylation and increased free radical

production. Our research demonstrates that the mammalian respiratory chain can be supplemented with respiratory proteins from other species not normally found in the vertebrate lineage. We have shown that this unique approach can alleviate some of the damage caused by the failing respiratory chain in various disease models including AD and PD, in mammalian cells and flies. We recently generated rat and mouse models that express the *Ciona instestinalis* alternative oxidase (AOX), an alternative oxidase capable of compensating for complex III and IV dysfunction, or the alternative NADH dehydrogenase (NDX), an alternative enzyme for complex I. These animals show no overt phenotype from the expression of the alternative enzymes, however, they confer resistance to toxic insults on the respiratory chain. They provide a unique opportunity to examine the potential of this exploratory approach in mammalian neurodegenerative models such as AD, PD and Huntington's disease.

Title: The vra1 locus plays a neuroprotective role in a 6ohda model of parkinson’s disease.

Authors: *M. JEWETT, I. JIMENEZ FERRER, E. N. LINDAU, M. SWANBERG; LUND UNIVERSITY, Lund, Sweden

Abstract: Parkinson’s disease (PD), like other major neurodegenerative disorders, is a complex disease: of the idiopathic cases (about 90%), an estimated 40% of the variation in disease risk is caused by unidentified genetic factors, while another 40% is caused by environmental factors. More work is needed to identify the unknown genetic risk factors for PD.
Thanks to linkage analysis, the Vra1 genetic locus, which includes Glutathione S-Transferase alpha 4 (GSTA4), has been identified in the PVG rat strain as being associated to neurodegeneration after nerve injury. Our goal is to determine whether this locus, isolated in a DA-congenic rat strain, is neuroprotective in a toxin model of PD: unilateral 6-hydroxydopamine (6-OHDA) injections in the striatum. Optical density and stereology data show 55% more

survival of midbrain dopaminergic neurons (mDNs) in DA-Vra1 rats compared to DA rats, indicating that the Vra1 alleles are somehow involved in mDN protection. These results allow us to continue investigating the role of Vra1 and study genes like GSTA4 that may be responsible for increased cell survival, first in rats, then in humans.

Title: Astrocytic High mobility group box 1 upregulates TH exprssion to maintain dopaminergic neurons in MPTP induced PD like model

Authors: ***S. KIM**, M. RYU, J. HAN, Y. JANG, J. KIM, M. LEE, I. RYU, G. KWEON, J. HEO;
Chungnam Natl. Univ. of Sch. of Med., Daejeon, Korea, Republic of

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disease that involves the loss of dopaminergic neurons from the substantia nigra (SN) and striatum. The inflammatory process with activated glial cells has been confused with dual functions as pathogenic and protective factor of PD development. Furthermore, we do not understand the molecular pathway through which dopaminergic neurons are lost via the actions of activated astrocytes and cytokines. High mobility group box 1 (HMGB1) can be actively secreted from inflammatory cells and is known to both promote inflammation and protect against disease propagation. Here we showed that the staining intensities of HMGB1 and Receptor for glycation end product (RAGE) are higher in the nigral area of methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated mice, a toxin-induced PD-like model, compared to those of saline-treated controls. HMGB1 was found to principally localize to astrocytes, and could affect the neighboring dopaminergic neurons, due to co-localization of RAGE with TH-positive cells. Treatment of a dopaminergic neuronal cell line with HMGB1 simultaneously induced JNK phosphorylation and

TH expression. A JNK inhibitor was found to block the HMGB1-induced upregulation of TH expression. Collectively, our results suggest that increased HMGB1 in astrocytes upregulates TH expression to maintain dopaminergic neurons in the progressive neurodegenerative disease, PD. Title: Neuroprotective effect of FTY720 in a mouse model of Parkinson's disease

Authors: *E. PEPIN, G. L.LEMIEUX, G. BUREAU, G. MASSICOTTE, M. CYR;
Biologie médicale, Univ. Du Québec À Trois-Rivières, Trois-Rivières, QC, Canada

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disorder characterized by rigidity, tremor and an overall lack of smooth motor control. These symptoms are triggered by the loss of dopamine (DA) neurons of the substantia nigra that projects rostrally to the striatum. The cause of this debilitating disease remains unknown. For this reason, current PD medications involve symptoms management as opposed to halting disease progression and DA neuronal degeneration. Fingolimod (FTY720) is a known sphingosine-1-phosphate receptor modulator, which has been shown to promote endogenous neuroprotective mechanisms. Whether FTY720 could prevent DA neuronal death in PD has never been investigated. We studied the effects of FTY720 treatment on the nigrostriatal loss and motor deficits induced by the administration of 1-methyl-4-phenyl-1,2,3,6-tretrahydropyridine (MPTP) in mice, a well-recognized animal model of PD. Mice were divided into four groups: vehicle (saline), FTY720, MPTP + vehicle (MPTP) and MPTP + FTY720 (MPTP/FTY720). Chronic FTY720 treatments (1 mg/kg, once a day for 14 days) were administered orally and began two days before the acute MPTP treatments (4 injections of 20 mg/kg, i.p, every 2 hours). Seven days after MPTP administration, behavioral tests were performed to evaluate motor ability. Mice performances at the beam, wire suspension, pole and rotarod tests were similar in all groups. At the biochemical level, Western blot analyses were performed to evaluate tyrosine hydroxylase (TH) levels as a marker of DA neuronal integrity. FTY720 treatments did not affect striatal TH levels whereas a reduction of 29% ($p < 0.05$) was observed in MPTP-treated mice compared to control. Disappointingly, TH levels in the MPTP/FTY720-treated mice were also reduced by 37% ($p < 0.05$) compared to control.

Striatal brain-derived neurotrophic factor (BDNF) levels were measured by Western blot and an increase of 20% ($p > 0.05$) was noticed following the FTY720 treatment. In the MPTP-treated mice, BDNF levels were decreased by 27% ($p < 0.01$) whereas the MPTP/FTY720 treatment increased these levels by 60% relative to MPTP ($p < 0.001$). Altogether, these preliminary data indicates that even with an enrichment of BDNF in the striatum, chronic FTY720 treatment was not able to prevent the DA depletion induced by MPTP. Despite that further investigations will be needed in order to reach stronger conclusion, we still established the interesting possibility that FTY720 could exhibit neuroprotective effects through the modulation of neurotrophic factors.

Title: GSK J4 protects neurons from oxidative stress via a catalase-like mechanism in Parkinson's disease model

Authors: ***M.-D. MU**[1], T. LIANG[1], Z.-M. QIAN[2], W.-H. YUNG[1], Y. KE[1];
[1]Sch. of Biomed. Sciences, The Fac. of Med., The Chinese Univ. of Hong Kong, Shatin, N.T., Hong Kong SAR, P.R. China, Hong Kong; [2]Lab. of Neuropharmacology, Fudan Univ. Sch. of Pharmacy,, Shanghai, China

Abstract: Parkinson's disease (PD) is the second most common neurodegenerative disease, which affects millions of people worldwide. Iron accumulation in the substantia nigra (SN) is one of the most invariable pathological hallmarks, which is believed to drive oxidative stress that leads to selective destruction of dopaminergic (DA) neurons. Therefore, to remove accumulated iron and reduce oxidative stress provide a new therapeutic strategy for PD. GSK J4, a novel histone demethylases inhibitor, has been found to cross blood-brain barrier and possess anti-brain tumor function. Recently, we found that only a trace amount of GSK J4 was sufficient to

reduce cellular labile iron in SH-SY5Y neuronal cells. Here the effects of GSK J4 on 6-OHDA-induced PD model were investigated. MTT assay and TUNEL staining showed that GSK J4 prevented 6-OHDA-induced cell death and apoptosis via a mechanism independent of KDM6, its known target. Although Calcein-AM assay showed that GSK J4 suppressed free labile iron accompanied by decreased ferritin, an iron storage protein, the neuroprotective action of GSK J4 could not be blocked by iron supplement. Interestingly, we found that GSK J4 displayed an anti-oxidant ability via catalase-like mechanism in the presence of iron in cell-free assay. Consistently, it was found that GSK J4 suppressed H_2O_2-induced cell death in SH-SY5Y. In addition, cells treated with GSK J4 showed lower levels of reactive oxygen species and malondialdehyde. In parallel, GSK J4 rescued the DA neurons loss and motor defects in 6-OHDA-induced PD rat. Taken together, we demonstrate that the iron-binding ability of GSK J4 is necessary, but not sufficient, to explain their capacity to protect neurons from oxidative stress. Instead, our data suggest that GSK J4 might act as a catalase mimetic after binding iron, then catalyzes the dissociation of H_2O_2 into water oxygen.

Title: Age effects on astrocyte-mediated neuroprotection against a Parkinson’s Disease model

Authors: ***B. YARBERRY**[1], A. NGUYEN[2], M. BAINS[3], J. L. ROBERTS[1];
[1]Neurosci., [2]Biochemistry/Molecular Biol., Trinity Univ., San Antonio, TX; [3]Univ. of Incarnate Word, San Antonio, TX

Abstract: A major function of astrocytes is to provide neurons with reparative cholesterol in times of oxidative stress by way of a transport molecule known as Apolipoprotein E (ApoE). This function is especially relevant in neurodegenerative diseases, such as Parkinson's disease (PD), that target mitochondria, damage their functional integrity, and lead to the production of reactive oxygen species. Previously, our lab has shown that astrocytes produce less ApoE as they

age and we hypothesize that this will manifest as a decreased ability to provide neuroprotection against a toxic drug that models PD, MPP+ (1-methyl-4-phenylpyridinium), which results in enhanced oxidative stress in the dopaminergic neuron. To examine this hypothesis, N27 dopaminergic cells were treated with 10 μM retinoic acid for 48 hours to induce differentiation and to upregulate the dopamine transporter, the dopaminergic protein required for toxin intake. Thirty minutes prior to toxin treatment, N27s were incubated in astrocyte-conditioned media from different aged mouse astrocytes (4-28mo). Cells were then treated with 500 μM MPP+ for 24 hours and cell viability was analyzed by Western Blot for tyrosine hydroxylase, a marker for dopaminergic cells. We expect that neurons pre-treated with conditioned media from younger astrocytes will have increased levels of tyrosine hydroxylase compared to neurons given conditioned media from older astrocytes and this will be verified through the use of co-cultures. We are currently trying to identify the age-related changes of the factor(s) in astrocyte secretions and these findings will help explain why many neurodegenerative diseases are exacerbated by age.

Title: Neuroprotective and anxiolytic effect of weak static magnetic field in the rat.

Authors: ***R. UZAN**, Y. LOBODA, L. SCHACHTER, J. FINBERG;
Technion-Israel Inst. of Technol., Haifa, Israel

Abstract: Objectives: There is an increasing evidence of interaction between static magnetic fields (SMF) and biological systems. In the study of Ben Yakir-Blumkin et al, 2014, SMF was found to protect against etoposide-induced apoptosis in primary neuronal cultures. The aims of the present study were to investigate whether SMF can protect against 6-hydroxydopamine (6-OHDA) induced neuronal degeneration in rat substantia nigra (SN) and to explore the effect of SMF on rat behavior as a function of age *in vivo*. Methods: Male SD rats were injected intracerebroventricularly (i.c.v) with 6-OHDA (125μg) \saline. Immediately after, a small (3 mm diameter, 0.5 mm thick) disc-shaped magnet was fixed to the rat's skull (or control- non-magnetic metal disc). The magnet was positioned above bregma causing a magnetic field strength of 10 Gauss in the SN area. Five weeks later the rat’s tissues were perfusion-fixed and numbers of tyrosine hydroxylase positive (TH+) cells in SN were counted. In the behavioral

experiment, male SD rats aged 3 months (Young, Y), 12 months (Middle-Aged, MA) and 24 months (Old, O) were implanted with a magnet or control implant as above. After 7 days of SMF exposure rats were subjected to the open field (OF) and the elevated-plus maze (EPM) tests, for behavioral assessment. At the end of the experiment hippocampi were taken for mRNA and protein expression using RT- PCR and western blot analysis, respectively. Results: In the 6-OHDA-control implant group, SN TH+ cell number was reduced by 41±0.06 % (SEM, n=5) in relation to sham-operated controls .However, in the 6-OHDA- SMF-exposed rats, TH+ cell number maintained at normal levels. In the behavioural tests, O and MA rats showed decreased anxiety-like behavior in the EPM test. Increased levels of hippocampal ERK and PKCε proteins were found in MA rats and increased mRNA levels of Neurotrophin-4 (Ntf-4) were found in Y rats exposed to 7 days of SMF. Conclusion: The results demonstrate a neuroprotective effect of SMF in rats exposed to 6-OHDA. Moreover, SMF had an anxiolytic effect in MA and O rats accompanied by alteration in expression of key proteins involved in neuroprotection and plasticity in MA rats. The results indicate a possibility of using weak SMF in treatment of neurodegenerative disorders as well as anxiety conditions in man. Title: Nicotine as a therapeutic candidate in a pre-clinical model of progressive PD: regulation of parkin function

Authors: ***S. M. LANTZ**, E. CUEVAS, S. SARKAR, S. FERGUSON, D. LAW, S. F. ALI, W. SLIKKER, Jr, M. G. PAULE, S. Z. IMAM;
Div. of Neurotoxicology, NCTR/FDA, Jefferson, AR

Abstract: Loss of dopaminergic (DA) neurons from the substantia nigra due to toxic protein aggregation is the primary pathological hallmark of Parkinson’s disease (PD). We have recently identified that the regulation of parkin--a major player in protein clearance--by stress-activated, c-Abl-mediated, tyrosine phosphorylation plays a significant role in PD pathogenesis. Numerous studies have shown that nicotine protects DA neurons and smoking reduces the risk of PD. Here,

we evaluated the possible molecular mechanism of nicotine-mediated protective pathways in an animal model of PD. Adult male C57BLJ6 mice were treated with an ip MPTP regimen as follows: 15 mg/kg free base on day 1, 25 mg/kg on day 2, and 30 mg/kg on days 3-7. Nicotine therapy was administered ip at 0.025, 0.05 or 0.1 mg/kg free base under two conditions, either A) given daily for 1 week before the first dose of MPTP and also 1 hr before each dose of MPTP (pre-MPTP nicotine therapy) or B) given daily for 1 week after the last MPTP dose (post-MPTP nicotine therapy). Behavioral changes, DA status and c-Abl/Parkin pathways were evaluated to see if nicotine therapy would prevent the progressive DA damage seen in this PD model. As revealed by HPLC analysis, MPTP-treatment alone resulted in a significant loss of DA (~80%) in the striatum. Nicotine therapy prevented the loss of dopamine in a dose-dependent manner with approximately 75% restoration seen at the 0.1mg/kg dose. Given this finding, to evaluate clinical applicability, post-MPTP nicotine therapy was employed to investigate whether parkin function was affected. Nicotine therapy significantly prevented c-Abl mediated tyrosine phosphorylation and reduced aggregation of the toxic parkin substrate, aminoacyl-tRNA synthetase (ARS) interacting multifunctional protein type 2 (AIMP2). For the first time, these data provide clear evidence that in a pre-clinical model of progressive PD, nicotine has the potential to serve as a viable therapeutic candidate by maintaining the protein clearance machinery, specifically diminishing the aggregation of AIMP2, in the DA system *after* the onset of PD. Additional studies are underway to further elucidate these mechanisms and to better understand the therapeutic potential of nicotine in PD.

Title: Environmental enrichment protects from transcriptional disturbances in a predisposition PD model.

Authors: Z. WASSOUF, T. HENTRICH, N. CASADEI, S. SAMER, M. CELKOVA, *O. RIESS, J. M. SCHULZE-HENTRICH;
Univ. of Tuebingen, Tuebingen, Germany

Abstract: Parkinson's disease (PD) is a progressive neurodegenerative disorder, characterized by accumulation of misfolded alpha-synuclein protein (aSYN) in intracellular structures called Lewy bodies and loss of dopaminergic neurons. In addition to the resulting motoric impairments, PD patients exhibit a variety of non-motor symptoms including neuropsychiatric disturbances and cognitive impairments. While genomic mutations and multiplications have been linked to rare familial forms of PD, the preponderance of PD cases cannot be explained by genetics alone and seems to occur sporadically. Moreover, disease characteristics often vary considerably despite identical gene defects in patients, and age as well as environmental factors correlate with onset and progression. This multi-factorial interplay suggests a highly complex pathomechanism that has remained largely enigmatic. Using a transgenic mouse model, which was generated in our lab and carries a Bacterial Artificial Chromosome (BAC) construct with the human wildtype full length *SNCA* gene, we measured genome-wide changes in gene expression induced by exposing animals to either an enriched environment -a combination of increased physical and cognitive stimulation- or a Chronic Unpredictable Mild Stress (CUMS) paradigm. Our data revealed features of the mouse genome that show intriguing changes in gene activity accompanied by distinctive epigenetic pattern. Age-dependent transcriptional disturbances were evident in disease background, while exposure to environmental enrichment exhibited protective effects on these disturbances. Further, bioinformatic analysis pointed towards several pathways and signaling cascades linked to aspects of the disease such as membrane potential, synaptic vesicle clustering, neurotransmitter transport, and regulation of cytoskeleton. Tracing down the key molecular regulators driving the observed effects, we suggest a mechanism involving interplay between transcription factors with a role in neuronal plasticity and homeostatic synaptic scaling, promoter methylation, and modulation of synaptic structures that, in concert, could explain the protective impacts of the EE. Utilizing identified features as anchor points, additional (epi-)genome-wide studies are already under way. We consider these efforts to be essential in assessing whether changes in life style can delay or ameliorate PD symptoms in human and whether the epigenome offers novel opportunities for better diagnosis and much-needed therapies of Parkinson's disease.

Title: Parkin modulates proteasome activity in dopamine axon terminals following neurotoxic insult

Authors: *T. LANSDELL[1], K. J. LOOKINGLAND[1], J. L. GOUDREAU[2];
[1]Pharmacol. and Toxicology, [2]Pharmacol. and Toxicology, Neurol. and Ophthalmology, Inst. for Integrative Toxicology, Michigan State Univ., East Lansing, MI

Abstract: The motor symptoms of Parkinson disease result from the chronic degeneration of nigrostriatal dopamine (NSDA) neurons. While NSDA neurons are susceptible, tuberoinfundibular dopamine (TIDA) neurons are spared. This pattern of DA neuronal susceptibility can be recapitulated with exposure to the selective DA neurotoxicant MPTP. Following exposure to MPTP, the recovery of DA neurons is dependent upon the induction of parkin expression, which occurs in TIDA, but not NSDA neurons following MPTP exposure. Parkin, an E3 ligase, is part of the ubiquitin proteasome system that targets proteins for degradation by the 26S proteasome. In cellular assays, parkin directly binds to the 26S proteasome and enhances its activity through an E3 ligase independent mechanism, suggesting that it maintains proteasome activity following neurotoxic insult. To test this hypothesis, chymotryptic-like activity of the proteasome was assessed *in vitro* and *in vivo* following exposure to MPTP or its active metabolite, MPP^+. In cell free proteasome assays MPP+, but not MPTP decreased proteasome activity and this effect was attenuated in the presence of purified parkin. Proteasome activity was decreased in striatal (ST) tissue and synaptosomes derived from $Park2^{-/-}$ mice compared to those from WT mice. MPTP caused a decrease in ST parkin expression as well as proteasome activity in both WT and $Park2^{-/-}$ mice. In contrast, proteasome activity was impaired in the median eminence (ME) of $Park2^{-/-}$ mice, but not in WT mice where parkin expression was increased. The role of parkin in promoting proteasome activity was further assessed *in vivo* with rAAV2/5 mediated over expression of parkin in $Park2^{-/-}$ mice. Unilateral over expression of parkin resulted in increased proteasome activity in ST synaptosomes compared to the contralateral side. Further studies mediating the overexpression of parkin in the substantia nigra will determine if parkin over expression in NSDA neurons will protect axon terminals from loss of proteasome activity. rAAV2/5 mediated over expression of parkin in the arcuate nucleus will determine if parkin expression is sufficient to restore proteasome activity in

the ME of Park2$^{-/-}$ mice. Collectively, these results indicate that parkin plays a role in maintaining proteasome activity following acute neurotoxicant injury in DA neurons.

Title: [^{11}C]PBR28 PET imaging of the exercise-induced reduction in neuroinflammation and behavior improvement in a rat model of Parkinson´s Disease

Authors: ***C. C. REAL**[1], P. KOPSCHINA FELTES[2], D. VÁLLEZ GARCÍA[2], J. DOORDUIN[2], L. R. G. BRITTO[1], E. F. J. DE VRIES[2];
[1]ICB - Univ. of São Paulo (USP), SAO PAULO, Brazil; [2]Dept. of Nuclear Med. and Mol. Imaging, Univ. Med. Ctr. Groningen, Groningen, Netherlands

Abstract: Previous human and animal studies have shown a link between microglial activation and dopaminergic neurons loss in Parkinson's Disease (PD). Moreover, it has been suggested that neuroinflammation contributes to the cascade of events that leads to neurodegeneration, and exercise can reduce the microglial activation. This study aims to evaluate exercise-induced reduction in the neuroinflammatory response by [^{11}C]PBR28 PET scan (a second generation of 18 kDa translocator protein PET tracers) and the behavior improvement in animals submitted to the PD model induced by unilateral striatal 6-hydroxydopamine and to a protocol of wheel running exercise (3 times per week during 40 minutes). 44 male Wistar rats were divided into 4 groups (sedentary - SED; exercised - EX; SED+PD; and EX+PD). A baseline, 10 and 30 day post surgery PET scan with [^{11}C]PBR28 was conducted to quantify neuroinflammation. Behavior was evaluated by novel object recognition (NOR) and the cylinder test. The scans were automatically registered to a tracer-specific PET template and the right/left striatum ratio was analyzed. Post mortem microglial activation was evaluated with Iba-1 on day 10 and 30. Statistical analyses were performed using Generalized Estimating Equations model.
The NOR data revealed that the animals from SED+PD group had a decreased discrimination

index for short memory when compared to the other groups (SED - 27%, $p<0.001$; EX - 24%, $p<0.05$; EX+PD - 29%, $p<0.0001$), and for long memory when compared to the SED group (9%, $p<0.05$). The cylinder test revealed that there was a increase in the asymmetry forelimb use for SED+PD (37%, $p<0.0001$). Iba-1 revealed that at 10 days there was an intense microglial activation in the SED+PD group (SED - 86%, $p<0.0001$; EX - 43%, $p<0.05$; EX+PD - 50%, $p<0.01$), which did not happen in the exercised rats. On day 30, no between groups difference was found. A higher [^{11}C]PBR28 uptake was observed in SED+PD rats on day 10 (62%, $p<0.01$), whereas the EX+PD rats increased 14% ($p<0.01$) when compared to baseline levels. On day 30, an increased uptake was only observed in the SED+PD animals (10%, $p<0.01$). The [^{11}C]PBR28 SUV was as sensitive as the staining with Iba-1, as the correlation of data was significant (R^2 linear:0.239; $p=0.0208$).
The present study suggests that exercise decreases the activation of microglia, measured by Iba-1 and [^{11}C]PBR28 PET. The exercise-induced attenuation of neuroinflammation seems to have a beneficial effect on behavioral symptoms in this PD rat model. The imaging data suggest that [^{11}C]-PBR28 PET can be a good marker for investigating pathophysiological aspects of neurodegenerative diseases.

Title: Manganese-enhanced magnetic resonance imaging for detection of vasoactive intestinal peptide receptor 2-agonist therapy in a model of Parkinson’s disease

Authors: *K. OLSON[1], A. BADE[2], C. SCHUTT[2], J. DONG[2], S. SHANDLER[3], M. BOSKA[2], R. MOSLEY[2], H. GENDELMAN[2], Y. LIU[2];
[1]Pharmamcology & Exptl. Neurosci., [2]UNMC, Omaha, NE; [3]Longevity Biotech, Philadelphia, PA

Abstract: Neuroprotective immunity is defined by transformation of T cell polarity for therapeutic gain. For neurodegenerative disorders and specifically, for Parkinson's disease (PD), vasoactive intestinal peptide receptor 2 (VIPR2)-agonists (referred to as LBT-3627) elicit robust anti-inflammatory responses leading to neuronal sparing in 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-intoxicated mice. While the neurotherapeutic potential has previously been demonstrated for PD, there remains inherent limitation in translating these inventions clinically. One obstacle for clinical translation centers on the availability of suitable noninvasive methods to track disease progression and therapeutic efficacy. To this end, we developed manganese-enhanced magnetic resonance imaging (MEMRI) assays as a method to assess glial activation and LBT-3627-induced neuroprotective immunity for MPTP-induced nigrostriatal degeneration. Following either PBS or LBT-3627 treatment, mice were intoxicated with MPTP. At two and seven days post MPTP intoxication, mice were scanned using MEMRI, and images were registered to an MEMRI-based brain atlas for comparison. Manganese-induced MRI signal enhancement was calculated. MEMRI revealed MPTP-induced inflammation as well as a coincident reduction in signal with LBT-3627 treatment. MPTP-treated mice showed a significantly higher signal enhancement within the hippocampus, the substantia nigra, and the striatum when compared to saline controls. LBT-3627 treatment reversed the signal enhancement indicating the ability of MEMRI to detect both an inflammatory state and the neurotherapeutic potential of LBT-3627, supporting MEMRI as a method to assess changes in nigrostriatal lesions following anti-inflammatory therapy use. Signal enhancement changes were associated with changes in both neuron numbers and astrocyte activation. Dopaminergic neurons were lost following MPTP intoxication. LBT-3627 treatment significantly spared dopaminergic neurons, resulting in a 62% and 64% survival when compared to PBS alone. Likewise, MPTP intoxication noticeably increased GFAP reactivity by nearly 6-fold, and LBT-3627 pretreatment attenuated astroglial response by significantly decreasing GFAP reactivity by ~50% when compared to MPTP treatment. Correlation analysis revealed a positive relationship between signal intensity and TH+ neuron number as well ($r = 0.3600$, $p = 0.0208$). Taken together, the data suggest that MEMRI can be developed as a biomarker tool to monitor neurotherapeutic responses that are relevant to common neurodegenerative disorders used to improve disease outcomes.

Title: Preclinical validation of Bach1 inhibition for the development of Parkinson's disease therapy

Authors: ***M. AHUJA**[1], N. AMMAL KAIDERY[1], J. MORGAN[2], K. IGARASHI[3], O. C. ATTUCKS[4], B. THOMAS[1];

Abstract: Parkinson's disease (PD) is a progressive and debilitating neurodegenerative movement disorder that is characterized by marked dopaminergic cell loss in the brain. Except for the palliative treatment, no preventive therapy or cure is yet available for PD. Based on recent pathophysiological findings, aberrant oxidative stress and inflammation are extensively targeted for developing novel PD therapies. The most promising target is the nuclear-factor-E2-related factor 2 (Nrf2)/antioxidant response element (ARE) signaling pathway which regulates the expression of a battery of genes encoding anti-oxidative, anti-inflammatory, and cytoprotective genes. However, all known Nrf2 activators are electrophilic and thus, may potentially result in oxidative stress. Transcription factor Bach1 [BTB (broad-complex, tramtrack and bric-a-brac) and CNC (cap'n'collar protein) homology 1] binds to ARE-like sequences, functioning as a transcriptional repressor, thus antagonizing the activator function of Nrf2 and hence, potentially be aimed to develop better non-elcetrophillic ARE activators. In our current target validation study, we employed genetic as well as pharmacological inhibition of Bach1. We investigated the effects of Bach1 inhibition on Nrf2/ARE signaling both *in vitro* and *in vivo* and the ability to block 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) induced neurotoxicity, associated oxidative damage, and inflammation in mice. Assessment of mRNA levels exhibited induction of several antioxidant, anti-inflammatory and cytoprotective genes in Bach1 null mouse and also with Bach1 inhibitors. In case of Bach1 null mouse, subacute MPTP induced dopaminergic neurotoxicity was found to be significantly blocked that was accompanied with decrease in the 3-nitrotyrosine (oxidative stress marker) and CD68 immunoreactivity (inflammatory marker) in the substantia nigra. Interestingly, activation of the Nrf2 ARE signaling pathway by oral

administration of a novel non-electrophilic Bach1 inhibitor at 10mg/kg showed good penetration in the brain that significantly blocked against MPTP neurotoxicity without affecting the MPP+ levels. Thus taken together, our results suggests that Bach1 inhibition is a very effective target against dopaminergic neurodegeneration by virtue of its ability to activate neuroprotective Nrf2/ARE genetic program. Hence, we validate, for the first time, Bach1 as a novel therapeutic target for PD.

Title: Simvastatin-loaded PEG-PLA polymersomes confers neuroprotection through inhibition of inflammation in parkinson's disease.

Authors: *D. MANICKAVASAGAM[1,2], K. NOVAK[2], J. R. RICHARDSON[2], M. O. OYEWUMI[2,1];
[1]Biomed. Sci. - Neurosciences, Kent State Univ., Kent, OH; [2]Pharmaceut. Sci., Northeast Ohio Med. university, Rootstown, OH

Abstract: Simvastatin, a cholesterol lowering drug has recently been studied in neurodegenerative conditions due to its potential protective properties. Despite being an attractive drug both for immune and survival mediated responses in glial and neuronal cells, the efficiency of simvastatin is hindered by its poor water solubility, low permeability and adverse side effects. In this regard, the objective of the present work is to develop a polymersome delivery system using PEG: PLA (methoxy polyethylene glycol: poly (D,L) lactic acid) diblock copolymer to improve simvastatin's delivery, solubility, bioavailability and assess their suitability as a neuroprotective agent in Parkinson's disease. Simvastatin-loaded polymersomes were prepared using a modified nanoprecipitation method at concentrations 5, 10 and 20 µg/mL. The preparation resulted in polymersomes of approximately 200 nm in size with a narrow size distribution. The resulting polymersomes also exhibited high drug entrapment efficiency of >97%. In addition, both blank and simvastatin-loaded polymersomes remained stable when stored as aqueous suspensions for up to 30 days after preparation with no evidence of agglomeration or pH change in dissolving medium. The *in-vitro* biocompatibility study

conducted using macrophage cell line did not show any signs of toxicity at all treated concentrations (0, 25, 50, 75 and 100 µg/ml). In cultured BV-2 microglia challenged with hydrogen peroxide or LPS, we observed that simvastatin-loaded polymersomes was superior to simvastatin alone in protecting cell death at drug concentrations ranging from 1-100 ng/mL. Additional mechanistic studies are being conducted in neuronal PC12 cells with the aim of delineating the basis of neuroprotective effects of simvastatin-loaded polymersomes. These results suggest that therapeutic efficacy of simvastatin-loaded polymersomes can be used as a strategy for attenuating inflammation which may be relevant in stopping the degeneration of dopaminergic neurons in Parkinson's disease.

Title: Inhibition of the enzyme 5alpha-reductase by dutasteride induces neuroprotection of dopaminergic neurons of male mice when administered before but not after MPTP

Authors: *N. LITIM[1,2], M. MORISSETTE[1], D. CARUSO[3], R. MELCANGI[3], T. DI PAOLO[1,2]; [1]Neurosci. Res. Unit, CHU De Quebec, Quebec, QC, Canada; [2]Laval University, Fac. of Pharm., Quebec City, QC, Canada; [3]Dept. of Pharmacol. and Biomolecular Sciences, Ctr. of Excellence on Neurodegenerative D, Univ. degli Studi di Milano, Milan, Italy

Abstract: Dutasteride and finasteride are inhibitors of the enzyme 5alpha-reductase used in humans to treat various endocrine conditions. We recently reported that dutasteride but not finasteride exhibited neuroprotective activity in the mouse model of Parkinson's disease (PD) intoxicated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). The present study further investigated the neuroprotective effects of dutasteride in intact as well as MPTP-lesioned mice. C57Bl6 male mice were treated with dutasteride (5 or 12.5 mg/kg) once daily for 10 days. Mice received 4 injections of MPTP (5.5 mg/kg) or saline on the 5th day. Analysis of the motor behavior of these mice showed that treatment with MPTP or MPTP + dutasteride did not affect their motor performance as planned using a low dose of MPTP to induce a moderate lesion modeling early stages of the disease. In these mice dutasteride prevented the depletion of striatal

DA as well as its metabolite DOPAC measured by HPLC while serotonin concentrations remained unchanged. DA and its metabolite levels were unchanged by dutasteride treatment in intact mice. Autoradiography of striatal dopamine transporter (DAT) and vesicular monoamine transporter 2 (VMAT2) specific binding showed that treatment with dutasteride decreased the effect of the toxin while it enhanced DAT specific binding in intact mice. MPTP-treated mice had levels of plasma and brain dihydrotestosterone (DHT) significantly lower than control mice. Dutasteride treatment elevated plasma and brain concentrations of testosterone when compared to control and MPTP mice while as expected from an inhibitor of the enzyme 5alpha-reductase decreased the levels of DHT. The plasma and brain levels of 17beta-estradiol remained low at/or under detection levels in the controls and treated mice of all experimental groups. Striatal glial fibrillary acidic protein (GFAP) levels measured by Western blots were found to be markedly elevated in MPTP mice compared to control mice and dutasteride at both doses significantly reduced the GFAP protein levels in MPTP mice supporting the hypothesis of an anti-inflammatory effect of dutasteride. Taken together these results suggest that dutasteride exhibited neuroprotective effects on DA neurons. A second experiment investigated dutasteride administered for 5 days starting 1 hour after MPTP administration. Analysis of DA contents showed that there was no significant change in the DA levels and metabolism in the striatum of mice post-treated with dutasteride compared with MPTP-lesioned mice. The above results propose dutasteride as promising therapeutic molecule for PD neuroprotection.

Title: A study on the relationship of pick1 and parkin

Authors: ***J. HE**[1], P. K. YEUNG[2], K. K. CHUNG[1], S. K. CHUNG[2], J. XIA[1];
[1]Life Sci. division, The Hong Kong Univ. of Sci. and Technol., Hong Kong, Hong Kong; [2]Li Ka Shing Fac. of Med., The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: Parkinson’s disease (PD) is a prevalent neurodegenerative disease, clinically characterized by resting tremor, rigidity, bradykinesia, and postural instability. Degeneration of

dopaminergic neurons in substantia nigra pars compacta and presence of Lewy bodies are the two pathologic hallmarks of PD. PD is primarily a sporadic disease, but 5-10% of PD cases are inherited. Loss-of-function mutations in Parkin are associated with familial PD, especially early-onset PD. Parkin is an E3 ligase, which preserves cell functions against various toxic paradigms. Parkin binds to PICK1 (protein interacting with C-kinase 1), which is a peripheral membrane protein important for protein trafficking. PICK1 regulates the trafficking of receptors, channels, and transporters in neurons and other types of cells. PICK1 is also involved in proacrosomal vesicle trafficking during spermiogenesis in testes, insulin granule trafficking in pancreatic beta-cells, and growth hormone secretion in brain. Here we demonstrate that PICK1 is a potential inhibitor of Parkin. PICK1 compromised Parkin-mediated prevention of cell death and mitophagy in neurons. Our data suggested that reducing PICK1 could reduce neuronal death by enhancing the protective effect of Parkin.

Title: Splice-variant and isoform-dependent isradipine-inhibition of recombinant L-type Ca^{2+} currents evoked by substantia nigra dopamine neuron-like activity patterns

Authors: *N. J. ORTNER[1], G. BOCK[1], A. DOUGALIS[2], M. KHARITONOVA[1], J. DUDA[2], P. TULUC[1], T. POMBERGER[1], N. STEFANOVA[3], F. PITTERL[4], T. CIOSSEK[5], H. OBERACHER[4], H. J. DRAHEIM[5], B. LISS[2], J. STRIESSNIG[1];

Abstract: Inhibition of brain L-type Ca^{2+} channel (LTCC) subtypes, in particular Cav1.3, by the dihydropyridine isradipine (ISR), is currently tested in a phase 3 clinical trial (NCT02168842) for neuroprotection in Parkinson's disease (PD) to prevent loss of *Substantia nigra* dopamine (SN DA) neurons.
We found that neither knockout of Cav1.3 nor in vivo pretreatment with therapeutic plasma levels of ISR was neuroprotective in a 6-OHDA PD mouse model. Compensatory upregulation of other voltage-gated Ca^{2+} channels may explain this finding in knockouts (Poetschke *et al.*, 2015). Instead, the absence of ISR neuroprotection could be due to weaker voltage-dependent inhibition of LTCCs in SN DA neurons compared to arterial smooth muscle (aSM) Cav1.2 channels, responsible for dose-limiting hypotensive effects in humans.
We confirmed robust transcript expression of both Cav1.3 variants and of Cav1.2 in micro-dissected mouse SN DA neurons, and established HEK293 cell lines stably expressing human long ($hCav1.3_L$) or short ($hCav1.3_S$) Cav1.3 splice variants or hCav1.2 (+β3, α2δ1). I_{Ca} characteristics and ISR sensitivity were quantified using whole-cell patch-clamp recordings during command voltages corresponding to SN DA- and aSM-like activity patterns. During sustained SN DA-like pacemaking (2.5 Hz) only 15–24 % of maximal LTCC current remained and only Cav1.3 splice variants conducted currents during the interspike interval. During a simulated 3-spike burst, integrated I_{Ca} increased significantly ($hCav1.3_S$: 2.0-fold, $hCav1.3_L$: 1.8-fold, hCav1.2: 2.9-fold). Integrated I_{Ca} of Cav1.3 isoforms but not of Cav1.2 was 1.5-fold higher during the first spike that followed the post-burst afterhyperpolarization (1.5 s). ISR sensitivity of Cav1.3 currents evoked by SN DA-like activity was splice variant-specific (IC_{50} $hCav1.3_L$: 7.7 (6.3-9.6) nM; $hCav1.3_S$: 17.0 (13.8-20.9) nM; mean (95% CI)) and significantly lower than those of hCav1.2 (3.1 (2.3-4.3) nM, n≥23). ISR inhibited hCav1.2 currents, evoked by aSM-like activity at 2-fold lower concentrations (IC_{50}=1.6 (1.3-1.9) nM, n=31).
We show that LTCC Ca^{2+} load increases significantly during and after SN DA-like bursts. The absence of neuroprotective effects of ISR can be explained by its weaker state-dependent inhibition of LTCCs in SN DA neurons as compared to aSM Cav1.2 channels. Cav1.3 channels which are considered the main target for ISR-mediated neuroprotection require 5-10-fold higher ISR concentrations for inhibition than aSM Cav1.2. Our data predict that only supratherapeutic doses of ISR, unlikely to be tolerated during long term treatment, could mediate Cav1.3-mediated neuroprotection in PD.

Title: Local inflammation associated with amyloid-beta deposition in postmortem retinas of AD and MCI patients

Authors: *Y. KORONYO[1], D.-T. FUCHS[1], E. BARRON[2], J. SHEYN[1], A. RENTSENDORJ[1], N. J. HART[1], C. A. MILLER[3], D. R. HINTON[2], K. L. BLACK[1], M. KORONYO-HAMAOUI[1,4]; [1]NeuroSurgery Dept., Cedar-Sinai Med. Ctr., Los Angeles, CA; [2]The Doheny Eye Institute, Pathology, Neurosurgery, Ophthalmology, [3]Dept. of Pathology and Neurol., Keck Sch. of Medicine, Univ. of Southern California, Los Angeles, CA; [4]Dept. of Biomed. Sci., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Background Until recently Alzheimer's disease (AD) was assumed to present only in the brain. We have shown that amyloid-β protein (Aβ) plaques, a pathological hallmark of AD, exist in postmortem retinas of AD patients and form at early stages. Subsequent studies have found the characteristic brain pathology pTau, Aβ-like deposits, and $A\beta_{42}$ peptide accumulation, in postmortem AD retinas. Furthermore, studies have shown nerve fiber layer thinning in live AD patients, retinal ganglion cell (RGC) degeneration in postmortem AD retinas, and most recently, a link between melanopsin-RGC degeneration and retinal Aβ accumulation. We hypothesize that retinal cell degeneration and Aβ plaques in AD patients similar to those observed in the brain will be accompanied by a surrounding inflammatory response.
Methods We studied postmortem retinal and brain Aβ plaques from the same AD patients. The geographical distribution, layer location, and ultrastructure morphology of Aβ deposits were analyzed using retina whole mounts and cross sections from neuro-pathologically confirmed MCI, AD patients, and age-matched controls. Retinas were examined for the phenotype of resident and infiltrating immune cells as well as astrocytes. The overall amount and morphological changes in RGCs were also studied.
Results In MCI and AD patients, retinal Aβ deposits manifested in distinct layers, mostly in the peripheral regions of the superior quadrant. They presented as extracellular and intracellular accumulation, and often associated with blood vessels. We identified a variety of retinal Aβ deposits and used electron microscopy to analyze their ultrastructure. These Aβ deposits were

associated with surrounding inflammation, including activated microglia as well as infiltrating lymphocytes and monocytes. The microglia, engulfing Aβ aggregates, exhibit a full-blown phagocytic amoeboid phenotype. Age-matched controls showed scarce retinal Aβ deposition with no inflammation. Moreover, we detected marked reactive astrocytosis in the vicinity of Aβ in the RGC layer. These changes along with degeneration of RGCs were detected in AD and at early-disease stages.
Conclusions We demonstrates accumulation of Aβ in AD and MCI retinas, abundant in certain retinal layers and geometric regions. Retinal Aβ deposition is associated with activated microglia, reactive astrocytes, infiltrating immune cells, and specific cell loss. Since the retinal pathologies observed in AD and MCI patients mimic those seen in the brain, the retina, which can be imaged noninvasively and repeatedly at high-resolution, may be targeted to assess disease progression and monitor response to therapies.

Sci., Soochow Univ., Suzhou, China

Abstract: Dysfunction of the innate immune system is believed to play a significant role in the pathogenesis of Alzheimer's disease (AD). However, the pathophysiological mechanisms underlying these dysfunctions are unclear. Microglia is the major effector and regulator for coordination of the immune response in the central nervous system. Studies using transgenic AD mouse models suggest that impairment of microglial function contributes to AD pathological progression and disease severity. Our laboratory previously reported that interleukin (IL)-33 ameliorates the amyloid pathology, suggesting a potential therapeutic role for this interleukin in AD. Here, we show that the attenuation of β-amyloid (Aβ) accumulation in APP/PS1 mice (transgenic mice with AD-like pathologies) by IL-33 is accompanied with the modulation of innate immune response in the brain. IL-33 skews microglia and macrophages towards an alternative activation state with enhanced Aβ phagocytic capacity and elevated anti-inflammatory gene expression such as Fizz-1 and Arg1. Furthermore, IL-33 administration significantly suppressed the increased gene expression of pro-inflammatory proteins such as IL-1β, IL-6, and NLRP3 in the cerebral cortex of APP/PS1 mice. Collectively, IL-33 modulates the inflammatory responses in the brain to ameliorate the AD-like disease pathogenesis of APP/PS1 mice. These results suggest a potential therapeutic role of IL-33 in AD.

Abstract: Alzheimer's disease (AD) is a devastating and currently incurable neurological condition characterized by cognitive decline as well as impaired locomotor ability, reasoning, and judgment. The accumulation of β-amyloid (Aβ) in the brain is believed to be a major cause of the synaptic and neuronal dysfunction, microglial activation, and neuronal loss in AD. Emerging evidence suggests that the innate immune response plays a major role in the pathogenesis of AD. Here, we show that interleukin (IL)-33, a crucial mediator of the innate immune response, contributes to the pathogenesis of AD. Serum levels of soluble ST2 (sST2), a decoy receptor of IL-33, were elevated in patients with mild cognitive impairment. Moreover, administration of IL-33 reversed hippocampal synaptic plasticity impairment and cognitive deficits in APP/PS1 mice, a mouse model with AD-like pathologies. Furthermore, IL-33 administration exerted a beneficial effect on the pathological conditions of AD by reducing soluble Aβ levels and amyloid plaque deposition in these mice. The results collectively demonstrate that the deregulation of IL-33/ST2 signaling contributes to the pathogenesis of AD.

Title: The role of extracellular vesicles in the neuroinflammation in Alzheimer's disease

Authors: *Y. YANG;
Exptl. Med. Sci., Lund Univ., Lund, Sweden

Abstract: Microglia are the immune cells in the central nervous system (CNS) and have an important function in brain pathologies. Under neurodegenerative conditions, activated microglia is a typical feature in the neuroinflammatory processes. Inflammatory activated microglia leads to neuronal dysfunction, and accelerates progression of neurodegenerative diseases, such as Alzheimer's disease (AD). AD is the most common cause of dementia and is characterized by amyloid plaques and neurofibrillary tangles (NFT) formation. Previous research has implicated both beneficial and detrimental roles of microglia in plaque degradation related to the neuropathology. A better understanding of the interaction between microglia and other cells in the brain will be crucial to eliminate detrimental effects of immune response as a strategy to intervene the progression of the disease.
Extracellular vesicles (EVs) are considered as one of the main participants in cell-cell interaction as well as post-modification of extracellularly neuropathogenical protein, for example beta-amyloid (Aß) and tau. They are able to carry pathogen-associated and damage-associated molecular patterns, cytokines, enzymes and nucleic acids. According to size, origin and functions, EVs are classified into different groups. We are specifically interested in exosomes (50-200nm) and microvesicles (100-1000nm). EVs are likely involved in propagation of inflammatory signals and act as mediators in the regulation of cell-cell communication.
In this study, we will investigate the dynamics of EVs released from microglia under inflammatory conditions. A murine microglia cell line, BV2, will be treated with lipopolysaccharide (LPS) to obtain fully activated microglial features, which could be verified with inducible nitric oxide synthase (iNOS) expression in the cells by western blot. EVs are collected from conditional medium by sequential ultracentrifugation. The size distribution of EVs will be assessed with Nanosight as well. The origins of EVs will be indicated by western blot using plasma membrane marker and endosomal marker, flotillin-1 and Alix, respectively. Importantly, inflammatory cytokines from EVs, pre-and post-ultracentrifugation conditional medium will be measured by multiplex ELISA. In order to understand potential roles of EVs in AD pathogenesis, EVs will be harvested from BV2 triggered with recombinant Aß.

We found size changes in the EVs upon Aß stimulus and presence of inflammatory markers, galectin3 and NLRP3, in LPS-EVs. These findings will shed light on the important roles of EVs for the neuroinflammation and pathogenesis of AD.

Title: Glial responses in the cerebral cortex of Lewy body diseases

Authors: *A. SERRANO-POZO[1], G. ALDRIDGE[1], Q. ZHANG[1], M. P. FROSCH[2], N. NARAYANAN[1], B. T. HYMAN[2];
[1]Dept. of Neurol. of the Univ. of Iowa, Iowa City, IA; [2]Massachusetts Gen. Hosp., Boston, MA

Abstract: Background: Diffuse cortical Lewy bodies are a pathological signature of Parkinson disease dementia (PDD) and dementia with Lewy bodies (DLB). However, there is considerable pathological overlap with pathological features of Alzheimer's disease (AD), especially amyloid plaques and, to a lesser extent, neurofibrillary tangles (NFTs). We have previously shown that glial responses - reactive astrocytes and activated microglia - associate not only with amyloid plaques but also with NFTs in AD. Here we focused on Lewy body diseases and hypothesized that glial responses in these disorders associate with the concurrent AD neuropathological changes rather than with alpha-synuclein aggregates (Lewy bodies and neurites). **Methods:** We conducted a quantitative neuropathological study in a cohort of consecutive patients who had an *antemortem* clinical diagnosis of PD, PDD, or DLB, and donated their brain to the Massachusetts General Hospital Alzheimer Disease Research Center Brain Bank. We applied peroxidase-DAB immunohistochemistry and measured the load of alpha-synuclein (LB509-immunoreactive), amyloid-beta (10D5 or 6F/3D-immunoreactive), and phospho-tau (PHF1-immunoreactive) pathology in paraffin-embedded sections from the frontal association cortex (BA8,9). We conducted an unbiased stereology-based quantitation of reactive astrocytes (GFAP-immunoreactive) and activated microglia (CD68 or MHC2-immunoreactive). We also performed

double fluorescence immunohistochemistry in selected cases. **Results:** Median (interquartile range) pathological burden was 0.0045% (0.001-0.017) for aggregated alpha-synuclein (LB509+ Lewy bodies and neurites); 0.02% (0.004-0.069) for hyperphosphorylated tau (PHF1+ NFTs, neuropil threads, and plaque-associated dystrophic neurites), and 0.96% (0.21-1.44) for amyloid beta (10D5+ or 6F/3D+ amyloid deposits). We performed correlations between the number of reactive astrocytes and activated microglia and the load of Lewy bodies/neurites, amyloid deposits, and tau pathology. Double fluorescence immunohistochemistry in selected cases enabled the study of the spatial relationships between reactive glia and these pathological protein deposits. **Discussion:** These results could have important implications in the pathophysiology of alpha-synucleinopathies.

Title: Aberrant T cells enter brain and induce Alzheimer’s-like neurodegeneration

Authors: *C. J. WHEELER;
Neurosurg., Cedars-Sinai Med. Ctr., Los Angeles, CA

Abstract: Sporadic Alzheimer’s disease (AD) is characterized by progressive neurodegeneration with amyloid-beta (Aβ) plaque and neurofibrillary deposits in brain. Rare familial AD is guaranteed by gene mutations that increase Aβ deposition, but aging is the only known cause of sporadic AD. Immune processes such as neuroinflammation contribute to AD pathophysiology, but whether human-specific features of immune aging do so remains unknown. We induced human-like age-related changes in CD8 T cells by homeostatic expansion in nude mice. The resulting homeostatically-induced CD8 T cells (“hiT cells”) precipitated human-specific features of AD not seen in current animal models, including neurodegeneration and neurofibrillary deposition. Neurodegeneration, but not proteinopathy, was dependent on both lytic (Perforin1) and proinflammatory (IFNγ) T effector functions. Transfer of hiT cells into wild-type mice

decreased neuronal metrics even more quickly, and synergized with brain injury to confer human-specific amyloidosis. Gene expression, effector protein, and immune receptor specificity associated with hiT cells in mice were all significantly elevated in AD brain. These findings introduce a pre-clinical model of AD-like neurodegeneration uniquely based on age-associated physiology. Further dissection of this model should increase our understanding of sporadic AD pathophysiology, identify novel targets for disease intervention, and elucidate physiological mechanisms of age-related tissue destruction.

Title: Microglial SOCS3 prevents IL6 production in Alzheimer's disease model mice

Authors: *N. IWAHARA;
Sapporo Med. Univ., Hokkaido, Japan

Abstract: [Objective] Inflammatory responses to Aβ increase expression of cytokines and production of reactive oxygen species (ROS) along with activation of microglia (MG). Suppressor of cytokine signaling (SOCS) family is a key regulator of JAK/STAT pathways, and SOCS3 is reported to regulate inflammatory processes. Recently, Waller D.G. et al. reported that SOCS3 expression was increased in brain of Alzheimer's disease (AD) patients. Here, we show that *SOCS3* expression was induced in AD model mice and SOCS3 prevented IL6 production of Aβ stimulated primary cultured microglia (pMG). [Methods] 3-18 month-old APPswe/PS1dE9 transgenic (APdE9) mice were used in this study. pMG were isolated from one brain hemisphere of APdE9 mice. pMG were treated with control or *SOCS3* specific siRNA then stimulated by oligomeric Aβ (oAβ) for 6h. Gene expression of *SOCS3* and pro-inflammatory cytokines (*TNFα, IL1β, IL6*) were measured by qRT-PCR. [Results] *SOCS3* mRNA expression level of MG derived from APdEd9 mice were increased in 9 months of age. Compared to up-regulation of *TNFα* and *IL1β* gene expression coinciding with *SOCS3*, induction of *IL6* was not significant. Up-regulation of *IL6* was observed only with knocking down of *SOCS3* expression in pMG.

[Conclusions] Increase of *SOCS3* and pro-inflammatory cytokines such as *TNFα* and *IL1β* were observed in APdE9 mice. However, induction of *IL6* was not observed in APdE9 mice, and gene expression of IL6 was suppressed by SOCS3 in pMG. Microglial SOCS3 might restrain the progress of AD through the suppression of IL6 production.

Title: TREM2 levels are preserved in the Frontal Cortex and Hippocampus in prodromal Alzheimer's disease

Authors: ***M. NADEEM**[1], S. PEREZ[2], B. HE[3], J. C. MIGUEL[4], M. M. AHMADI[7], L. MAHADY[5], E. MUFSON[6];
[1]Dept Neurol, [2]Dept Neurol., [3]Dept. of Neurol., [4]Dept.Of Neurol., [5]Neurol., [6]Dept.of Neurol., Barrow Neurolog. Inst., Phoenix, AZ; [7]Banner Hlth., Phoenix, AZ

Abstract: Loss of function of the mutations encoding for the triggering receptor expressed on myeloid cells 2 (TREM2), a transmembrane glycoprotein expressed selectively on the cell surface of microglia and macrophages, is associated with increased risk of Alzheimer's disease (AD). Studies in cases carrying TREM2 variants showed that altered TREM2 levels translate to functional and morphological dysfunction of the microglia and phagocytosis that may lead to accelerated plaque and neurofibrillary tangle formation. Recently, it has been shown that TREM2 levels are also altered in brains of sporadic AD, suggesting a role for TREM2 in the pathogenesis of AD. However, whether TREM2 levels are altered in prodromal AD is unknown. In this study, TREM2 levels were measured in the frontal cortex (n=49) and hippocampus (n=46) of people who died with an ante-mortem clinical diagnosis of non-cognitive impairment (n=18,

mini-mental state examination score (MMSE) ≥ 28), mild cognitive impairment (n=18, MMSE ≥ 27), mild AD (n=16, MMSE ≥ 20) from the Rush Religious Orders Study and severe AD (n=13, MMSE < 15) from the Rush Brain Bank using quantitative immunoblotting. Our findings revealed that TREM2 levels in the frontal cortex were significantly increased in severe AD compared to NCI, MCI and mild AD ($p = 0.002$), while hippocampal TREM2 levels were unchanged across the clinical groups examined. Interestingly, cortical TREM2 levels were significantly higher compared to hippocampus in each of the clinical groups examined ($p < 0.05$). In addition, there was no association between cortical and hippocampal TREM2 levels across clinical groups or with Aβ load, neuritic and diffuse plaques neuropathological criteria (CERAD, NIA-Reagan and Braak stage) or cognitive test scores (episodic memory and global cognitive score) during AD progression These findings indicate that TREM2 levels within the frontal cortex and hippocampus are not dysregulated during the early stages of AD

Title: Effect of granulocyte and macrophages colonie stimulating factor (GM-CSF) in the hippocampus of transgenic animals for Alzheimer's disease

Authors: *D. S. PAIVA, Y. L. GIULIO, S. A. A. ROMARIZ, P. M. MARTIM, M. L. QUINTELLA, S. W. HAN, B. O. MONTEIRO;
Unifesp, São Paulo, Brazil

Abstract: Progressive cognitive impairment and emotional disorders are the major characteristics of Alzheimer´s disease (AD). Neuropathological signs of AD are mainly described as amyloid-β protein (Aβ) deposit forming Aβ plaques, neurofibrillary tangles and disseminated state of inflammation in the CNS. *The Granulocyte-Macrophage Colony-Stimulating Factor* (GM-CSF) is a hematopoietic cytokine that stimulates bone marrow stem cells and neural progenitors, but has showed ambiguous activities upon inflammation. Here, we

questioned whether the hippocampal transduction with a lentiviral vector expressing GM-CSF could reduce inflammation, amyloid plaques and ameliorate cognitive deficits. Double transgenic male adult mice with APPswe/PS1dE9 mutation between 4-5months old were used as Alzheimer's disease model, and the respective wild type mice (WT) used as controls forming the following groups: AD; AD-GM-CSF; WT; WT-GM-CSF. Saline or lentivector carrying GM-CSF gene were infused into the hippocampus at 5 months of age. After 2 months from recovery, animals were subjected to the Open Field (OF) and Morris Water Maze (MWM) tests for exploratory behaviour and learning and memory evaluation. After the last day of the MWM, animals were euthanasied for quantification by ELISA or perfused for brain histology. The slices were processed for immunohistochemistry to stain amyloid plaques and microglia in the hippocampus. There was an increase in the expression of GM-CSF in the CNS of GM-CSF transduced animals ($p< 0.05$). The GM-CSF was detected by immunohistochemistry for GFP that was highly expressed in the hippocampusof AD-GM-CSF mice. Also, GM-CSF increased the number of microglial cells and reduced the quantity of Aβ plaques in the hippocampus,when compared with non-infected AD ($p< 0.05$). No improvement in learning and memory was observed in Morris Water Maze test of GM-CSF transduced AD animals compared with AD non-transduced mice, although the AD-GM-CSF group improved the exploratory behavior in OF ($p< 0.05$). We suggest that, despite not having important behavioral changes, GM-CSF overexpression in the hippocampus of AD mice modified the pattern ofinflammatory response,which have a direct effectin amyloid plaques involved in Alzheimer´s disease.

Title: Amyloid pathology and microglial cells are affected life-long after stress exposure in early-life.

Authors: *L. HOEIJMAKERS[1], A. AMELIANCHIK[1], D. IVAN[1], A.-M. VAN DAM[2], P. J. LUCASSEN[1], A. KOROSI[1];

[1]Swammerdam Inst. for Life Sci., Univ. of Amsterdam, Amsterdam, Netherlands; [2]Dept. of Anat. and Neurosciences, VU Med. Ctr., Amsterdam, Netherlands

Abstract: Alzheimer's disease (AD) is characterized by accelerated cognitive decline, neuroinflammation and abundant neuropathology. The risk to develop AD is, next to genetic causes, modified by environmental factors that might affect the onset and gravity of AD symptoms. Early-life stress (ES) exposure is hypothesized to be a modulator of AD development. However this hypothesis has not yet been tested. Interestingly stress in adulthood is well known to modulate the neuroimmune system. We here tested whether exposure to ES 1) aggravates amyloid (Aβ) pathology and if 2) ES primes neuroimmune functions (i.e. microglia) in wildtype (WT) mice 3) as well as in an AD transgenic mouse model to test if such priming might mediate ES-induced alterations in amyloid pathology. 4) Finally we tested in vitro whether glucocorticoids are the key element in the priming of microglial cells.
We used WT and APPswe/PS1dE9 overexpressing mice. The APP/PS1 transgenic mouse line exhibits Aβ plaque accumulation from ±4 months onwards and cognitive impairments after 6 months. Both WT and APP/PS1 mice were subjected to a chronic ES mouse model consisting of exposing dams to limited nesting/bedding material from postnatal day (P)2-P9, that results in cognitive impairments in 4 month old WT mice. Thus to test for ES-induced acceleration and/or aggravation of AD hallmarks, including cognitive functioning, Aβ load and microglial activity were studied at ages 3 to 4 months and 8 to 10 months. To further explore the role of glucocorticoids in the ES-induced priming of microglia we exposed primary glia cultures to ex vivo lipopolysaccharide following dexamethasone.
Although ES exposure did not accelerate or aggravate cognitive decline in APP/PS1, ES affected Aβ load in an age dependent manner. ES exposed APP/PS1 showed less cell-associated amyloid at 4 months, but elevated Aβ plaque load at 10 months. In addition to this pathological change, ES increased microglial CD68 expression in WT. This increase was further exacerbated under APP/PS1 overexpression in the hippocampus at 4 months, indicating possible increased phagocytic activity. Further characterization of microglial activity and the inflammatory profile following ES and/or APP/PS1 overexpression is currently ongoing.
Our results so far suggest that ES exposure modulates microglial functioning in adulthood both in WT and under pathological conditions, with possible implications for the progression of AD related neuropathology. Insights into the effects of ES on neuroimmune functions and AD pathology may not only lead to new mechanistic insights but also to the identification of vulnerable populations for neurodegenerative diseases.

Title: TYROBP/DAP12 and its role in Alzheimer's disease

Authors: *J.-V. HAURE-MIRANDE[1], S. KIM[1], M. WANG[2], B. ZHANG[2], E. SCHADT[2], S. GANDY[1], M. EHRLICH[1];
[1]Neurol., [2]Dept. of Genet. and Genomic Sci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Alzheimer's disease (AD) is a progressive neurodegenerative disorder characterized by amyloid beta (Aß) peptide accumulation which is believed to be a major pathophysiologic factor of the disease. An inflammatory component in AD has long been recognized, and it was first assumed that the chronic neuroinflammation associated with AD may be a secondary or even protective event in response to Aß deposition and may occur only in late stages of AD. Recent genetic studies, however, identified an association between AD and mutations in genes encoding important immune mediators, e.g. *CD33* and *TREM2*, highlighting the role of a dysregulated immune response and neuroinflammation in AD and suggesting an earlier, and perhaps causative, role in pathogenesis. In addition, integrative genomic analyses of human AD brain transcriptomes have provided convincing data regarding the role of microglia in the pathogenesis of AD. Microglial activation may therefore be causative, reactive, and/or protective, perhaps varying with disease stage. For example, phagocytosis of Aß peptides may prevent their deposition into plaques. Alternatively, microglial activation leads to the release of proinflammatory cytokines that can contribute to synaptic dysfunction and neuronal death. *TYROBP* (aka *DAP12*) was identified by members of our team as a hub gene mediating microglial activation, and its expression is increased in human AD and mouse AD model brains. Naturally occurring mutations of *TYROBP* cause Nasu-Hakola disease. *TYROBP* encodes a transmembrane signaling polypeptide which contains an immunoreceptor tyrosine-based activation motif (ITAM) in its cytoplasmic domain and is a downstream adaptor of immune receptors associated with AD risk factor such as *TREM2, CR3* and *SIRPβ1*. However, the role of *TYROBP* in the pathogenesis of AD and microglial function clearance remains unclear.
We sought to determine the *in vivo* effect of loss of function of *Tyrobp* in an AD mouse model. We crossed *Tyrobp*-deficient mice and the *APP/PSEN1*$^{\Delta exon9}$ AD mouse model. The *Tyrobp*-null mouse was developed via deletion of exons 3 and 4 of *Tyrobp* gene, including the transmembrane region, part of the cytoplasmic region, and the first tyrosine of the ITAM motif. We will present phenotypic assays in male and female mice of *APP/PSEN1*$^{\Delta exon9}$ and

APP/PSEN1$^{\Delta exon9}$*xTyrobp*-null genotypes, including behavior, Aβ and Aβ oligomer levels, microglial phagocytic ability, cytokine expression, and plaque deposition accumulation. This study should advance our understanding of the normal function of *TYROBP* and its role in AD, including its role as a potential therapeutic target.

(QBI), The Univ. of Queensland, Brisbane, Australia

Abstract: The microtubule-associated protein tau has been implicated in Alzheimer's disease (AD) pathogenesis. Although inflammation is positively correlated with tau hyperphosphorylation and aggregation, the impact of tau pathology on the immune response remains elusive. Here, we provide evidence that tau aggregation drives the failure of critical molecular events that limit and resolve inflammation. Specifically, pathological tau impairs interleukin-37 (IL-37), a unique cytokine that belongs to the IL-1 family and possesses potent anti-inflammatory properties, inhibiting both innate and adaptive responses. Brains from AD subjects show lower soluble IL-37 levels compared with the brains of non-demented subjects. Mechanistically, IL-37 is sequestered by tau into neurofibrillary tangles, and tau pathology

progressively impairs neuronal IL-37 release. Notably, IL-37 overexpression in aged AD transgenic mice with robust amyloid plaques and neurofibrillary tangles mitigates the critical pathological features of AD, including inflammation, synaptic toxicity and cognitive decline. Our findings provide clear evidence that targeting the IL-37 anti-inflammatory network will provide a new approach for the treatment of AD. Likewise, therapies that ameliorate tau-mediated neurodegeneration and further accumulation of pathological tau species could be validated with the development of an IL-37 biomarker assay.

Title: Innate immune cell circadian rhythms in aging and Alzheimer’s disease

Authors: *C. TSAI, K. I. ANDREASSON;
Stanford Univ., Stanford, CA

Abstract: Recent systems biology approaches have identified innate immune cell dysfunction as a dominant risk factor for developing Alzheimer’s disease, underscoring the importance of understanding basic innate immune cell biology. On important aspect of innate immune biology is circadian regulation of gene expression and cellular function in microglia and macrophages. Young macrophages exhibit circadian rhythms in cytokine release, cell trafficking, phagocytosis capacity, and gene expression. How these myeloid circadian rhythms change with aging or Alzheimer’s disease remains unclear. Using unbiased transcriptomic approaches and in vitro assays, we tested the hypothesis that aged microglia and macrophages exhibit less robust circadian rhythms and lead to an increased risk for developing Alzheimer’s disease. Our results suggest that aging impairs circadian regulation of microglial clearance activity and increases accumulation of amyloid beta.

Title: Trem2 deficiency reduces proliferation, increases cell death and exacerbates inflammation in a mouse model of Alzheimer's disease

Authors: *T. R. JAY[1], **M. BROIHIER**[2], G. LANDRETH[2], B. LAMB[3];
[1]Neurosciences, [2]Case Western Reserve Univ., Cleveland, OH; [3]Indiana Univ., Indianapolis, IN

Abstract: Alzheimer's disease (AD) is a neurodegenerative disorder characterized pathologically by amyloid-beta plaques. Myeloid cells, which are comprised of microglia and peripherally derived macrophages, can alter AD pathology through inflammation or plaque clearance. Variants in the Trem2 (Triggering Receptor Expressed on Myeloid Cells 2) gene confer increased risk for developing AD. It was previously found in a study of Trem2 WT and KO AD mouse models that Trem2 is expressed on plaque-associated myeloid cells, and that Trem2 is necessary for the recruitment of myeloid cells to plaques. We explored several mechanisms as potential explanations for reduced myeloid cell number around plaques in Trem2 deficient APPPS1-21 AD mice including changes in cell proliferation and cell death. Cell proliferation was examined by measuring incorporation of bromodeoxyuridine (BrdU) in myeloid cells in APPPS1-21;Trem2+/+ and APPPS1-21;Trem2-/- mice. Using immunohistochemistry (IHC), brain tissue of these mice was co-stained for BrdU and the myeloid cell marker Iba1. The number of cells with colocalization between the two stains was measured in the cortex and the hippocampus, brain regions where amyloid pathology is prevalent. The number of BrdU+Iba1+ cells was significantly reduced in both the hippocampus ($p<0.01$) and cortex ($p<0.001$). Myeloid cell apoptosis was quantified with IHC by counting the number of cells expressing cleaved-caspase 3, an apoptotic cell marker, and Iba1. There was a strong trend towards increased cell death in the Trem2 KO mice. These findings suggest that the reduction in cell number in the Trem2 KO mice is at least partially explained by both a reduction in proliferation of those cells and possibly increased myeloid cell death. Next, we wanted to assess if a change in myeloid cell number affected general myeloid cell functions related to AD. First, phagocytosis between the two models was examined using an *ex vivo* slice phagocytosis assay, which measures phagocytosis of florescent beads in myeloid cells within a brain slice.

However, there was no significant change in phagocytosis between the Trem2 KO and WTs. Second, we measured the general inflammatory response by means of qPCR with pro-inflammatory markers (IL1β, IL6, iNOS, TLR4, and TNFα) and anti-inflammatory markers (Fizz1, Arg1, TGFβ, and Arg1). We found that Trem2 KOs expressed significantly reduced levels of pro-inflammatory markers and increased levels of anti-inflammatory markers. Understanding how Trem2 affects myeloid cell number, phagocytosis, and inflammation may help to elucidate Trem2's role as a risk factor for AD.

Title: Soluble epoxide hydrolase regulates astrocyte immune responses and GFAP expression through suppression of STAT3 phosphorylation

Authors: *F.-S. SHIE[1], S. SHEN[1,2], Y.-T. HSU[1], P.-C. HSU[2], Y.-H. LEE[2];
[1]Ctr. For Neuropsychiatric Research, Natl. Hlth. Res. Inst., Zhunan Town, Taiwan; [2]Inst. of Physiol., Natl. Yang-Ming Univ., Taipei, Taiwan

Abstract: Astrocyte activation is a common pathological feature in many brain diseases and plays an important role in the pathogenesis of Alzheimer's disease (AD). Here, we demonstrate that soluble epoxide hydrolase (sEH) immunoreactivity was escalated in activated astrocytes in the vicinity of β-amyloid (Aβ) aggregates in parallel with the progression of AD-like pathology in APP/PS1 transgenic mice. Importantly, our results show that silence against sEH mRNA enhanced, but overexpression of sEH ameliorated the LPS-induced expression of pro-inflammatory markers, such as inducible nitric oxide (iNOS), cyclooxygenase 2 (COX-2), and pro-inflammatory cytokines. These findings suggest that sEH negatively regulates astrocyte immune responses. Data from primary astrocytes with sEH knockout (sEH-/-) background also support the notion that sEH functions to suppress astrocyte activation. Similarly, sEH-/- mice received intraperitoneal injection of LPS displaced an exacerbated astrocyte activation in the

brain as evidenced by the elevated expressions of glial fibrillary acidic protein (GFAP) and pro-inflammatory markers at both levels of protein and mRNA. We further demonstrate that phosphorylation of signal transducer and activator of transcription 3 (STAT3) was up-regulated in activated astrocytes of sEH-/- mouse brain and pharmacological blockade of STAT3 activity alleviated the pro-inflammatory effects of sEH deletion in LPS-activated primary astrocytes. In conclusion, our results provide evidence for the first time showing that sEH negatively regulates astrocytic immune responses and GFAP expression, while the underlying mechanism is at least partly involved in the down-regulation of STAT3 phosphorylation. The discovery of the novel function of sEH in the negative control of STAT3-mediated astrocyte activation confers further insights into the regulatory machinery of astrocyte activation in the diseased brain.

Title: Soluble TREM2 (sTREM2) inhibits cellular apoptosis and induces pro-inflammatory response in microglia

Authors: ***X. CHEN**, L. ZHONG, T. WANG, Z. WANG, G. BU;
Inst. of Neuroscience, Med. College, Xiamen, Fujian, China

Abstract: Triggering receptor expressed on myeloid cells 2 (TREM2) is an innate immune receptor expressed on the surface of myeloid cells including microglia. Loss-of-function mutations of TREM2 are associated with increased risk for a spectrum of neurodegenerative disorders including Alzheimer’s disease (AD). A soluble form of TREM2 (sTREM2) derived

from proteolytic cleavage of the cell surface receptor is abundantly detected in the cerebrospinal fluid (CSF) and plasma. The CSF sTREM2 levels are elevated in AD and associated with the onset of cognitive decline. Moreover, sTREM2 levels are correlated with those of total and phosphorylated tau in the CSF. However, the physiological and pathological functions of sTREM2 remain unknown. To dissect the roles of sTREM2 in microglia, we investigated the functions of purified sTREM2 protein in primary microglial cultures from wild-type (WT) and Trem2-knockout (KO) mice. We found that sTREM2 triggers robust pro-inflammatory cytokine expression but inhibits apoptosis induced by GM-CSF withdrawal in both WT and Trem2-KO microglia. The presence of NF-κB inhibitor, Bay 11-7082, completely abrogated the pro-inflammatory response induced by sTREM2. Importantly, sTREM2 exposure led to the activation of Akt/GSK3β/β-catenin signaling pathway. Interestingly, sTREM2 that carried AD-associated mutations (R47H and R62H) partially lost their ability in suppressing apoptosis and triggering pro-inflammatory response. Taken together, the presence of sTREM2 but not the AD-associated mutants triggers pro-inflammatory responses in microglia via the NF-κB signaling pathway, yet prevents microglial apoptosis by modulating the activity of Akt/GSK3β/β-catenin signaling pathway. Thus, sTREM2 exhibits opposing effects on microglia-mediated neuro-inflammation and their survival.

Title: Soluble TREM2 levels in neurodegenerative disorders.

Authors: ***L. BEKRIS**[1], M. KHRESTIAN[2], Y. SHAO[2], J. LEVERENZ[2];
[1]Cleveland Clin. Genomic Med. Inst., Cleveland, OH; [2]Cleveland Clin., Cleveland, OH

Abstract: Alzheimer’s disease (AD) has been both genetically and pathologically associated with neuroinflammation. Genetic variants of triggering receptor expressed on myeloid cells 2 (*TREM2*) have been linked to late-onset AD and other neurodegenerative diseases including Parkinson’s disease (PD). *TREM2* rare coding variants are associated with increased late-onset AD risk, while loss of function mutations in the gene lead to Nasu-Hakola disease an autosomal

recessive early-onset degenerative disorder. Genome-wide association study (GWAS) analyses have found associations between a genetic variants at the *TREM2* locus and sTREM2 levels in biofluids from neurodegenerative disease patients and with C-reactive protein (CRP) levels in healthy African American and Hispanic American women. TREM2 is a microglial receptor involved in innate immunity. Soluble TREM2 (sTREM2) is a cleavage product of TREM2 present in cerebrospinal fluid (CSF) and plasma. CSF levels of sTREM2 have been reported as changed during the clinical course of AD. In addition, CSF sTREM2 levels have been described as higher in mild cognitive impairment due to AD compared to AD and cognitively normal controls. Furthermore, increased CSF sTREM2 levels have been associated with higher CSF total tau and phosphorylated-tau, which are markers of neuronal degeneration and tau pathology. These reports suggest that a change in this inflammatory marker may occur in response to neuronal degeneration, or perhaps participates in driving neurodegeneration. Therefore, the hypothesis of this investigation is that not only are markers of neuronal degeneration associated with sTREM2 in neurodegenerative disorders, but also markers of inflammation are associated with sTREM2 in neurodegenerative disorders. The aim was to demonstrate a correlation between sTREM2 and CRP as well as other inflammation markers in multiple neurodegenerative disorders. We found that inflammation markers are indeed associated with sTREM2 levels in certain neurodegenerative disease disorders, but not others. These results suggest that TREM2 is linked to the inflammatory processes related to neurodegeneration. Furthermore, CSF sTREM2 may be an important biomarker for inflammatory activity in neurodegenerative disease.

Title: Determine the mechanism of lysophosphatidic acid (LPA)-induced apoptosis

Authors: Y. DONG[1], Y. WU[2], H. CHEN[3], M.-Z. CUI[4], *X. XU[4];
[1]Harvard Children's Hosp. Boston, Boston, MD; [2]Univ. of California, Riverside, Riverside, CA; [3]Oklahoma Med. Res. Fndn., Oklahoma, OK; [4]Pathobiology, Univ. of Tennessee, Knoxville, TN

Abstract: Oxidative stress is now at the forefront of Alzheimer's disease (AD) research. Evidence suggests that oxidized lipids in the central nervous system (CNS) function as risk factors in AD. The human brain is composed of approximately 60-70% lipids by dry weight. Most of the lipids are actively synthesized in the CNS itself. In addition, lipids are taken up by brain cells throughout life. These various forms of brain lipids serve not only as structural components but also as essential signaling molecules. Among them, lysophosphatidic acid (LPA) is the most potent bioactive lipid species that can be produced within brain tissues under pathological conditions such as oxidation of low-density lipoprotein (LDL). LPA is involved in many cellular processes, including cell survival and apoptosis. LPA has been shown to induce apoptosis in different cell types including neuronal, vascular, and cancer cells. Thus, LPA, at pathophysiological levels, can induce neuronal apoptosis and thereby participate in neurodegenerative disorders, such as AD. However, the molecular mechanism by which LPA induces apoptotic cell death remain unknown. In this study, we investigated this issue using cultured cell model. Our data showed that treatment of cells with LPA induced apoptosis and a dramatic increase in the level of death receptor 6 (DR6). More interestingly, our data also revealed that knockdown of DR6 blocked LPA-induced apoptosis. Thus, our results strongly suggest LPA-induced apoptosis is mediated by upregulation of DR6 expression. In this study, we have also determined the intracellular signaling cascades that are involved in LPA-induced DR6 expression.

Title: ^{3}H-PK11195 binding reflects astrogliosis and reduces pathological neuroinflammation in TgAPP Alzheimer's disease mice

Authors: *S. SEDDIGHI[1], B. BRERA[2], M. L. DE CEBALLOS[2];
[1]Col. Scholars, Univ. of Tennessee, Knoxville, Knoxville, TN; [2]Dept. of Cellular, Mol. & Developmental Neurobio., Cajal Inst., Madrid, Spain

Abstract: Glial cell activation is an invariant feature of Alzheimer's disease (AD) neuropathology and is largely responsible for the ongoing, deleterious inflammation in patients suffering from this condition. A large body of literature suggests that increased binding of ^{3}H-PK11195, a translocator protein (TSPO 18kD) receptor ligand, reflects microglial activation. However, astrocytes may also be involved. The objectives of this project were first, to investigate whether ^{3}H-PK11195 binding is coupled to astrogliosis and second, to assess the impact of long-term treatment with PK11195 on AD-like neuroinflammatory responses. For the first experiment, rats received either a single or 7 daily intracerebroventricular injections of β-Amyloid (Aβ, 20 μg/day/rat, ICV). Control rats received a peptide with identical amino acids in a scrambled sequence. Animals were sacrificed at 3 weeks after initiation of treatment, and ^{3}H-PK11195 binding was assessed via a membrane filtration assay. Results indicated a 3-fold increase in ^{3}H-PK11195 binding in the hippocampus of rats receiving the 7-day treatment with Aβ. A significant increase in binding of ^{3}H-PK11195 was also observed in cultured astrocytes treated with Aβ (1μM) for 24 or 48 h. Finally, prolonged oral treatment with PK11195 (1mg/kg/day, 5 months, administered in drinking water) diminished the increased astrocyte hippocampal density (GFAP immunostaining) in TgAPP 2576 AD mice, while microglial cell counts (Iba1 immunostaining) were unaltered. Taken together, these results suggest that astrogliosis contributes to enhanced ^{3}H-PK11195 binding, as observed in PET studies of AD patients, and that astrocytes are a target for the anti-inflammatory effects of this TSPO ligand. Our studies thereby reveal a potential dual-role nature of this synthetic ligand in both the diagnosis and treatment of Alzheimer's disease neuropathology.

Title: Effects of IL-34 on macrophage immunological profile in response to Alzheimer's-related amyloid-beta$_{42}$ assemblies

Authors: *N. J. HART[1], L. R. ZUROFF[1], T. TORBATI[1,3], D.-T. FUCHS[1], J. SHEYN[1], A. RENTSENDORJ[1], Y. KORONYO[1], E. Y. HAYDEN[3], D. B. TEPLOW[3], K. L. BLACK[1], M. KORONYO-HAMAOUI[1,2];
[1]Neurosurg., [2]Dept. of Biomed. Sciences, Applied Cell Biol. & Physiol., Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]Dept. of Neurology, David Geffen Sch. of Med., UCLA, Los Angeles, CA

Abstract: Background. Interleukin-34 (IL-34) is a newly-discovered cytokine that acts as a second ligand of the colony stimulating factor 1 (CSF1; also called macrophage colony-stimulating factor) receptor. Similar to CSF1, but with lower binding affinity, IL-34 stimulates viability of bone marrow (BM)-derived monocytes (Mo) and formation of macrophage (MΦ) progenitors. The expression of IL-34 in the brain shows a pattern distinct from that of CSF1, particularly in the hippocampus and cerebral cortex. Increasing evidence indicates a key role for peripheral Mo/MΦ in the physiological clearance of cerebral amyloid-β protein (Aβ), especially neurotoxic Aβ_{42} which is tightly associated with Alzheimer's disease (AD). As a second ligand of the CSF1 receptor, IL-34 may be relevant to the innate immune responses in AD.
Methods. To investigate how IL-34 affects macrophage phenotype in response to structurally-defined and stabilized Aβ_{42} oligomers and preformed fibrils, we characterized murine BM-derived Mo/MΦ (BMM) primary cultures supplemented with media containing CSF1, IL-34, or a regimen involving both cytokines.
Results. Immunological profile and activation phenotype of IL-34-stimulated BMM were altered in comparison to those of cells cultured with CSF1 alone. Surface expression of type B scavenger receptor CD36, known to facilitate Aβ recognition and uptake, was modified following treatment with IL-34. Uptake of fibrillar or oligomeric Aβ_{42} differed between groups stimulated by IL-34 versus CSF1. Intracellular compartmentalization of Aβ visualized by staining of early endosome antigen 1 (EEA1) was also distinct in IL-34-treated BMM. Expression of triggering receptor expressed on myeloid cells 2 (TREM2), which is implicated in Aβ uptake and clearance, as well as matrix metallopeptidase 9 (MMP-9), an Aβ-degrading enzyme, decreased dramatically in IL-34 groups when compared with CSF1 controls. Elongated cell morphology associated with a pro-healing MΦ phenotype was also quantified, yielding an elongation factor (EF). The BMM group initially stimulated with CSF1 and then with IL-34 showed a significant increase in EF compared to BMM treated with CSF1 alone. Further, monocytes treated with IL-34 alone yielded fewer mature MΦ in comparison to CSF1 controls. This reduction was attenuated in BMM treated with a combination of CSF1 and IL-34.
Conclusion. Our data may indicate that IL-34 affects monocyte differentiation into MΦ and their ability to resist pathological forms of Aβ. Future experimentation should investigate how IL-34 may differentially stimulate Mo/MΦ and brain-resident microglia, which may in turn contribute to neuronal protection in AD.

Title: Class a scavenger receptor deficiency impairs immune response of microglia and astrocytes in app/ps1 transgenic mice

Authors: ***F. A. CORNEJO**, M. VRUWINK, P. MUÑOZ, M. ANDRES, R. VON BERNHARDI;
Pontificia Univ. Católica De Chile, Santiago, Chile

Abstract: Neuroinflammation has become an attractive mechanism for understanding progression of Alzheimer's disease (AD), because of the increasing evidence showing a central role for glial cells in AD development. We have focused on alterations of glial cell activation that could participate in AD pathophysiology. Class A Scavenger Receptor (SR-A) has emerged as a key modulator of microglia and astrocytes inflammatory response. Scavenger receptors appear to be crucial for microglia Aβ uptake. However, little is known about how SR-A regulates glial activation in response to Aβ. Here, we used a triple congenic mice strain developed in our laboratory, which accumulates Aβ and is knockout for SR-A (APP/PS1/SR-A$^{-/-}$) to address the inflammatory role of SR-A in an AD animal model. Our results show that glial cells from triple transgenic mice had an impaired oxidative response and nitric oxide induction, produce up to 7-fold more pro-inflammatory cytokines with a 12-fold reduction in anti-inflammatory cytokines basal release. Moreover, we observed significant impairments in the glial inflammatory response after LPS stimulation, and a reduced phagocytic activity in microglia isolated from young and adult mice, both *in vitro* and *ex vivo*. Our *in vivo* results show that lifespan was greatly reduced in triple transgenic mice, accompanied by a 3-fold increase in plasmatic pro-inflammatory cytokines levels, with increased IL-1β and reduced TGF-β levels in the hippocampus as mice ages. We conclude that dysfunction of glial inflammatory response induced by impaired SR-A

contributes to AD progression. Key words: scavenger receptor, APP/PS1, microglia, astrocytes, neuroinflammation.

Abstract: Despite substantial clinical and epidemiological evidence supporting an intriguing connection between Alzheimer's disease (AD) and depression, the molecular and cellular mechanisms underlying this association are still largely unknown. We recently found that soluble amyloid-β oligomers (AβOs), toxins that accumulate in AD brain and are thought to be responsible for synapse failure and memory loss,induce depressive-like behavior in mice, a process associated with gliosis. Here, we report that AβOs directly activate microglia, leading to increased production and secretion of TNF-α. Intracerebroventricular (i.c.v.) injection of AβOs causedsignificant increases in brain levels of TNF-α mice. Consistent with a role of microglia in brain inflammation and mood alterations, pharmacological inactivation or ablation of microglia blocked the elevation in brain TNF-α and depressive-like behavior in AβO-injected mice. These findings establish that aberrant activation of microglia by AβOs may be a key trigger of mood alterations in AD.

Title: Examining the role of adaptive immunity and peripheral immune cell infiltration in Alzheimer's disease pathogenesis

Authors: ***S. E. MARSH**[1], E. M. ABUD[1], L. L. MCINTYRE[2], A. KARIMZADEH[2], A. LAKATOS[3], S. T. YEUNG[3], L. LAU[3], M. A. INLAY[2], C. M. WALSH[2], W. W. POON[3], M. BLURTON-JONES[1];

Abstract: Alzheimer's disease is complex neurodegenerative disorder characterized pathologically by amyloid and tau accumulation, synaptic and neuronal loss, and widespread inflammation. Research over the last few decades has enumerated many of the complexities of the inflammatory state in the AD brain. However, almost all of these studies have focused on the role of the innate immune system in disease pathogenesis. However, the adaptive immune system often interacts closely with the innate immune system to modulate the peripheral immune response to bacteria and other pathogens, but the impact of the adaptive immune system has largely been ignored in AD and other neurodegenerative disorders.
To examine the role of adaptive immunity in AD pathogenesis, we generated an immune-deficient AD mouse model by backcrossing the 5xfAD mouse onto a Rag2-/- il2rg-/- immune-deficient background, that lacks T-, B-, and NK-cells. Investigation of the resulting 'Rag-5xfAD'

mice revealed significantly accelerated disease pathogenesis, including a more than 2-fold elevation in Aβ. Significant changes were also observed in Rag-5xfAD neuroinflammation indicated by shifts in microglial gene expression, morphology, and phagocytosis. Interestingly, we find non-amyloid reactive IgG associated with microglia in the brains of immune-intact 5xfAD mice and demonstrate that the addition of preimmune IgG to Rag-5xfAD mice can reduce pathology.
Furthermore, analysis of GFP-bone marrow chimeras established without radiation or chemotherapeutic myeloablation, has revealed significant peripheral infiltration into the brain parenchyma of 6-month-old Rag-5xfAD mice. Additional analyses of these infiltrating cells including their phenotype and association with disease pathology will yield valuable data not only on the mechanisms of infiltration but also the interactions between these peripheral immune cells, resident CNS microglia, and AD-associated pathology.

Title: Inflammasome activation in the pre clinical and clinical stages of alzheimers disease pathology in down syndrome

Authors: *L. FLORES AGUILAR[1], M. IULITA[2], T. WISNIEWSKI[3], J. BUSCIGLIO[4], A. CUELLO[1];
[1]McGill Univ., Montreal, QC, Canada; [2]Dept. of Neurosci., Univ. de Montreal, Montreal, QC, Canada; [3]New York Univ. Sch. of Med., New York, NY; [4]Univ. of California, Irvine, CA

Abstract: Before clinical presentation, Alzheimer’s disease (AD) develops silently for decades. The identification of this AD silent stage is an unmet need. We have reported the occurrence of an early disease-aggravating pro-inflammatory process in transgenic rat and mouse models of AD-like amyloid pathology (1-3). While the neuroinflammation in AD has been well-characterized at late stages of the pathology, little is known about the CNS inflammatory process at the silent stages of AD.Given the triplication of the amyloid precursor protein, Down

Syndrome (DS) individuals show a gradual intraneuronal amyloid beta (AB) accumulation before the development of a full-blown AD pathology and dementia (4). In order to study the AD pre-clinical stage, we are studying the early AB-driven inflammatory process occurring at the silent stages of AD in DS. We hypothesize that the early intraneuronal accumulation of AB, unleashes a toxic pro-inflammatory process which differs from the late, and well-established amyloid-plaque-associated overt inflammatory reaction. We are interested in defining the characteristics of this pro-inflammatory process at early stages of AD pathology in DS. We are currently investigating the possible activation of the inflammasome, a molecular complex that contributes to the onset of the inflammatory response and, whenever possible, correlating it to the ongoing, silent, AD pathology in post-mortem brain samples of individuals with DS. Towards the above objective, we have analyzed the expression of several pro-inflammatory and inflammasome-related genes via qPCR and a qPCR array (Qiagen, CA) in postmortem frozen frontal cortex tissue of DS infants (3 weeks-13 months old) and DS adults with AD (44-66 years old) from the UCI and NYU brain banks. Gene expression analysis in DS infants revealed an upregulation of several classical pro-inflammatory mediators such as IL-1B, IL-6, IL-12b, and the monocyte recruitment-chemokines MCP-1 and RANTES. Furthermore, inflammasome receptors (NLRP3, NLRP4, and NLRP6) and pro-inflammatory caspases (1 and 5) were found upregulated. While DS adults with AD also show an inflammatory profile, it is more attenuated when compared to the DS infants. Thus, preliminary results would indicate a differential expression in silent and preclinical AD stages in DS. We propose that the early AD inflammatory process is linked to the abnormal intraneuronal accumulation of AB (1). References: (1) C. E. Hanzel et al. *Neurobiology of aging,* 2014; (2) M. T. Title: Synaptic effect of glatiramer acetate immunomodulation in a mouse AD model

Authors: ***S. LI**[1,2], Y. KORONYO[2], D.-T. FUCHS[2], D. DALEY[2], J. SHEYN[2], T. TORBATI[2], A. RENTSENDORJ[2], E. HAYDEN[3], K. BLACK[2], D. TEPLOW[3], M. KORONYO[2];
[1]The Inst. of Life Sci., Wenzhou Uinversity, Zhejiang Province, China; [2]Cedars-Sinai Med. Ctr., Los Angeles, CA; [3]UCLA, Los Angeles, CA

Abstract: Synaptic changes in multiple brain regions play a crucial role in Alzheimer's disease (AD). The loss of synapses may contribute directly to the profound cognitive impairment in this disease. Our previous studies showed that glatiramer acetate (GA) immunomodulation improved the cognitive function of AD mice. We now further investigated the synaptic protection by GA immunotherapy using a mouse AD model. The brain tissues were stained with the presynaptic marker (anti-VGluT1) and postsynaptic marker (anti-PSD95). Synaptic puncta areas were precisely quantified with Puncta Analyzer. Our comprehensive analysis of entorhinal cortex (ENT) and hippocampal substructures in symptomatic $APP_{SWE}/PS1_{\Delta E9}$ transgenic mice indicated significant 50-68% pre- and 38-51% post-synaptic loss ($P < 0.001$-0.05) as compared to non-transgenic littermate onces (6 mice/group). This loss of synapses was strikingly preserved by immunomodulation with GA ($P < 0.001$-0.05; 6 mice/group). Specifically, following GA immunization of ADtg mice a remarkable synaptic preservation was found in the ENT, molecular layer (ML) of dentate gyrus, stratum lacunosum-moleculare (SLM), stratum oriens (SO), and stratum radium (SR) of the CA1 region. Also, peripheral blood enrichment with $CD115^{+}$-monocytes in ADtg mice produced a significant increase of synapses in ENT, ML and SLM. In addition, increased synapses following GA treatment was noted to correlate positively with reduced neuropathology and retained cognition ($P < 0.01$-0.05). Our data suggest that GA immunization protects specific brain areas from synaptic loss and holds great promise for AD therapy, the mechanism by which is currently being studied.

Abstract: Tenascin-C (TN-C) is an extracellular matrix glycoprotein implicated in inflammatory reactions in the CNS and in peripheral organs, and may play a role in the pathogenesis of Alzheimer's disease (AD). This study examined the localization and distribution of TN-C immunoreactivity in autopsy brains from Rush Religious Order study subjects with clinically and neuropathologically diagnosed AD compared to aged-matched non-demented controls with amyloid-β (Aβ) pathology (NC+Aβ) or free of pathology (NC-Aβ). In all cases TN-C immunoreactivity was detected in the white matter and in the pia/cortical layer 1, and occasionally in blood vessels. In NCI+Aβ controls and AD cases, but not in NC-Aβ cases, TN-C immunoreaction was also prominent in large (~100 microns) extracellular deposits which co-localized with and completely surrounded classic cored Aβ-immunoreactive (-ir) plaques in the cortex and hippocampus. TN-C deposits also encapsulated GFAP-ir astrocytes and processes, Iba-1-ir microglia, phosphorylated tau-ir neurites, and amyloid cores which were prominently fluorescent for 6-CN-PiB, a highly fluorescent derivative of the amyloid PET ligand Pittsburgh Compound-B (PiB). TN-C deposits were absent from diffuse Aβ plaques in the cortex, caudate nucleus and cerebellum, and Aβ-ir blood vessels were only weakly TN-C-ir. These results demonstrate that extracellular deposits of TN-C are associated primarily with classic Aβ plaques characterized by fibrillar cores of amyloid and presence of inflammatory and tau phosphorylation markers. TN-C may play a role in the formation or removal of amyloid plaques, and has potential value as a target for therapy in AD.

Title: Lipopolysaccharide (LPS) associates with amyloid in Alzheimer's brain

Authors: X. ZHAN[1], B. STAMOVA[1], L.-W. JIN[2], C. DECARLI[1], B. PHINNEY[3], *F. R. SHARP[1];
[1]Neurol., Univ. of California At Davis, Sacramento, CA; [2]Univ. of California at Davis, Sacramento, CA; [3]Univ. of California at Davis, Davis, CA

Abstract: We have demonstrated that administration of gram negative bacteria (*E. coli)* derived LPS followed by ischemia/hypoxia (IS-H) produces amyloid β (Aβ) aggregates in rat brain. This LPS-IS-H model produces foci of damaged axons and myelin in cortex and hippocampus over several weeks. By 3 months aggregates of myelin basic protein and other myelin proteins occur in the deep layers of ischemic cortex which are associated with deposition of Aβ and APP. By 5 to 7 months Aβ decreased in the deep cortical layers and appeared in the superficial cortical layers and in periventricular ependymal cells. The appearance and distribution of these myelin aggregates that associate with Aβ and APP at 3 months is similar to that seen in mouse genetic AD models. In addition to this neuropathology following the LPS-IS-H, there was a progressive increase of IL1β, Granzyme B and LPS in cortex that occurred over a period of 3 months (Zhan et al., JAD, 2015; 46(2): 507-523).
These results in the rat led us to ask whether LPS and other molecules from *E. coli* bacteria are detectable in sporadic late onset Alzheimer's disease (LOAD) human brain. Western blots for LPS showed much more LPS in cortex of LOAD (n=3) compared to control brains (n=3). Immunocytochemistry for LPS showed that LPS co-localized with $A\beta_{1\text{-}40/42}$ in amyloid plaques and with $A\beta_{1\text{-}40/42}$ around vessels in AD brains. Assessment of *E coli* K99 pili protein levels by Western blots were greater in AD compared to control brains ($p < 0.01$) and K99 was localized to neurons in AD but not control brains. *E. coli* DNA or the E. coli K99 pili protein were detected in 9/10 control and 13/13 AD brains.
These results suggest that LPS associates with AD pathology in human brain. The rat LPS-IS-H model and human AD brain data support the hypothesis that LPS could be involved in the formation of amyloid plaques in human AD brain.

Title: CCL4 and CXCL10, two chemokines in neurovascular unit controlled by blood mononuclear cells from patients with Alzheimer's disease.

Authors: ***J. VERITE**[1], G. PAGE[1], A. JULIAN[1], D. CHASSAING[1], P.-O. COURAUD[2], M. PACCALIN[1], T. JANET[1];

Abstract: Alzheimer's disease (AD) is the most common cause of dementia worldwide. Senile plaques, neurofibrillary tangles and neuron loss are the classical neuropathological hallmarks of AD. For the past three decades, it has been demonstrated that AD is accompanied by a neuroinflammation. Even if its beneficial or deleterious role is still a matter of debate in the scientific community, we cannot exclude its involvement in the progression of the disease. To go further, this situation of central nervous system distress could be helped by peripheral blood mononuclear cells (PBMCs), which after transmigration through the Blood Brain Barrier (BBB) could reduce amyloid plaques in the brain of patients with AD. To this purpose, we tested production and release of five chemokines (CCL2, CCL4, CCL5, CXCL10 and CX3CL1), already known to be implicated in the progression of AD, in three experimental conditions: in isolated cells constituting the BBB model, in a free PBMCs BBB model (H4 and hCMEC/D3 cells), and in a complete BBB model with PBMCs from AD patients (n=14 at a moderate state), hCMEC/D3 and H4 cells treated or not with 20μM Aβ42 for 48 hours. Results showed that CCL2 production was significantly increased in hCMEC/D3 cells in complete BBB model, compared to the other two conditions. CCL5 and CXCL10 had the same pattern of expression, with a reduced level in PBMCs in the complete BBB model, and an increase in hCMEC/D3, compared to isolated cells. For CCL4, the presence of PBMCs induced a robust and significant increase in H4 and hCMEC/D3. Furthermore, PBMCs triggered a significant increase of CX3CL1 in hCMEC/D3. No significant effect of Aβ42 treatment has been shown in the

complete BBB model in all cases. These findings also showed the interest of having the most accurate BBB model in order to explore chemokine production; each cellular actor forming the neurovascular unit and PBMCs from patients with AD influenced each other in a bi-directional manner. Here, PBMCs from patients with AD controlled production of CCL4 and CXCL10 in healthy BBB model. Further investigations will be needed to assess the role of PBMCs of patients with AD in the chemotactic environment and the functionality of BBB.

Title: Antibiotic-induced perturbations in gut microbial diversity influences neuro-inflammation and amyloidosis in a murine model of Alzheimer's disease.

Authors: *M. R. MINTER[1], C. ZHANG[3], V. LEONE[2], D. L. RINGUS[2], X. ZHANG[1], P. OYLER-CASTRILLO[1], M. W. MUSCH[2], R. E. TANZI[3], E. B. CHANG[2], S. S. SISODIA[1]; [1]Neurobio., [2]Med., The Univ. of Chicago, Chicago, IL; [3]Neurol., Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Background: Severe amyloidosis and plaque-localized neuro-inflammation are key pathological features of Alzheimer's disease (AD). In addition to astrocyte and microglial reactivity, emerging evidence suggests a role of gut microbiota in regulating innate immunity that in turn leads to CNS dysfunction. Considering neuro-inflammation, proposed to be regulated in part by the host microbiome, is closely linked to amyloid pathology and cognitive decline in AD, we hypothesize that composition of the intestinal microbiome plays a key role in modulating neuro-inflammation and influences Aβ deposition.
Materials and Methods: 2 week old male $APP_{swe}/PS1_{\Delta E9}$ mice were gavaged daily with combinatorial antibiotics (ABX; gentamicin (1mg/ml), vancomycin (0.5mg/ml), metronidazole (2mg/ml), neomycin (0.5mg/ml), ampicillin (1mg/ml), kanamycin (3mg/ml), colistin (6000U/ml) and cefaperazone (1mg/ml)) for 1 week and then supplemented with ABX (1/50 concentration)

in drinking water until cull at 6 months of age and subsequent tissue harvesting.
Results: Illumina® Miseq amplicon sequencing, terminal restriction fragment length polymorphism analysis and Q-PCR of the bacterial 16s rRNA gene from fecal and cecal contents of ABX and vehicle control $APP_{swe}/PS1_{\Delta E9}$ mice revealed distinct changes in microbial community diversity, but not total abundance, at the time of cull (n=10, $p<0.001$). Elevated circulating levels of CCL11, CXCL16, TIMP1 and sTNFαR1 were confirmed by cytokine array in the sera of ABX-treated $APP_{swe}/PS1_{\Delta E9}$ mice (n=10, pooled sera). Significantly, serial sectioning and subsequent immunohistochemistry (using α-Aβ mAb 3D6) revealed decreased Aβ plaque size and total burden in brains of ABX-treated $APP_{swe}/PS1_{\Delta E9}$ mice (n=9, $p=0.0175$). These results were confirmed by MSD bioassay of TBS-insoluble Aβ1:40 and Aβ1:42 levels in these same mice. Intriguingly, this ELISA-based assay identified significant elevations in TBS-soluble Aβ1:40 and Aβ1:42 levels in ABX-treated $APP_{swe}/PS1_{\Delta E9}$ mice (n=9, $p<0.05$). IBA-1 and GFAP immunohistochemistry revealed significant decreases in the number of plaque-localized microglia and astrocytes in ABX-treated $APP_{swe}/PS1_{\Delta E9}$ mice (n=8, $0.001<p<0.01$) and 3D-IMARIS-based reconstruction of these cells confirmed altered branching morphology (n=4, $0.001<p<0.01$). Immunohistochemistry of plaque-localized microglia in ABX-treated $APP_{swe}/PS1_{\Delta E9}$ mice identified altered CD14, CD206 and CD86 cell surface expression indicative of a mixed M1/M2 inflammatory phenotype.
Conclusions: Our findings suggest gut microbiome composition regulates host innate immunity mechanisms that impact Aβ amyloidosis.

Title: Cerebrospinal fluid soluble triggering receptor expressed on myeloid cells 2 (TREM2) in aging and Alzheimer's disease

Authors: K. HENJUM[1], I. S. ALMDAHL[2], V. ÅRSKOG[1], L. MINTHON[3], O. HANSSON[3], T. FLADBY[2], *L. N. NILSSON[1];
[1]Univ. of Oslo and Oslo Univ. Hosp., Oslo, Norway; [2]Dept. of Neurology, Fac. Division, Akershus Univ. Hospital, Univ. of Oslo, Lørenskog, Norway; [3]Dept. of Clin. Sci. Malmö, Memory Clinic, Clin. Memory Res. Unit, Lund, Malmõ, Sweden

Abstract: Alzheimer's disease (AD) neuropathology is associated with neuroinflammation, but there are few useful biomarkers. Such markers may complement the existing biomarkers and may also be used for monitoring the effect of future therapies. Variants of triggering receptor expressed on myeloid cells 2 *(TREM2)* have been linked to late-onset AD and other neurodegenerative disorders. TREM2 is a microglial receptor involved in innate immunity. It is known to mediate phagocytosis and anti-inflammatory reactions, but there is limited data of its function in brain health. A cleaved fragment of the TREM2 receptor, soluble TREM2 (sTREM2), is present in the cerebrospinal fluid (CSF). We therefore investigated the potential of sTREM2 as an AD biomarker, how it relates to the established AD core markers and to aging, the main risk factor of AD. To determine sTREM2 levels in CSF we developed a novel TREM2 ELISA with high sensitivity and low variability. We then assayed the level of sTREM2 in CSF in two independent patient/control cohorts. CSF sTREM2 did not discriminate between controls and patients with AD or mild cognitive impairment. However among cognitively healthy control subjects CSF sTREM2 correlated positively with T-tau (Spearman Rho 0.57; $p<0.001$; n=50), P-tau (Spearman Rho 0.63; $p<0.001$; n=50) and amyloid-β1-42 (Aβ42) (Spearman Rho 0.35; p=0.01; n=50). When applying a higher CSF Aβ42 cut-off (700pg/ml) in this cohort to ensure absence of amyloid deposits the positive correlation between sTREM2 and Aβ42 was stronger (Spearman Rho=0.44; p=0.002; n=46). We also found a positive correlation between sTREM2 and age, the main AD risk factor (Spearman Rho=0.50; $p<0.001$; n=75) among all controls. Our findings indicate that sTREM2 in CSF is a marker of preclinical AD as it in healthy controls correlates with aging, and with the neurodegenerative markers CSF-T-tau/P-tau and the amyloid biomarker Aβ42 among controls who are negative for the AD CSF core biomarkers Aβ42, T-tau or P-tau. We are currently exploring sTREM2 in cohorts with other clinical measures and also the basic TREM2-biology in slice models.

Title: Fine motor control impairment in chronic HIV is similar to and less severe to that seen in Parkinson's disease

Authors: *T. MARTIN[1], M. TRAGER[1], A. VELISAR[1], M. MILLER KOOP[1], E. MÜLLER-OEHRING[3,2], K. POSTON[1], T. SCHULTE[3,4], H. BRONTE- STEWART[1];
[1]Neurol. and Neurolog. Sci., [2]Psychiatry and Behavioral Sci., Stanford Univ., Stanford, CA; [3]Neurosci. Program, SRI international, Menlo Park, CA; [4]Pacific Grad. Sch. of Clin. Psychology, Palo Alto Univ., Palo, CA

Abstract: Objective: People with human immunodeficiency virus (HIV) infection now live longer due to antiretroviral therapy and may show age- or disease-related Parkinsonian motor deficits and neurodegenerative changes in the basal ganglia. We hypothesized that subjects who have aged with HIV infection will exhibit deficits in fine motor control similar to mild/moderate Parkinson's disease (PD). We have shown that the rhythmicity of repetitive alternating finger tapping on a keyboard (Quantitative DigitoGraphy (QDG)) was the most highly correlated with bradykinesia and of total motor disability in PD (Bronte-Stewart 2000, Taylor-Tavares 2005, Trager 2015).
Methods: Twenty-four healthy controls (age 56.6 +/- 8.0), ten HIV subjects (age 58.8 +/- 7.5), and thirteen moderate stage PD subjects (67.3 +/- 9.3) performed rapid alternating finger tapping (RAFT) on an engineered keyboard and the Unified Parkinson's Disease Rating Scale (motor, UPDRS III). HIV and controls were of similar age but the PD group was older than both other groups($P<0.05$). The PD subjects were tested in the off therapy state. Analysis was performed in MATLAB (The MathWorks, Inc.) to determine inter-strike interval (ISI) and amplitude (AMP) of key presses and their variability using the coefficient of variation (CV_{ISI}, CV_{AMP}). A two-way ANOVA was performed for each parameter in SigmaPlot (Systat Software).
Results: HIV subjects were significantly less rhythmic/regular than controls in RAFT in both the frequency and amplitude of tapping (CV_{ISI} : $P=0.006$, CV_{AMP} : $P=0.001$), yet significantly more rhythmic/regular than the PD group ($P=0.001$ for both). HIV subjects did not differ from controls in the overall mean frequency or amplitude of RAFT, however there was a wide variation in performance among HIV subjects. Both HIV subjects and controls tapped with greater mean amplitude than the PD group but only the control group tapped with a greater frequency than the PD group. PD group's off therapy UPDRS III score ± SD was 34.5 ± 9.9. The HIV group's

UPDRS III score ± SD was significantly lower at 3.6 ± 3.8 (P<0.001).
Conclusions: These preliminary results demonstrate impairment in fine motor control in a small cohort of people with chronic treated HIV infection compared to normal controls. Their deficits were similar to those seen in Parkinson's disease but of less severity than a group of PD subjects with moderate stage disease. There was a wide variation among HIV subjects and correlations with age, disease duration, and other HIV markers may be possible as the cohort expands.

Abstract: Leprosy is a chronic infectious disorder of the peripheral nerves and skin macrophages caused by the intracellular pathogen *Mycobacyerium leprae* (*M. leprae*). There are growing evidences suggesting that leprosy neuropathy is due to Schwann cell dedifferentiation. Of importance, our group demonstrated that *M. leprae* is also able to modulate Schwann cells energy metabolism for its own benefit. Our results clearly show that infected Schwann cells increase glucose uptake with a concomitant upregulation in glucose-6-phosphate dehydrogenase

(G6PDH) activity, the key enzyme of the oxidative pentose pathway. We also found a two-fold reduction in lactate release from infected cells when compared to control ones. In addition, we observed mitochondria shutdown in infected cells *in vitro* and mitochondrial swelling in histological analysis of nerve biopsies from patients diagnosed with pure neural leprosy. When we blocked the key enzyme of the oxidative phase of pentose phosphate pathway, the G6PD, we successfully recover the production of lactate by infected Schwann cells along with a drop in *M. leprae* viability. The pentose cycle is an important pathway that generates NADPH for reductive biosynthesis and glutathione regeneration. We observed that infected Schwann cells have increased G6PD activity and expression, being more resistant to oxidative stress than control non-infected cells. This oxidative stress protection was avoided when we applied 6-ANAM (a specific pentose cycle inhibitor) or by the glutathione synthesis inhibitor BSO, an inhibitor of gamma-glutamylcysteine synthetase. In short, our current data points to the notion that low levels of lactate produced by infected wrapping Schwann cells might induce energy deprivation to their counterparts axonal units, which are highly dependent of this fuel source. As conclusion, we identified the enzyme G6PD, as a new host-target to be explored in leprosy neuropathology treatment, since its inhibition restored lactate levels in infected Schwann cells and, more important, was able to kill the intracellular pathogen.

Title: Magnetoencephalography as a biomarker of HIV central nervous system impact among young adults with HIV: Preliminary findings

Authors: *S. L. NICHOLS[1], A. ROBB SWAN[2], A. ANGELES[2], C. FENNEMA-NOTESTINE[3], R. R. LEE[2], M.-X. HUANG[2];
[1]Dept. of Neurosciences, Univ. of California San Diego, La Jolla, CA; [2]Dept. of Radiology, [3]Departments of Psychiatry and Radiology, UCSD, La Jolla, CA

Abstract: Although central nervous system (CNS) effects of HIV infection have become more subtle in the era of antiretroviral treatment (ART), sensitive biomarkers are critical for monitoring continued impacts of chronic inflammation, ART, and immune activation. Magnetoencephalography (MEG) measures brain functional activation across frequency bands with fine-grained spatial and temporal resolution. This preliminary study compared brain activity of youth with HIV (YWH) and uninfected controls using MEG.
Methods: Twelve male youth age 18-24 with behaviorally acquired HIV (YWH) on ART and 13 age- and education-matched uninfected male controls completed tests of verbal learning and memory, processing speed, verbal fluency, and inhibition; a MEG working memory (N-back with 0, 1- and 2-back) task; and structural MRI. MEG data were processed using Fast-VESTAL source imaging program. Activation for control subjects was subtracted from that of YWH across frequency bands and cortical areas. Task performance and activation differences were compared using t-tests with $p < 0.01$ and an additional cluster analysis with size > 500 voxels. Nadir and current CD4 t-cell count and viral load were abstracted from clinical records for YWH.
Results: Mean current CD4 count for YWH was 494; 10 had undetectable current plasma viral load. HIV+ had significantly lower verbal learning and memory and marginally lower 0-back d' scores. Analysis of MEG during the N-back task showed numerous significant areas of hyper- and hypoactivation in YWH compared to controls. Bilateral hyperactivation across frequency bands and conditions included dlPFC, anterior cingulate/paracingulate gyrus, superior parietal lobe, fusiform and insular cortex; and supplementary motor area in beta and gamma frequencies. Areas of significant hypoactivation included bilateral frontal pole across frequency bands and conditions, and widespread superficial cortical gray areas in beta and gamma frequencies.
Conclusion: YWH show a distinct pattern of both hyper- and hypoactivation on MEG during performance of a working memory task relative to controls. In general, areas of hypoactivation were in more superficial areas in higher frequency bands, possibly reflecting decreased activity in inhibitory GABAergic interneurons. Hyperactivation, seen in deeper areas, may reflect increased excitatory response. The findings support further study of MEG as a sensitive marker of early CNS impact in relatively healthy individuals with HIV. Future research will explore the direct attribution of effects to HIV controlling for comorbid factors, along with correlations with task performance and impact of disease severity.

Title: MMP-9 facilitation of HIV neuropathogenesis

Authors: *R. B. MEEKER[1], Y. XIE[1], K. S. WILLIAMS[2];
[1]Neurol., Univ. of North Carolina at Chapel Hill Dept. of Neurol., Chapel Hill, NC; [2]Univ. of Pennsylvania, Philadelphia, PA

Abstract: Activation of macrophages and microglia in the central nervous system (CNS) by HIV plays a pivotal role in the progressive development of neural damage and cognitive deficits. No current treatments are available that effectively reduce the inflammatory response and neural damage. Although it is widely acknowledged that substances secreted from macrophages and microglia induce neuronal damage, the precise mechanisms of pathogenesis are not well understood. To identify potential neurotoxic factors secreted by macrophages we cultured human monocyte-derived macrophages, challenged them with inactive HIV virions, verified neurotoxic activity on primary neurons and then assessed the medium content on an antibody based array to screen for the presence of 507 proteins. The results revealed robust expression of matrix metalloprotease-9 (MMP-9) as well as a variety of other proteins involved in chemotaxis, angiogenesis and growth and differentiation. MMP-9 release was verified by zymography which revealed predominantly proMMP-9. Small amounts of MMP-3, which cleaves proMMP-9 to generate active MMP-9, were also present and correlated with the toxic activity of the medium. Activation by HIV was also associated with a shift in macrophage morphology toward expression of podosomes, adhesive structures associated with the release of MMPs. Based on these observations we evaluated the potential contribution of MMP-9 to neurotoxicity by adding 1-5 ng/ml activated MMP-9 to primary cultures of cortical/hippocampal neurons and assessing calcium and cytoskeletal dysregulation. A gradual rise in mean intracellular calcium was seen over 66 min in the absence of any acute effects of the MMP-9. Individual cells showed calcium spikes which increased in frequency with time and were prevented by co-incubation with the NMDA receptor antagonist AP5. Addition of MMP-9 inhibitors to conditioned medium from HIV treated macrophages strongly suppressed the ability to evoke calcium dysregulation and addition of a neutralizing antibody to tissue inhibitor of metalloprotease-1 (TIMP-1) increased

the toxic activity of the medium. Since MMP-9 is involved in the metabolism of neurotrophins we evaluated NGF content in culture mouse microglia activated with HIV virions. Endogenous NGF was significantly reduced by HIV. These results indicate the MMP-9 may cause neural dysfunction in response to inflammation by enhancing NMDA receptor activity while at the same time reducing neurotrophin support. Compounds that suppress the actions of MMP-9 are protective and have potential application for the prevention of HIV-associated neural damage.

Title: Matrix metalloproteinase-mediated mislocalization of aquaporin-4 and impaired metabolite clearance in HIV

Authors: *P. BOZZELLI, M. ALLEN, K. CONANT;
Neurosci., Georgetown Univ., Washington, DC

Abstract: Impaired metabolite waste clearance is implicated in HIV-associated neurocognitive deficits (HAND); however, mechanisms by which this occurs have not yet been explored. Aquaporin-4 (AQP4), the brain's primary water channel, is a major conduit through which waste is cleared from the brain. AQP4 requires polarized localization in perivascular endfeet in order to efficiently clear waste. Total levels of AQP4 are increased in the HIV brain however localization has yet to be examined in this context. AQP4 mislocalization occurs in normal aging and we hypothesize that HIV accelerates this process. Using a mouse model of HIV, this study is evaluating AQP4 localization as well as impaired waste clearance by using *in vivo* magnetic resonance spectroscopy (MRS). Furthermore, we hypothesize that the matrix metalloproteinase (MMP) class of enzymes, which are upregulated in HIV, promote mislocalization through proteolytic cleavage of AQP4-anchoring proteins. Preliminary data suggest that MMP-1 in particular promotes increased GFAP immunofluorescence while concomitantly reducing that of the AQP4-anchoring protein beta-dystroglycan. Additionally, *in vivo* MRS reveals that the hMMP-1 Tg mouse brain has significantly higher levels of the glial metabolite myo-inositol.

This increase in myo-inositol metabolite levels is consistent with enhanced glial production and/or impaired waste clearance. Thus, this study is examining the role of MMP-1 in disrupting AQP4 localization through the use of an *in vitro* model of the blood-brain barrier, whereby cultured astrocyte endfeet exhibiting polarized expression of AQP4 are treated with recombinant MMP-1 or vehicle control. Given these preliminary data it is possible that MMP inhibition could provide a new therapeutic target in treating impaired waste clearance in HAND.

Title: IFNβ protects neurons in a CCL4-dependent fashion against HIV-1 GP-120 induced injury

Authors: *V. E. THANEY[1], M. M. HOEFER[2], R. MAUNG[2], M. KAUL[2];
[1]Infectious and Inflammatory Dis. Ctr., [2]Sanford Burnham Prebys Med. Discovery Inst., La Jolla, CA

Abstract: Human immunodeficiency virus-1 (HIV-1) invades the central nervous system (CNS) soon after peripheral infection and often causes HIV-associated neurocognitive disorders (HAND). Type I interferons are critical mediators of the anti-viral immune response and interferon-β (IFNβ) has been implicated in the control of HIV and SIV infection in the brain. Key neuropathological features of AIDS patients include the loss of neuronal dendrites and presynaptic terminals, and activation of glial cells, and these hallmarks are recapitulated in transgenic (tg) mice expressing HIV gp120 in the brain (HIVgp120tg). Moreover, we recently identified in a genome-wide, central nervous system (CNS) gene expression analysis of HIVgp120tg mice genes that factors of the innate immune response are differentially expressed in association with the neuropathological phenotype. In the present study we employed quantitative reverse transcription polymerase chain reaction (qRT-PCR) to investigate an anti-viral immune response mounted by HIV/gp120tg mice, inducing the expression of interferon stimulated genes (ISGs). Quantitative RT-PCR analysis confirmed the transient expression of

IFNβ in 1.5 month-old HIV/gp120tg mouse brains, but not in brains from 3- and 6 month-old animals.. A four-week intranasal IFNβ treatment delivered to mice at 3-4 months of age, which is after endogenous IFNβ levels had become undetectable, triggered IFN-induced gene expression and abrogated neuronal damage in HIV/gp120tg mice without altering astrocytosis. In *vitro* experiments showed that the neuroprotective effect of IFNβ against toxicity of HIV gp120 required the presence of IFNα receptor 1 (IFNAR1) and the induction of CCL4, a known HIV-suppressive factor. Taken together, these results identify IFNβ as a neuroprotective agent that can ameliorate HIV gp120-induced brain injury *in vivo* after intranasal application.

Title: Aging with HIV - neurofunctional correlates of cognitive interference and motor demands: A comparison with Parkinson's disease

Authors: *E. M. MULLER-OEHRING[1,3], K. L. POSTON[2], H. M. BRONTE-STEWART[2], C. HARDCASTLE[3], T. MARTIN[2], A. PFEFFERBAUM[3], E. V. SULLIVAN[1], T. SCHULTE[3,4]; [1]Dept. Psychiatry & Beh. Sci., Stanford Univ. Sch. of Med., Palo Alto, CA; [2]Neurol., Stanford Univ. Sch. of Med., Stanford, CA; [3]Neurosci. Program, SRI Intl., Menlo Park, CA; [4]Pacific Grad. Sch. of Clin. Psychology, Palo Alto Univ., Palo Alto, CA

Abstract: With the widespread use of antiretroviral therapy, patients with human immunodeficiency virus (HIV) infection live longer and may show age-related functional decline similar to those of Parkinson's disease (PD), given that both diseases affect subcortico-cortical

pathways subserving cognition and motor function. We used functional MRI to assess brain responses in 15 aging HIV-infected individuals compared with 11 PD patients and 15 controls using a Stroop Match-to-Sample task. The task required matching the color of a cue to the font color of a Stroop word and examined cognitive interference from incongruent (inc) Stroop words (the word RED written in blue font) relative to congruent (con) words (the word RED written in red font). Motor functional demands were manipulated by requiring subjects either to switch response types (RS) or to repeat the same response (RR). All groups showed significant behavioral Stroop effects (inc>con). HIV, but not PD, exhibited more cognitive interference and slower response speed than controls. PD showed enhanced cognitive performance (faster response times (RTs), fewer errors) off- compared to on-dopaminergic medication. fMRI analysis was conducted with SPM8 using a full-factorial ANOVA with group (HIV, PD, CTL) and cognitive (inc, con) and motor demands (RR, RS) as factors (analysis threshold $p<0.05$ corrected for multiple comparisons). Fronto-parietal cortices were activated with cognitive demands (inc>con) and fronto-cerebellar regions with motor demands (RS>RR). HIV and PD off-dopaminergic medication did not differ in cognitive and motor demand activation maps despite enhanced cognitive interference and RT slowing in HIV. However, for high motor response demands (RS>RR), PD on-dopaminergic medication exhibited greater fronto-cerebellar activation than off-medication, and greater activation compared to HIV and controls. In controls, older age was associated with less precentral motor cortical activity (to RS>RR) (Rho=-.66); yet, faster RT to high motor demands (Diff. RTRS-RR) correlated with greater cerebellar activation (Rho=-.63) indicative of compensation through redistribution of resources within the fronto-cerebellar system. HIV subjects in our sample did not elicit activation for neurofunctional adaption to manage deficits or counteract RT slowing potentially rendering them vulnerable to functional decline with aging.

Title: Excitability of mPFC pyramidal neurons is increased in older HIV-1 transgenic rats through alteration in K^+ channel activity

Authors: *L. CHEN[1], C. E. KHODR[1], L. AL-HARTHI[2], X.-T. HU[1];
[1]Dept. of Pharmacol., [2]Dept. of Immunol. and Microbiology, Rush Univ. Med. Ctr., Chicago, IL

Abstract: The medial prefrontal cortex (mPFC) plays an important role in regulating cognitive function and is profoundly dysregulated in HIV-infected patients. Despite combined antiretroviral therapy (cART), HIV-induced neurological and psychological deficits occur in >50% of HIV^+ patients and these deficits may worsen as the HIV infected population ages. We evaluated the the impact of HIV and age on mPFC using HIV Tg older (12 months) rats. Our previous studies have demonstrated that acute exposure to a toxic HIV-1 protein, Tat, induces an abnormal increase in the excitability of mPFC pyramidal neurons. Such mPFC neuronal hyperactivity is also found in adolescent (6-7 weeks old) and young adult (5-6 months old) HIV-1 transgenic (Tg) rats (which express 7 of 9 HIV-1 genes), and is due in part to over-activation/expression of the voltage-gated Ca^{2+} channels (VGCCs, specifically the L-type). We show here that the excitability of mPFC pyramidal neurons is increased in older HIV-1 Tg rats. To assess the mechanism driving the hyperactivity of mPFC pyramidal neurons in aged HIV-1 Tg rats, we focused on HIV-mediated changes in K^+ channel activity. Whole-cell patch-clamp recordings were conducted under blockade of Na^+ and Ca^{2+} channels, as well as glutamate and GABA receptors, to isolate K^+ channel activity. We found that the input resistance (R_{in}) was increased (reflecting reduced activity of K_{2P} channels), inward rectification was reduced (suggesting reduced activity of K_{ir} channels), and voltage-gated K^+ efflux was also decreased (indicating reduced activity of K_v channels)(all $p<0.05$) in mPFC pyramidal neurons from older HIV-1 Tg rats as compared to those from age-matched non-Tg rats. The reduced K_{2P} and K_v channel activity is in agreement with the decreased rheobase and increased firing, while the reduced K^+ influx via K_{ir} channels could increase extracellular K^+ levels, which ultimately contributes to neuronal hyperactivity. Intriguingly, in a parallel study presented in the meeting (Khodr et al., 2016), we found that there was no significant difference in Ca^{2+} influx through VGCCs in neurons from HIV-1 Tg rats and age-matched non-Tg rats. Together, these novel findings suggest that the increased mPFC neuronal excitability in older HIV-1 Tg rats is mediated mainly by reduction of K^+ channel activity. Thus, K^+ channels could be a potential target for treating HIV^+ patients with neurological and psychological deficits.

Title: Co-morbid Effects of Methamphetamine and HIV-1 Tat inMicroglia Neurotoxic Activity: Role of CX3CR1/CX3L1 Axis

Authors: J. LIU[1], E. XU[2], H. LIU[1], *H. (. XIONG[1];
[1]Univ. of Nebraska Med. Ctr., Omaha, NE; [2]Univesity of Nebraska Med. Ctr., Omaha, NE

Abstract: Methamphetamine (Meth) abuse not only increases the risk of HIV-1 infection but potentiates HIV-1 associated neurotoxicity as well. The mechanisms underlying this potentiation are not fully understood. Recently, CX3CL1/CX3CR1 axis has gained attention as promising targets for specific immunomodulation. Increasing evidence indicates that deficient neuron-microglia signaling impairs brain functionality and results in neurodegenerative abnormalities and cognitive deficits. It has also been demonstrated that infected brain cells continuously express and release Tat protein despite control viral replication. We hypothesize that Meth and HIV-1 protein Tat may impair CX3CL1/CX3CR1 function leading to an alteration of microglia neurotoxic activity. To test this hypothesis we studied the co-morbid effects of Meth/Tat on rat microglia neurotoxic activity associated with CX3CL1/CX3CR1. Our data showed that Meth/Tat synergistically inhibited microglia CX3CR1 expression and induced microglia neurotoxic secretion. Neutralizing CX3CR1 by a specific CX3CR1 antibody in microglia significantly enhanced Meth/Tat-induced microglia activation and resulting in neuronal injury. Augment of CX3CR1 signaling by treatment microglia with recombinant CX3CL1 (rCX3CL1) protected against Meth/Tat-induced microglia neurotoxicity. These results suggest that Meth/Tat induce microglia neurotoxicity via regulation of CX3CL1/CX3CR1. We also found that rCX3CL1 increase of microglia expression of Rac1 and MFG-E8 was attenuated by Meth/Tat. The increase of Rac1 expression provoked rearrangement of microglia cytoskeleton and propelled microglia migration towards to apoptotic neurons while the increase of MFG-E8 expression promoted microglia engulfment and clearance of apoptotic neurons. Our data suggest that activation of CX3CL1/CX3CR1 axis may have the potential in suppression of Meth/Tat-associated microglia neurotoxicity. Supported by NIH grant R01NS077873

Title: Neuroprotective effects of fatty acid amide hydrolase inhibition in a HIV-1 tat model of neuoAIDS

Authors: *D. J. HERMES[1], C. XU[1], M. J. NIPHAKIS[2], K. MACKIE[3], B. F. CRAVATT[2], A. LICHTMAN[4], B. IGNATOWSKA-JANKOWSKA[5], S. FITTING[1];

Abstract: The advent of combined antiretroviral therapy (cART) has greatly improved the prognosis of patients infected with human immunodeficiency virus type 1 (HIV-1). However, a significant proportion of this population still exhibits a marked decrease in cognitive abilities known as HIV-1 associated neurocognitive disorder (HAND). HIV-1 does not infect neurons but produces viral toxins, such as transactivator of transcription (Tat) protein, that have been shown to disrupt cellular calcium equilibrium resulting in excitotoxic conditions. Loss of calcium regulation can give rise to synaptodendritic injuries and cell death, the former of these is highly correlated with loss of cognitive function in HIV-1 patients. Cannabinoids are known to show neuroprotective effects in several models of neurodegenerative diseases, however, the role of the endocannabinoid system in neuroAIDS is not well known. Here, we investigated neuroprotective effects of inhibiting fatty acid amide hydrolase (FAAH), a major catabolic enzyme of an endogenous cannabinoid N-arachidonoyl ethanolamine (anandamide/AEA). Specifically, we aimed to test whether a selective and potent FAAH inhibitor, PF3845, produces neuroprotective effects in a Tat-treated, murine primary prefrontal cortex neuron culture. To assess neuronal damage and viability after exposure to Tat, with or without PF3845, we used calcium imaging, structural analysis of dendritic volume and length, and measured neuronal survival over 72 hours. PF3845 significantly reduced excitotoxic levels of intracellular calcium and neuronal death induced by Tat. Neuroprotective effects of PF3845 were fully blocked by CB_1, but not CB_2 receptor antagonism. This indicates that effects observed following PF3845 application are mediated by the CB_1 signaling pathway and are likely the result of increased levels of AEA following FAAH inhibition. Finally we showed that neurons exposed to Tat show reduced

dendritic volume and length changes that are partially blocked by PF3845. In conclusion, our results indicate that selective FAAH inhibition protects against Tat-induced neuronal damage and promotes neuronal survival in cell culture. Further studies are necessary to determine the therapeutic potential of endocannabinoid catabolic enzymes in models of neuroAIDS.

Title: Resveratrol analog timbd modifies hiv-1 gp120 associated inflammation in astrocytes

Authors: *F. E. ABDALLA[1], A. NOOKALA[2], A. KUMAR[2], H. BHAT[2];
[1]Pharmacol. and Toxicology, Univ. of Missouri Kansas City, Kansas City, MO; [2]UMKC, kansas city, MO

Abstract: SNIP Abstract
Resveratrol Analog (TIMBD): Implication in HIV-Gp120 Associated Neuro-inflammation in Astrocytes
Human Immunodeficiency Virus (HIV)-associated neurocognitive disorder (HAND) is one of the undermining disorders that affect majority of HIV infected patients. Patients with HAND suffer from both cognitive and motor dysfunction which is characterized by memory loss and changes in personality. Astrocytes are considered the major reservoirs of the HIV in the brain. Resveratrol (Res) is one of the known phytoestrogens with potential anti-inflammatory activity. However studies suggests resveratrol's poor specificity and bioavailability as a reason for its poor efficacy. To overcome these problems associated with Res, our research group has developed novel Res analog (TIMBD). The inflammatory cytokines and chemokines associated with HIV-gp120 in astrocytes plays a critical role in HAND development in HIV patients. Patients with HIV are reported with high levels of IL6 and IL8 which have been shown to be critical in the damage process. In this study we demonstrated that TIMBD downregulated inflammatory mediators-induced by HIV-gp120 transfection in SVG astrocytic cell lines which suggests that TIMBD has the potential to inhibit HIV-gp120 induced neuro-inflammation. Briefly, SVG astrocytic cell line was cultured in growth media. Cells were transfected with mock/or HIV gp120 plasmid and treated with TIMBD for up to 48 h. RNA was isolated and mRNA levels of IL6 and IL8 were quantified. The expression of HPRT RNA was used for

normalization. Protein levels of transcription factors AP1, pSTAT3 and NFKB were measured using western blotting. We demonstrated increased expression of inflammatory cytokines IL6 and IL-8 with gp120 transfection in SVGA astrocytes cell line. TIMBD but not Res was able to decrease the expression of those pro-inflammatory mediators. We concluded that Res analogs TIMBD is able to modify the inflammatory mediators in HIV-gp120-transfected astrocytes.

Program, Henry M. Jackson Fndn. for the Advancement of Military Med., Bethesda, MD

Abstract: *Background*: Combination antiretroviral therapy (cART) has been shown to improve cognitive performance and suppress its decline. However, the effect of cART, and the timing of its initiation in prenatally infected children may have affects on brain development. Here, we set out to compare brain white matter microstructure development in HIV-infected children to that

of uninfected individuals, HIV+ children on cART to those who are not on cART, and look further at differences between those administered cART at the start of the study compared to those who deferred initiation until they met past global criteria based on immunosuppression set by the WHO. *Methods*: T1- and diffusion- weighted images (DWI) were collected one year apart from 92 children (39 HIV+, 30 on cART at the initial scan and 53 HIV-; Figure 1) from the PREDICT study (Figure 1. Right). Fractional anisotropy (FA) and diffusivity averages in regions of interest (ROIs) were extracted from DWIs processed using ENIGMA-DTI protocols and the rate of change in the measures was calculated. The false discovery rate ($q<0.05$) was used to account for multiple tests. *Results*: We found a lower rate of change in FA and higher rate of change in radial diffusivity (RD) in children on cART compared to children without treatment for regions including the corpus callosum (CC). The rate of change in FA and RD was also found to be significantly associated with proportion of life on cART, (time on cART over age) (Figure 2. Left). The annual change in FA of the CC in children not on cART at the time of the first scan was found to be higher than for the HIV- children (P=0.0181, Beta=0.0266); no difference was found between HIV+ children initially on cART and HIV- children. *Conclusion*: Results indicate differences in white matter microstructure between on-cART and without-cART children, which are correlated with proportion of life on treatment. On-cART children show similar diffusivity as HIV- group, suggesting neurodevelopment in HIV+ children without-cART is altered. Additional follow up is needed to determine long-term deficits.

Title: Diminished nestin positive neurons in pediatric SIV infection

Authors: L. RODRIGUEZ[1], R. JOBARTEH[1], M. SWANG[1], A. CHARLES[1], N. ALGARZAE[1], K. VAN ROMPAY[2], K. DE PARIS[3], *M. W. BURKE[4];

Abstract: Pediatric HIV infection remains a global health crisis with an estimated 650 children under the age of 15 years becoming infected with HIV-1 each day. Perinatally HIV-1 infected individuals are disproportionately affected by HIV-1 related neurological impairments. The proposed studies take advantage of ongoing pediatric SIV pathogenesis and vaccine studies to test the hypothesis that pediatric SIV infection diminishes actively proliferating stem cells and neurogenesis in the dentate gyrus. Newborn rhesus macaques (*Macaca mulatta*) received intravenous inoculation of SIVmac251 or vehicle within 72 hours after birth. After a 6-18 week survival time, the animals were sacrificed and the brains prepared for quantitative histopathological analysis. Serial-sections spanning the entire hippocampus were immunostained for GFAP, nestin, or doublecortin (putative markers for astrocytes and immature neurons respectively). We report here a significant reduction in nestin and doublcortin immunoreactive cells in the dentate gyrus of SIV-infected compared to age-matched control subjects. We also found an elevation in GFAP positive cells, possibly a consequence of inflammation. Matched sections were double labeled for GFAP/nestin or nestin/doublecortin for confocal analysis revealing few/none double-labeled cells. The loss of immature neurons may contribute to the rapid and persistent neurocognitive decline associated with pediatric HIV infection. This model

presents a platform in which to test therapeutic interventions aimed at ameliorating the negative consequences of HIV-1 through the neurogenesis pathway.

Title: Characterizing cathepsin B/serum amyloid p complex-induced neuronal dysfunction in a mouse model of HIV-associated encephalitis

Authors: *A. M. OGANDO VÉLEZ[1], Y. M. CANTRES-ROSARIO[1], M. PLAUD[1], S. GORANTLA[2], L. M. MELÉNDEZ[1];
[1]Microbiology and Med. Zoology, Univ. of Puerto Rico, Med. Sci. Campus, San Juan, Puerto Rico; [2]Univ. of Nebraska Med. Ctr., Omaha, NE

Abstract: HIV-infected macrophages infiltrate the blood brain barrier to the brain, where they secrete viral and cellular proteins, triggering neuronal dysfunction and death. Despite the efficacy of antiretroviral therapy, mild forms of HIV-associated neurocognitive disorders (HAND) remain prevalent. Infected macrophages secrete cathepsin B, a lysosomal protease, which interacts with serum amyloid p component (SAPC) at the extracellular level. Cathepsin B and SAPC secreted from HIV-infected macrophages induce apoptosis of primary rat neurons *in vitro*, which can be decreased by the pre-treatment of macrophage-conditioned media (MCM) with anti-cathepsin B and SAPC antibodies. The pre-treatment of HIV-infected MCM with these antibodies also reduces β-amyloid peptides in neurons. In addition, both proteins co-localize with β-amyloid peptides in tissues from HIV-associated dementia (HAD) patients and Alzheimer's disease patients, compared to healthy individuals, suggesting a role of the complex in neurodegeneration. We have demonstrated that recombinant active cathepsin B added in MCM is

internalized by neurons. Moreover, the levels of cathepsin B internalization are proportional to the levels of HIV infection. Therefore, we hypothesize that targeting cathepsin B/SAPC complex in MCM represents a viable approach to elucidate the mechanism of cathepsin B-induced neuronal dysfunction and test its potential as a candidate for drug development against HAND. To test this hypothesis, we exposed SK-N-SH neuroblastoma cells to histidine-tagged cathepsin B in neuronal culture media alone or in presence of anti-cathepsin B antibody, and localized the histidine tag in neurons by intracellular flow cytometry. Histidine-tagged cathepsin B was internalized by neurons (52.0%), a mechanism that was partially reduced by the pre-treatment of the media with anti-cathepsin B antibody (34.9%). The neuroprotective potential of cathepsin B antibody was confirmed by immunofluorescence, demonstrating increased MAP2 staining and recovered morphology. Then, we examined the presence of cathepsin B and SAPC in the brain of a mouse model of HIV-encephalitis (HIVE), generated by intracranial inoculation of control and HIV-infected human MDM. Cathepsin B and SAPC were identified in the striatum of the mice inoculated with HIV-infected MDM by western blot, along with increased expression of cleaved caspase-3, compared to animals inoculated with uninfected MDM. Our results reveal a novel mechanism by which cathepsin B triggers neuronal dysfunction, and validate the use of HIVE mice as an *in vivo* model to test the effectiveness of anti-cathepsin B and SAPC inhibitors against HAND.

Title: Anti-n-methyl-d-aspartate receptor encephalitis: from model to medicine

Authors: *B. JONES, A. GOEHRING, E. GOUAUX, G. L. WESTBROOK;
Neurosci., OHSU Vollum Inst., Portland, OR

Abstract: Anti-N-Methyl-D-Aspartate Receptor (NMDAR) encephalitis is a severe autoimmune disease associated with anti-NMDAR immunoglobulin (Ig) synthesis. First described by Dalmau

and colleagues in 2007 patients with this condition develop a profound neuropsychiatric syndrome consisting of psychosis, seizures, cognitive impairment, and autonomic instability. The progressive nature of the illness is thought to result from CNS penetrance of antibodies directed against the NMDAR GluN1 subunit. These anti- GluN1 IgG's are hypothesized to induce receptor internalization producing global hypofunction in NMDAR mediated (glutamatergic) synaptic transmission. To investigate the immune complement contributing to anti-NMDAR encephalitis and the electrophysiological aberrations generated by anti- NMDAR immunoglobulins we developed a autoimmune mouse model that recapitulates the pathogenesis of the disease. To create our model we inoculated animals (Balbcj and C57Bl6; male/female @ 2m.o.) with fully assembled NMDA receptor holo-protein embedded in a vesicle-like lipid bilayer. This proteoliposome preparation maintains the quaternary structure of the NMDAR promoting the generation of antibodies with conformational specificity. Unlike mice exposed to NMDAR subunit peptide fragments in adjuvant, mice immunized with NMDAR proteoliposome develop symptomology resembling that observed in human patients including seizures, stereotyped dyskinesias, and hyperactivity. Approximately twenty-five percent of treated mice died suddenly within six weeks of NMDAR proteoliposome exposure. Immunoglobulins isolated from the serum of these mice specifically targeted the GluN1 subunit of the NMDA receptor, confirmed by immunofluorescent labeling of NMDAR expressing HEK293 cells, primary neuronal cultures and in mouse brain sections. At six weeks post inoculation neuropathology conducted in our NMDAR encephalitis model showed significant perivascular lymphocyte cuffing and brain parenchyma infiltration of activated macrophages, T, B and plasma cells. We are investigating the electrophysiological properties of primary neuronal cultures acutely and chronically exposed to antibodies derived from our mouse model.

Title: Efficacy and mechanism of action of low dose emetine against human cytomegalovirus

Authors: *R. MUKHOPADHYAY;
Dept. of Pediatric Infectious Dis., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Human cytomegalovirus (CMV) is a ubiquitous β-herpesvirus whose infection is a major public health concern. CMV causes serious neurodevelopmental sequelae in congenitally-

infected children, including mental retardation, cerebral palsy, and sensorineural hearing loss. HIV-infected children infected with CMV suffer from rapid neurological deterioration. HIV-associated CMV encephalitis is one of several central and peripheral nervous system infections seen in late-stage disease. Despite highly-active antiretroviral therapy CMV infection is associated with retinitis, encephalitis, ventriculitis, myelitis, radiculoganglionitis, and peripheral neuropathies. These infections usually occur in patients with end stage AIDS or those non-compliant with therapy. Although limited drugs are available for HCMV therapy, development of new agents is desired. Through screening of the LOPAC library, we identified emetine as HCMV inhibitor. Additional studies confirmed the anti-HCMV activities of emetine in human foreskin fibroblasts, with EC_{50} - 40±1.72 nM, CC_{50} - 8±0.56 μM, and selectivity index of 200. HCMV inhibition occurred after virus entry, but before DNA replication, and resulted in decreased expression of viral proteins. Since emetine efficacy decreased significantly in low denstiy cells *in vitro*, virus inhibition through cell cycle regulators was suspected. HCMV favors interaction of MDM2, a cell cycle protein with p53, a cellular protein and IE2, a viral protein. HCMV inhibition by emetine depended on disruption of MDM2 from its interacting partners p53 or IE2. This is achieved by nuclear translocation and binding of ribosomal processing S14 (RPS14) to MDM2. However, in low-density infected cells, despite nuclear localization of RPS14, the pre-existing interaction of MDM2-p53 could not be disrupted by RPS14 resulting in virus escape and loss of emetine effect. Knockdown of RPS14 resulted in lack of HCMV inhibition by emetine, confirming its requirement for emetine activities. Summarized, emetine may represent a promising candidate for HCMV therapy through a novel host-dependent mechanism.

Title: Altered fractional anisotropy in developing white matter after congenital heart surgery in a piglet model

Authors: ***N. ISHIBASHI**[1], A. V. KOROTCOV[2], L. KOROTCOVA[1], S. LIN[2], S. RAMACHANDRA[1], S. KUMAR[3], K. AGEMATSU[1], P. WANG[2], R. A. JONAS[1]; [1]Childrens Natl. Med. Ctr., Washington, DC; [2]Howard Univ., Washington, DC; [3]George Washington Univ., Washington, DC

Abstract: Clinical studies with standard MRI have demonstrated an important incidence of white matter (WM) injury after congenital heart surgery. Diffusion tensor imaging (DTI) allows measurement of macroscopic organization of WM pathology but has rarely been applied after cardiopulmonary bypass (CPB). The piglet is a suitable size for investigation using CPB and the brain displays a highly evolved gyrencephalic WM. The aims of the present study were: 1) to characterize WM development of the gyrencephalic piglet brain; 2) to define changes in DTI after CPB-induced insults; and 3) to define correlation of DTI changes with cellular events. Normal WM development was assessed between 3w and 7w of age. 3w female piglets were also randomly assigned to one of 3 levels of CPB-induced insults: i) no CPB (Control); ii) CPB-induced systemic inflammatory response syndrome (SIRS)(Mild-CPB); and iii) CPB-induced SIRS with ischemia-reperfusion and reoxygenation (Severe-CPB). 40 DTIs were undertaken on pre-CPB and post-CPB day 3 and week 4. 31 WM structures were constructed and further subcategorized based on: i) deep or superficial WM; ii) 3 fiber categories; and iii) 6 subdivisions. Fractional anisotropy (FA) was analyzed in each WM area. Responses of oligodendrocytes, astrocytes, and microglia to CPB were immunohistologically defined. Correlation between FA and cellular changes were analyzed in corresponding WM regions. Under normal physiological conditions, FA values were significantly different among tested WM structures and at ages 3w vs 7w. FA in the deep WM was higher than in superior WM at both ages. Within 3 fiber categories, FA was highest in projection fibers and lowest in association fibers, demonstrating a region-specific maturation pattern similar to human WM. Using regression analysis we found that FA in piglet WM at postnatal 3w and 7w is equivalent to early infancy in human WM. FA on post-CPB week 4 varied among WM structures and among the 3 CPB groups. Our data suggested maturation dependent WM vulnerability to CPB. In addition FA changes after CPB were both region-specific and insult-dependent. When the correlation between FA changes and cellular responses was analyzed, FA in Control and Mild-CPB positively correlated with oligodendrocyte cell numbers but not after Severe-CPB, suggesting that FA can be used as a biomarker for WM maturation only under normal conditions or after a mild pathological insult. Both CPB-induced astrogliosis and microgliosis affected FA changes after cardiac surgery. In summary the piglet brain is a powerful model to study human WM development. Further studies in this model will provide exceptional data needed to interpret human DTI studies.

Title: Modification of commensal gut bacteria induces protection from ischemic stroke brain injury

Authors: *C. BENAKIS[1], C. POON[1], G. SITA[1], M. MURPHY[1], D. BREA[1], J. MOORE[1], G. RACCHUMI[1], L. LING[2], E. PAMER[2], I. COSTANTINO[1], J. ANRATHER[1];
[1]Feil Family Brain and Mind Res. Inst., Weill Cornell Med., New York, NY; [2]Mem. Sloan Kettering Cancer Ctr., New York, NY

Abstract: Commensal gut bacteria have a profound impact on the host physiology, metabolism and immune function and influence disease processes from the gut to the brain. We and others have recently shown that intestinal microbiota can impact stroke pathophysiology by modulating the immune or the autonomic nervous systems. Here we sought to determine whether antibiotics that target different classes of intestinal bacteria affect the outcome of ischemic brain injury in a mouse model of transient middle cerebral artery occlusion (MCAo).
To deplete gut microbiota across all phyla, C57Bl/6 male mice received a cocktail of antibiotics in the drinking water that targets a broad spectrum of bacteria (ampicillin, A; metronidazole, M; neomycin, N; vancomycin, V; AMNV). Four weeks later, fecal bacterial numbers were quantitated by PCR of the bacterial 16S ribosomal RNA gene. To rule out off target effects of antibiotics, their administration was discontinued three days prior to MCAo. Infarct volume was measured 3 days after ischemia in cresyl violet stained brain sections. AMNV treatment resulted in a marked reduction of fecal bacterial load ($1.5x10^9$ vs $2x10^4$ copies/mg fecal mass; n=5-6; $p<0.01$) and a significant decrease of the infarct volume (34±22 mm^3, n=9, mean±SD) compared to control mice (56±21 mm^3, $p<0.05$, n=10). Recolonization of AMNV-treated mice with wild type flora for two weeks reestablished the number of fecal bacterial copies to control levels ($1x10^9$ copies/mg; n=4) and abolished the observed neuroprotection (72±18 mm^3, $p>0.05$ from controls; n=8). The protective effect was not due to additive effects of different antibiotics, because treatment with V or A alone reduced infarct volume as much as AMNV treatment (controls: 58±24 mm^3, V: 35±19 mm^3, A: 20±6 mm^3; n=10/group), whereas N treated mice where not protected (N: 52±20 mm^3; n=10). Interestingly, bacterial density in single antibiotic treated mice was not as drastically reduced as in AMNV mice (controls: $1.5x10^9$ copies/mg, N: $1x10^9$ copies/mg, V: $5x10^8$ copies/mg, A: $8x10^7$; n=6/group). Sensorimotor deficits were tested 3 d after MCAo by the contact and removal adhesive tape test. Mice treated with either V or A

performed better than controls and N treated mice (Contact time, controls: 82±55 s, N: 110±72 s; V: 46±31 s; A: 75±71 s and remove time, controls: 149±46 s, N: 169±19 s; V: 140±53 s; A: 105±72 s; n=9-12).
Modification of the intestinal microbiota has a substantial impact on stroke outcome. The bacterial composition involved in the protective effect remain to be defined. Efforts to modify the intestinal flora may provide new preventive approaches to reduce ischemic brain injury in high-risk patients.

Title: Involvement of HMGB1-RAGE signaling on the regulation of central post-stroke pain

Authors: ***S. TOKUYAMA**[1], W. MATSUURA[1], S. HARADA[1], K. LIU[2], M. NISHIBORI[2]; [1]Kobe Gakuin Univ., Kobe, Japan; [2]Okayama Univ., Okayama, Japan

Abstract: Central post-stroke pain (CPSP) is one of the most under-recognized consequences of cerebral stroke, but the development of an effective treatment strategy is urgent. High-mobility group box 1 (HMGB1) and the receptor for advanced glycation end products (RAGE, one of the receptors of HMGB1) have recently been shown to be critical in the modulation of nociceptive transduction following peripheral neuropathy. The aim of this study was to determine the interactions between CPSP and HMGB1/RAGE signaling.
Male ddY mice were subjected to 30 min of bilateral carotid artery occlusion (BCAO). The development of hind paw mechanical allodynia was measured after BCAO using the von Frey test. Neuronal damage was estimated by histological analysis on day 3 after BCAO. Expression of each protein levels was analyzed by western blot and immunofluorescence staining.

The expression levels of the HMGB1 protein in the spinal cord and the sciatic nerve were significantly increased on day 3 after BCAO, although no effects of BCAO were noted on RAGE protein expression. HMGB1- or F4/80 (macrophage marker)-positive cells were clearly observed in the spinal cord on day 3 after BCAO and were only marginally observed in the sham group. Furthermore, HMGB1-positive cells were partially co-localized with F4/80-positive cells in the spinal cord. BCAO-induced mechanical allodynia was significantly decreased by the intravenous and intrathecal administration of anti-HMGB1 monoclonal antibody. The BCAO-induced increase of phosphorylation of extracellular signal-regulated kinase (ERK) was canceled by the administration of anti-HMGB1 monoclonal antibody. In addition, BCAO-induced mechanical allodynia was significantly decreased by intrathecal administration of U0126, an inhibitor of ERK.
The results in this study suggest that the regulation of BCAO-induced CPSP involves alterations in HMGB1/RAGE signaling. Furthermore, we can speculate that the suppression of HMGB1 is a potential therapeutic target in efforts to control the painful symptoms of CPSP.

Title: *In vivo* reprogramming factor expression promotes functional recovery in a mouse model of ischemic brain injury

Authors: *J. SEO[1,3], J. YU[1,3], S. WI[1,3], Y. SHIN[1,3], M. KIM[1,3], H. KIM[2], S.-R. CHO[1,3]; [1]Dept. and Res. Inst. of Rehabil. Med., [2]Dept. of Pharmacol., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [3]Brain Korea 21 PLUS Project for Med. Science, Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Introduction: Recovery from ischemic tissue injury can be promoted by cell proliferation and neovascularization. Transient expression of four pluripotency factors (Pou5f1, Sox2, Myc, and Klf4) has been used to convert cell types but never been tested as a means to

promote functional recovery from ischemic injury. Here we aimed to determine whether in vivo reprogramming factor expression can improve neurobehavioral function, which has not previously been achieved.
Methods: Transgenic mice in which the four reprogramming factors, i.e., *Pou5f1*, *Sox2*, *Myc*, and *Klf4*, are expressed in a doxycycline-inducible manner were used. Global cerebral ischemia was induced by transient bilateral common carotid artery occlusion, after which doxycycline, low (12 ng/day) or high (1,200 ng/day) amounts of doxycycline or control buffer (phosphate buffered saline), was administered into the lateral ventricle for 7 days using a micro-osmotic pump. To label newly generated cells, bromodeoxyuridine (BrdU) was given to the mice. Rotarod and ladder walking tests and histological evaluations were conducted.
Results: Rotarod and ladder walking tests showed that this transient reprogramming factor expression dramatically promoted the best functional restoration from the ischemic injury in high amounts of doxycycline group. This functional recovery was associated with the increases both in the numbers of astrocytes and/or neural progenitors in the subventricular zone and the striatum, but not neurons or glial scar. Furthermore, this reprogramming factor expression increased the number of blood vessels. Dysplasia or tumor development was not observed.
Conclusion: *In vivo* transient expression of the reprogramming factors in the brains of mice with cerebral ischemia leads to functional improvement. These results give us insight into the effects of expressing reprogramming factors and the mechanisms of tissue recovery, potentially providing a basis for novel therapeutic modality development for tissue damage such as cerebral ischemia.

Title: Disruption of brain cholesterol homeostasis following neonatal hypoxia-ischemia

Authors: F. LU[1], J. ZHU[2], F. CHEHAB[2], D. M. FERRIERO[3], *X. JIANG[1];
[1]Dept. of Pediatrics, [2]Dept. of Lab. Med., [3]Dept. of Pediatrics and Neurol., UCSF, San Francisco, CA

Abstract: Brain cholesterol is important for myelination, synaptogenesis and neurotransmission in the developing brain. Cholesterol that is required for rapid brain growth in the neonatal period is produced locally from de novo synthesis with acetyl-CoA as raw material and HMG-CoA reductase (HMGCR) as the rate-limiting enzyme. Brain cholesterol is metabolized through hydroxylation by neuron-specific cholesterol 24-hydroxylase (CYP46A1) to form 24S-hydroxycholesterol, which is able to traverse the blood brain barrier and enter the circulation to the liver for excretion. In this study, we investigated cholesterol synthesis and turnover following neonatal brain hypoxia-ischemia (HI). Using the Vannucci model in postnatal day 9 C57Bl6 mice, we found that HMGCR expression decreased over time during the first 24 hours after HI, indicating that HI disturbs brain cholesterol synthesis. The expression of CYP46A1 was up-regulated significantly at 6hr and 24hr post-HI, which corrected with the higher levels of 24S-hydroxycholesterol at the same time points compared to the sham-operated animals in the brain, as well as in the serum. The increase in 24S-hydroxycholesterol in both brain and serum was sustained until 48hrs after HI and returned to normal levels at 72hr. Our work suggests an imbalance of cholesterol synthesis and metabolism early following neonatal HI. Disruption of cholesterol homeostasis may contribute to pathogenesis of neuronal death and white matter injury, and have adverse effects on brain development.

Title: Spinal grafting of allogeneic neural precursors (NPCs) in a rat model of spinal ischemic and traumatic injury: assessment of descending motor tract and primary afferent synapse formation with grafted cells.

Authors: *T. TADOKORO, M. R. NAVARRO, O. KAKINOHANA, S. MARSALA, M. MARSALA;
Dept. of Anesthesiol., UCSD, San Diego, CA

Abstract: BACKGROUND: In previous studies we have demonstrated a functional improvement after spinal grafting of human hNT neurons and human and rat fetal NPCs in rat models of spinal ischemic and contusion injury. In our current study using a novel subpial axon-labeling technique and primary afferent labeling, the time course of synapse formation between descending motor tracts and primary afferents with grafted allogeneic NPCs was studied. METHODS: Sprague-Dawley (SD) rats (200-300 g) were exposed to i) spinal ischemia (10 min), or ii) L4-5 spinal compression injury by placing a 30g circular rod on the exposed L4-5 spinal segment for 15 min. Two weeks after injury, animals received cervical subpial injection of AAV9-SYN-RFP to label descending motor axons. At 4 weeks after spinal injury, animals received spinal grafts of allogeneic fetal (E14-16) NPCs isolated from GFP+ rats. After cell grafting, animals were immunosuppressed for 3 weeks with Prograf (3 mg/kg/day) and then survived without immunosuppression for an additional 1-6 months. Three days before sacrifice animals received sciatic nerve injection of cholera toxin B to label primary afferents. At the end of survival, animals were perfusion fixed with 4% paraformaldehyde. Differentiation profile of grafted cells and development of putative synapses with labeled descending motor axons and primary afferents was studied by immunofluorescence. RESULTS: In both models consistent grafted cell survival was seen at intervals up to 6 months after cell grafting. The presence of mature neurons (NeuN, MAP2) and astrocytes (GFAP) in GFP+ cells was seen. RFP+ descending axons were identified within the grafts. The highest degree of axonal ingrowth was seen at 6 months after cell grafting and was more pronounced in animals with previous spinal ischemic injury (if compared to contusion injury). Similarly, the presence of labeled primary afferents was seen within the graft(s) and was more developed in grafted animals previously exposed to spinal ischemic injury. CONCLUSIONS: i) These data demonstrate that descending motor tracts and primary afferents in rats with previous ischemic or traumatic injury retain their capacity to develop new synaptic contacts with grafted neuronal precursors. ii) In addition, these data suggest that long periods after cell grafting are required for higher density synapse formation with grafted terminally-differentiated neurons. iii) Similarly, these data also demonstrate that a long cell-post-transplant survival interval (6-12 months) will need to be studied to assess the full therapeutic potential associated with cell replacement therapies in spinal ischemic or traumatic injury.

Title: Extension of therapeutic time window of tissue plasminogen activator with sp-8203 combination therapy in rat embolic stroke models

Authors: *W.-K. KIM[1], A. M. A. ANTHONY JALIN[1], H. SONG[1], C. JU[1], K. PAHK[1], H. NOH[1], C. JOUNG[1], G.-S. CHO[2], B.-S. KIM[2], J.-M. RYU[2];
[1]Col. of Med. Korea Univ., Seoul, Korea, Republic of; [2]Central Res. institute, Shin Poong Pharm. Co. Ltd, Ansan, Korea, Republic of

Abstract: Although tPA is the only approved therapy for ischemia, its clinical use is limited by narrow therapeutic time window; e.g., mostly up to ~3 h after the onset of ischemia. Limited use of tPA for post-ischemic treatment is related with hemorrhagic transformation and reperfusion injury by delayed thrombolysis. Since the hemorrhagic transformation and reperfusion injury by delayed thrombolysis involves multiple cytotoxic pathways including excitotoxicity, oxidative stress and inflammatory responses, the combined use with multi-target directed neuroprotectants has an emerging potential to extend the time window of tPA and simultaneously to reduce tPA- and ischemia-induced brain injury. We recently identified a novel multipotentneuroprotectant SP-8203(Shin Poong Pharm. Co. Ltd, South Korea) and confirmed itsfeasible safety in Phase I clinical studies. Inrodent embolic stroke models, while early 3-h reperfusion with tPA effectively restored perfusion and reduced infarction, late 6-h tPAtreatment did not decrease infarction but instead worsened hemorrhagic conversion and mortality. Treatment of SP-8203 (3 mg/kg, i.v. bolus)1.5 h prior totPA infusion reduced the infarct volume, edema and neurobehavioral deficit aggravated by delayed tPA treatment. Moreover, SP-8203 significantly attenuated delayed tPA treatment-worsened cerebral hemorrhage and mortality.Even simultaneous treatment tPA and SP-8203 at 4.5 h ameliorated survival and brain atrophy over 30 days. In situ zymography study revealed that SP-8203 largely decreased the expressions and activities of matrix metalloproteases, which were significantly correlated with increase of hemorrhage and mortality in delayed tPAtreatment. Accordingly, the combination significantly attenuate the infiltration of inflammatory cells, the BBB leakage, and related degradation of tight junction proteins in penumbral regions.Thus, the combined treatment of SP-8203 with tPA would be a therapeutic strategy to overcome the limitation of tPA therapy, reduce ischemic brain tissue damage and maximize clinical outcome. (W-KK and AMAAJ equally contributed)

Title: Sprouting and "side-switch" of contralateral corticospinal fibers in the spinal cord after large unilateral cortical stroke in adult mice

Authors: *J. KAISER[1], A. RICCIARDI[2], A.-S. WAHL[2], N. HAGENBUCH[4], C. FÖLDY[5], M. E. SCHWAB[3];
[1]Brain Res. Inst., Zürich, Switzerland; [2]Brain Res. Inst., Univ. and ETH Zurich, Zürich, Switzerland; [3]Brain Res. Inst., Univ. and ETH Zurich, Zurich, Switzerland; [5]Brain Res. Inst., [4]Univ. Zurich, Zurich, Switzerland

Abstract: Functional recovery of skilled forelimb movements after a large insult to the primary motor and premotor cortex involves activation of the contralateral hemisphere with the contralesional cortex growing new collaterals crossing the midline into the denervated hemi-cord on cervical levels of the spinal cord. The underlying molecular mechanisms of growth induction in these adult, intact, fully wired and functional corticospinal tract fibers, midline crossing and target innervation are yet unclear. Such mechanisms could be of high importance for future therapies. Microglia, which have repeatedly been linked to brain repair after lesion and are known to react quickly to changes in their environment, are a high priority candidate for participation in sprout induction-, shaping of a growth-permissive tissue environment and attraction of fibers to the denervated hemi-cord. To address the involvement of microglial cells in this lesion paradigm, adult mice were subjected to a unilateral photothrombotic stroke of the right primary as well as pre-motor cortex ablating >90% of the descending projections of the corticospinal tract (CST). Microglial activation was analysed morphologically at different time points in the cervical spinal cord. We show a lesion-dependent transient activation of microglia in the grey matter of the denervated hemicord at early time points, i.e. 2-4 days after the stroke. Activation is correlated in space to the density of CST innervation of the corresponding areas. Molecular analysis of these activated cells will give insights into the microglial involvement into the processes of sprouting, synaptogenesis and and circuit plasticity.

Title: Inhibition of glucose transporters attenuate recurrent hypoglycemia-induced increase in intra-ischemic acidosis in insulin-treated diabetic rats.

Authors: ***A. K. REHNI**[1], V. SHUKLA[2], K. R. DAVE[2,3];
[2]Neurol., [1]Univ. of Miami Sch. of Med., Miami, FL; [3]Neurosci. Program, University of Miami Miller School of Medicine, FL

Abstract: Stroke is a serious manifestation of diabetes. Glucose lowering therapies available for correcting diabetic hyperglycemia causes recurrent hypoglycemia (RH). In an earlier study we observed that RH exacerbates ischemic brain damage in insulin-treated diabetic (ITD) rats. We have previously observed that ischemia causes enhanced increase in hippocampal lactate levels and a profound drop in pH in ITD + RH rats compared to controls. We tested hypothesis if administration of alkalizing agent (Tris-(hydroxymethyl)-aminomethane: THAM) modulates intra-ischemic acidosis in ITD + RH rats. Also, since RH is shown to increase levels of glucose transporters (GLUTs), we also determined if glucose transporters are responsible for observed drop in intra-ischemic acidosis in ITD + RH rats. Rats were made diabetic by streptozotocin injection and 2-3 weeks later, received insulin pellets for treating diabetes. After 2-3 weeks, moderate hypoglycemia was induced by insulin injection for 3 hours per day for 5 consecutive days. Animals were divided into following groups: (I) THAM treatment: A. ITD + RH (representing treated diabetic population experiencing RH) (n = 7) and, B. ITD + RH + THAM (0.3 M, 3 ml / kg / hr, i.v.) (n = 6); II: 4,6-O-Ethylidene-α-D-glucose (OEDG; GLUT inhibitor) treatment: A. ITD + RH + Vehicle (n = 6), B. ITD + RH + OEDG (2 mmol / kg, i.v. bolus dose followed by 0.2 mmol / kg / min, i.v. maintenance infusion) (n = 6). On the day after last hypoglycemia exposure, global cerebral ischemia was induced by bilateral carotid artery occlusion with hypotension for eight minutes. Rats were treated with THAM or OEDG from 15 minutes prior to ischemia to 80 minutes of reperfusion. CA1 hippocampal pH and lactate (in microdialysate) were measured using microfiber optic pH meter and lactate plus meter, respectively. The pH drop in THAM-treated rats was significantly lower than in the controls

from 4 minutes of ischemia to 4 minutes of reperfusion and from 11 to 18 minutes of reperfusion compared to the control group (change in Δ pH in THAM group *vs* control group was 37 % to 57 %). The fall in pH in OEDG-treated group was significantly lower than in control group from the onset of ischemia to 80 min of reperfusion (change in Δ pH of OEDG group *vs* control group was 17 % to 64 %). Changes in lactate level in OEDG treatment group was significantly lower than the control group, when measured 4 min after ischemia and from 20 to 60 minutes of reperfusion. Our results demonstrates that ischemia causes pronounced acidosis via a GLUTs mediated increase in acidosis in ITD + RH rats. Studying the mechanism of acidosis in RH exposed ITD rats may help lower ischemic brain damage during diabetes.

Title: A multi-potent neuroprotectant LMT356 reduces tissue plasminogen activator-evoked adverse effects in rat embolic stroke

Authors: K. PAHK[1], *C. JU[1], A. M. A. ANTHONY JALIN[1], H. SONG[1], H. NOH[1], C. JOUNG[1], G.-S. CHO[2], W.-K. KIM[1];
[1]Neurosci, Korea Univ. Med. Col., Seoul, Korea, Republic of; [2]Central Res. Institute, Shin Poong Pharm. Co. Ltd, Ansan, Korea, Republic of

Abstract: Acute ischemic stroke causes over 10% of all deaths in western countries as well as in Korea. Despite severity of ischemic stroke, development of neuroprotectants is still in its infancy. Although tissue plasminogen activator (tPA) is currently approved by FDA for treatment of acute ischemic stroke, its clinical use is strictly limited due to adverse effects caused by delayed treatment of tPA (e.g., over 4.5-h after ischemia onset). The narrow therapeutic time window of tPA is related with its time-dependent adverse effects such as excitotoxicity, radical formation, cerebral hemorrhage, and inflammation. Thus, the combined use of a multi-target directed neuroprotective agent with tPA would be a therapeutic strategy to simultaneously reduce

both tPA and ischemia-induced brain tissue damage. In this sense, we recently designed LMT356 as a multi-target directed neuroprotectant with anti-excitotoxic, antioxidant and anti-inflammatory properties. While early 3-h thrombolysis restored perfusion and largely reduced infarction, late 6-h tPA did not decrease infarction and even worsen hemorrhagic conversion and mortality. LMT-356 (50 mg/kg, i.v. bolus) reduced the aggravation of infarction, edema and neurobehavioral deficits caused by delayed tPA-treatment in embolic stroke. Combined treatments of LMT356 with delayed (6-h post-ischemic) treatment of tPA ameliorated mortality and brain atrophy over 30 days in rats subjected to embolic stroke. LMT356 also reduced the expression and activity of matrix metalloproteases that are closely correlated with cerebral hemorrhage and mortality. Thus, the combined use of a multi-target directed neuroprotectant LMT356 could be beneficial to overcome the limitation of tPA therapy in acute cerebral ischemic stroke. (KP and CJ contributed equally)

Title: Effect of CD49d-positive allogeneic mesenchymal stromal cells on transmigration across blood-brain barrier after intra-arterial delivery into rats

Authors: *L. CUI, J. JOLKKONEN;
Neurol., Univ. of Eastern Finland, Kuopio, Finland

Abstract: Cell-based therapy is one of the most attractive treatments to enhance post-stroke recovery. Positive effects of systemic mesenchymal stromal cells (MSCs) transplantation have been seen in some animal models, but the functional outcome is still not optimal. One of the limitations for systemic delivery of MSCs could be the inappropriate homing of the cells, and the

mechanism of MSCs across the blood brain barrier (BBB) is still poorly understood. Intra-arterial infusion can increase the cell homing to the ischemic hemisphere by circumventing the pulmonary circulation. Cell surface engineering might also increase homing capacity by promoting adhesion to endothelium. Alpha4 integrin (ITGA-4) is an important surface integrin for endothelial adhesion of inflammatory cells. Its receptor, vascular cell adhesion molecule-1 (VCAM-1) is upregulated early after stroke. In our experiment, rat bone marrow derived MSCs were genetically modified to over-express ITGA-4 and also labeled with tdTomato. Adult male RccHan Wistar rats (200-300g) undergo sham or transient middle cerebral artery occlusion surgery. 24h later they are transplanted with 1×10^6 ITGA-4 positive rat MSCs or control cells via the external carotid stump. Two photon fluorescent microscope is used to observe the in vivo behavior of infused cells in the brain during and up to 24h after delivery. Rats are perfused 24h after cell transplantation and histology will be done to confirm the imaging results. We hypothesize that ITGA4/VCAM-1 plays an important role in the transmigration of allogeneic MSCs across BBB, and over-expression of ITGA-4 on MSCs could increase cell homing into the injured brain, thereby increase the functional outcome.

Title: Roles of protein disulfide isomerase-A3 against neuronal damage induced by spinal cord and transient forebrain ischemia

Authors: *D. YOO[1], I. HWANG[1], J. CHOI[2], J.-H. CHO[3], D. KIM[4], Y. YOON[1];
[1]Col. of Vet Med, Seoul Natl. Univ., Seoul-City, Korea, Republic of; [2]Col. of Vet. Medicine, Kangwon Natl. Univ., Chuncheon, Korea, Republic of; [3]Dept. of Neurobiology, Sch. of Medicine, Kangwon Natl. Univ., Chuncheon, Korea, Republic of; [4]Dept. of Biochem. and Mol. Biology, Res. Inst. of Oral Sciences, Col. of Dentistry, Gangneung-Wonju Natl. Univ., Gangneung, Korea, Republic of

Abstract: In this study, we investigated to find out neuroprotective effects of protein disulfide isomerase-A3 (PDI-A3) after transient ischemia of the rabbit spinal cord and the gerbil forebrain. Tat-PDI-A3 fusion protein was made and injected intraperitoneally to facilitate the cross into the

blood-brain barrier and delivery to the spinal cord and the hippocampus immediately after ischemia/reperfusion. Administration of PDI-3A significantly improved the Talove's neurological scores after spinal cord ischemia and ameliorated ischemia-induced hyperactivity after transient forebrain ischemia. In addition, the treatment of PDI-3A significantly ameliorated the reduction of NeuN-immunoreactive neurons in the spinal cord 2 days after spinal cord ischemia and in the hippocampal CA1 region 4 days after ischemia. In addition, the administration of PDI-3A significantly reduced the oxidative stress and increased the Cu,Zn-superoxide dismutase levels after transient spinal cord or forebrain ischemia. These results suggested that PDI-A3 has neuroprotective effects against ischemic damage by modulating the oxidative stress and antioxidant in the central nervous system.

Title: Neonatal hypoxia/Ischemia in rats - Short term hypothermia induced neuroprotection and tissue sparing as evidenced by MRI

Authors: *L. TOLPPANEN[1], K. LEHTIMÄKI[1], G. VILLETTI[2], A. NURMI[1], F. FACCHINETTI[2];
[1]Charles River Discovery, Kuopio, Finland; [2]Chiesi Farmaceutici S.p.A, Parma, Italy

Abstract: Therapeutic hypothermia has become standard therapy for term neonates with moderate to severe hypoxic-ischemic encephalopathy (HIE). In rodent animal models of neonatal brain hypoxia-ischemia, hypothermia showed different degrees of tissue sparing and reduced brain swelling and in some cases no protective effects, due also to variables in hypotermia protocols. To date, there is no well described published data about the MRI assessment of the brain tissue viability, lesion and oedema following 5 hours of hypothermia in neonatal H/I. To fill this gap, we evaluated acute brain tissue changes in the neonatal rat brain at 48 h after H/I by using MRI techniques. Postnatal day 7 (P7) rat (Wistar) pups (both genders) were subjected to neonatal hypoxia-ischemia model (Rice et al. 1981) for 120 min followed by either normothermic (+37C) or hypothermic (+33C) condition for 5 h. Absolute T2 mapping for tissue viability and volumetric analysis of tissue loss and oedema were evaluated with 7T small animal

MRI system acutely 48h following H/I insult. At the end-point, immediately following MRI assessments pups were euthanized and brains were processed for histology/IHC analysis to be conducted later. On day 2 (P9) following H/I, under above conditions and interventions, MRI revealed unilateral infarcts/lesions in each neonatal pup equaling to ~60-70 % tissue loss of hemispheric volume. Anatomical T2-MRI analysis revealed significant (~20%) reduction in tissue loss in H/I + hypothermic group when compared to H/I + normothermic group. Compromised tissue viability in ipsilateral hemisphere was seen as elevated T2 values (ms) compared to contralateral non-injured hemispheres. But when T2 values in H/I normothermic group were compared against H/I+ hypothermic group, significantly reduced (normalized) T2 values were seen in the brains of H/I + hypothermic group. T2 mapping allowed also more detailed and accurate delineation of the injured tissue for lesion analysis. Furthermore, analysis revealed significant reduction in brain oedema (volumetric) in H/I + hypothermic group when compared to H/I + normothermic group. Taken together, this study confirms that short term hypothermia is effective method to alleviate ischemic brain injury in the neonatal brain. Hypothermia effectively reduced lesion size and oedema and alleviated the tissue viability change. Furthermore, the use of MRI allowed us to define ischemic lesion more accurately and with the potential of performing longitudinal assessment as opposed to conventional histology and other terminal methods.

Title: Effects of deletion of peroxiredoxins II on bilateral common carotid artery occlusion-induced impairments of hippocampal function

Authors: ***Y.-S. LEE**[1], W. JEON[2], J.-S. HAN[1];
[1]department of Biol. sciences, Konkuk Univ., Seoul, Korea, Republic of; [2]Herbal Med. Res. Div., Korea Inst. of Oriental Med., Daejeon, Korea, Republic of

Abstract: Peroxiredoxins (Prxs) acts as antioxidant enzymes that reduce peroxide levels. More than one isoform of Prx including at least six Prxs(PrxI-PrxVI) have been identified in mammalian cells. Especially, Prx II immunoreactivity is predominantly found in hippocampal neurons, suggesting that Prx II be associated with physiological function in the hippocampus. Previous studies have demonstrated that Prx II against mitochondrial oxidative damage protects physiological events relating to age-associated cognitive decline. The present experiment was conducted to examine whether Prx II has a protective role for neuronal death which is caused by increased intracellular reactive oxygen species (ROS) in hippocampal pyramidal neurons in response to a sudden injury. Prx II−/− mice received transient bilateral common carotid artery occlusion (BCCAo), one of the experimental animal model for ischemic stroke. Mice were divided into 4 groups, Prx II−/− group with sham-operated procedure, Prx II−/− group with BCCAo, Prx II+/+ group with sham-operated procedure, and Prx II+/+ group with BCCAo. Cognitive status of these mice was examined using the hidden platform version of Morris water maze task, object/location novelty recognition test, and contextual fear conditioning. Prx II−/− group with BCCAo showed poor retention of spatial memory and severe cell damage in the CA1 region of hippocampus relative to the other groups. These findings indicate that Prx II plays a role in the pathological process of ischemia. Supported by the National Research Council of Science & Technology (NST) grant by the Korean government (MSIP) (No. G15120 and CRC-15-04-KIST).

Title: Obesity moderates racial and ethnic differences in white matter hyperintensity volumes between African Americans and European Americans

Authors: *A. SEIXAS[1], G. JEAN-LOUIS[1], V. NEWSOME[1], M. DE LEON[2], R. OSORIO-SUAREZ[2], A. R. RAMOS[3], T. OYEGBILE[4], L. GLODZIK[2];
[1]Population Hlth., NYU Sch. of Med., New York, NY; [2]Psychiatry and Ctr. for Brain Hlth., NYU Sch. of Med., NY, NY; [3]Miller Sch. of Med., Univ. of Miami, Miami, FL; [4]Neurol., Georgetown Univ., Washington DC, DC

Abstract: Background: The high prevalence of ischemic white matter hyperintensity volume (WMHV), a robust subclinical indicator of future stroke, may explain racial/ethnic stroke disparity comparing African Americans (AAs) and European Americans (EAs). However, the mechanism underlying this disparity is not fully understood. We hypothesized that obesity may explain the racial/ethnic difference in WMHV between AAs and EAs.
Method: Data were collected from 298 individuals enrolled across several NIH-funded studies at NYU School of Medicine's Center for Brain Health. Obesity was derived using body mass index (height/weight, kg/m^2); a body mass index greater than or equal to 30 kg/m^2 was used to categorize obese individuals. WMHV load total was defined, based on FLAIR images, as the sum of deep and periventricular volumes and was scored using the Fazekas scale (0-6 scale), where low-moderate WMHV=0-3 and high WMHV $\geq$4.
Results: Of the total sample, 61.4% were female, 91.6% were EA and 8.4% AA, 42.6% were hypertensive, 92.2% had no smoking history, 22.8% were obese, and 83.1% had low-moderate WMHV and 16.9% had high WMHV. The percentage of obese individuals among AA and EA did not differ. Logistic regression analysis indicated that age and the interaction between race and obesity were significant predictors of WMHV, thus indicating that obesity significantly moderated the relationship between race and WMHV. Age increased the odds of WMHV by 15% (OR=1.15, 95% CI= 1.09-1.22, $p<.001$), and obesity among AAs increased the odds of WMHV by 43% (OR=1.43, 95% CI = 1.04-1.98, $p<.05$).
Conclusion: Based on our findings, obesity significantly moderated the relationship between race/ethnicity and WMHV. Therefore, we argue that obesity explains a significant portion of racial/ethnic differences in WMHV between AAs and EAs.

Abstract: Introduction: blood glutamate grabbing has becoming in a novel preclinical strategy to reduce the excitotoxic effect of glutamate released in acute phase of stroke, however its clinical demonstration has not been demonstrated so far. Aiming to demonstrate the clinical efficacy of glutamate grabbing, we have performed a screening analysis of repositioning drugs with blood glutamate grabbing activity and then we have tested the selected drugs in *in vivo* ischemic animal models and then in stroke patients. **Methods**: Prestwick Chemical Library composed of 1120 HITS were used to detect drugs with blood glutamate grabbing activity. The drug selected in the *in vitro* test was later probed in ischemic model animals. Infarct volume (determined by means of MRI), blood glutamate levels and functional test were determined during 7 days after ischemic onset. The drugs selected was then tested in a randomized clinical trial (ClinicalTrials.gov Identifier: NCT02446977) with 50 stroke patients. Two treatment arms were compared; one arm with 25 placebo treatment patients and other arm with 25 durg treatment patients. Primary outcome measures: reduction of serum glutamate concentration defined as difference between serum glutamate concentrations from basal (prior to medication infusion) and levels at 3±1 and 6±1 hours, from administration point of the medication. Secondary outcome measures: 1) days of hospitalization, 2) difference in days, between patient arrival and the patient's discharge, 3) percentage of clinical improvement. **Results:** We have discovered the effect of the Riboflavin (Vitamin B_2) as a novel high blood glutamate grabber, characterized through *in vitro* and *in vivo* analysis. Administration of Riboflavin (1 mg/Kg) in ischemic animal induced a significant ($p<0.05$) lowering of blood glutamate levels and a reduction ($p<0.05$) of infarct volume at 7 days after ischemia. Improvement on neurological deficit was also observed in Riboflavin treated animals. Patients treated with Riboflavin 20 mg (Streuli®) showed a significant ($p<0.05$) reduction of blood glutamate levels, 6 hours after treatment administration and a neurological improvement at 3 months. **Conclusions:** In this study we have described the use the Riboflavin as new a potential treatment for ischemic stroke. Due to Riboflavin has been used previously in humans for other pathologies, human toxicity and pharmacokinetic analysis are not needed before to test its effects in stroke patients. Repositioning

drugs represent an interesting alternative to reduce the risk in the study of new drugs in the field of ischemic pathology.

Title: Astrocytes and new CA1 neurons in rat forebrain ischemia

Authors: ***Y. OUYANG**, L. XU, L. LI, R. G. GIFFARD;
Dept Anesthesia, Stanford Univ. Sch. of Med., Stanford, CA

Abstract: The pyramidal neurons of the hippocampal CA1 region are essential for spatial learning and memory, and are selectively destroyed after transient forebrain cerebral ischemia. The reappearance of hippocampal CA1 neurons after ischemia was associated with recovery of learning and memory. We found that selective dysfunction of hippocampal CA1 astrocytes contributes to delayed neuronal death after transient forebrain ischemia and astrocyte targeted protection reduces neuronal loss.

Here we examined whether glial fibrillary acidic protein (GFAP) positive cells have a relationship with reappearance of CA1 neurons in a model of forebrain ischemia at 8, 14 and 22 days of recovery. Immunofluorescence microscopy was used to detect bromodeoxyuridine (BrdU), a marker for proliferation, doublecortin (DCX), a marker for immature neurons, brain lipid-binding protein (BLBP), a marker for immature neurons, NeuN, a marker for mature neurons and GFAP a marker for astrocytes and radial glia.

Forebrain ischemia for 10 min caused disappearance of NeuN stained neurons in hippocampal CA1 regions at 8 and 14 days after ischemia (DAI) consistent with previous studies. At 22 DAI there was a tendency to an increased number of NeuN positive cells in CA1. There were no change of neuronal numbers in hippocampal dentate gyrus (DG) regions at all time points.

To detect newly divided cells, rats were intraperitoneally injected with 50 mg/kg BrdU every

other day starting from the ischemic day. BrdU positive cells increased at 8 DAI, peaked at 14 DAI and began to decrease at 22 DAI in DG but no change was observed in CA1 region. Both immature neuronal markers (DCX and BLBP) as well as astrocyte marker GFAP, however, began to increase at 8 DAI, peaked at 14 DAI, and tended to decrease at 22 DAI both in DG and CA1 regions of hippocampus. A low percent of BrdU positive cells co-expressed immature neuronal marker DCX in DG, but a high percentage of new neurons (DCX and BLBP positive) colocalized with GFAP. It is concluded that the DCX and BLBP positive neurons in CA1 region of hippocampus are not from proliferation of cells but from quiescent neural progenitors with radial-glia-like properties (GFAP+). To have a substantial impact on recovery, this potential mechanism for self-repair needs to be enhanced.

Title: Automated assessment of forepaw force production in rodents: Application in a rodent model of cortical ischemia

Authors: *H.-J. PARK, J. COOPERRIDER, H. CHAN, C. WATHEN, J. T. GALE, K. B. BAKER, A. G. MACHADO;
Cleveland Clin., Cleveland, OH

Abstract: The ability to objectively and reliably quantify motor function is essential to characterizing the natural progression of stroke recovery in preclinical models and the efficacy of experimental interventions. In many cases, however, such tasks can be cumbersome and time-consuming to administer and score. In this study, we developed and evaluated a simple and inexpensive robotic assessment device that required the animal to reach through an aperture to grasp and pull a lever with a specified amount of force in order to trigger delivery of a food reward. The position of the lever is controlled by two servo motors. One servo motor is located underneath the vertical slot in front of the cage, and controls the angle of the lever with respect to the slot opening. The other servo motor controls the distance from the slot using a gear rack. The servo motors are controlled by the PWM output channels of an Arduino board, with the lever position command sent from a Raspberry Pi board through a USB connection. The Raspberry Pi generates the sequence of the lever positions for the task, measures the lever pulling force for given positions using serial parallel interface (SPI) with an analog to digital converter

(MCP3008), and controls the pellet dispenser. A pellet is delivered to the rat when the force transducer detects that the pulling force has exceeded a predetermined threshold. A Raspberry Pi can control more than one robot concurrently using multi-threading. The status of the system is monitored with a personal computer using either Ethernet or Wi-Fi connection. We have built other robot configurations including a two link joint planar robot and a parallel robot. However, the limited range of motion, torque and accuracy of the servo motors in addition to the lack of off the shelf mechanical components made the robots less desirable to use in the measurement of the lever pulling force. A primary advantage of the current design is that it can be implemented using inexpensive, off the shelf components, allowing multiple systems to be made in a cost-effective manner for concurrent assessment of motor performance in large experimental colonies.

Abstract: Activated protein C (APC) is a blood protease with anticoagulant activity and cell-signaling anti-apoptotic and anti-inflammatory activities. 3K3A-APC (Lys191-193Ala), a recombinant analog of APC with reduced (90%) anticoagulant activity but normal cell signaling activity, has been shown to provide benefit in preclinical models of neurologic disorders including ischemic stroke, brain trauma, multiple sclerosis and amyotrophic lateral sclerosis, and has advanced as a neuroprotectant to Phase 2 clinical trial in ischemic stroke. Previously, we reported that 3K3A-APC stimulates neuronal production by human fetal neural stem cells (NSCs) *in vitro* via a PAR1-PAR3-sphingosine-1-phosphate receptor 1-Akt pathway. Here, we studied the effects of 3K3A-APC and NSCs combination therapy in a mouse model of stroke. We found that late post-ischemic treatment of mice with 3K3A-APC 7 days after stroke stimulates *in vivo* neuronal production by transplanted human NSCs, promotes restoration of disrupted neural circuitry and improves long-term functional recovery. In the present study, human NSCs were transplanted into ischemic cortex 7 days after distal middle cerebral artery occlusion (dMCAo). Mice were treated with human 3K3A-APC (0.2 mg/kg, i.v.) at 7, 9, 11, and 13 days after stroke. 3K3A-APC substantially enhanced proliferation of NSCs and their differentiation into neuronal cells, and promoted functional integration of transplanted NSCs into the host neural circuitry resulting in significant improvement motor deficits as early as 2 weeks after transplantation. These findings suggest that 3K3A-APC-potentiated neuronal recruitment from engrafted NSCs may offer a new approach to the treatment of stroke and related neurologic disorders.

Title: Intranasal erythropoietin administration protects CA1 hippocampal neurons against cerebral ischemia in wistar rat

Authors: *R. MACIAS-VÉLEZ, M. RIVERA CERVANTES;
Univ. De Guadalajara, Guadalajara, Mexico

Abstract: Erythropoietin (EPO) in interaction with its receptor (EPOR) transduce multiple signals that activate cellular process like growing, differentiation and survival of hematopoietic stem cells. This receptor has been found not only in bone marrow but also in nervous tissue, in some regions like hippocampus, internal capsule, cortex and midbrain; where, it can activate survival signaling cascades. Research on animal models had demonstrated that EPO might be effective against hypoxic, ischemic, and traumatic brain injuries, administrated by peritoneal and intravenous way. But, a new and non-invasive approach to deliver EPO to the brain could be the intranasal pathway. Establishing this pathway as a potential and useful strategy to treat some CNS disorders, including stroke. The aim of this work was to establish an effective dose and time of administration to treat the detrimental effects of ischemia. For that reason, we administrated EPO in three different doses (500, 1000, 2500 UI/kg bw.) within three different times (1, 6, 24 h after blood reperfusion) after 20 minutes of cerebral ischemia carried on male wistar rats (250-300g bw). Cellularity was assessed by Nissl stain using a cresyl violet solution at 0.13% on coronal 10 um brain slices, counting the total number of cells with normal morphology (neurons with a round or oval nucleus, located in the center and surrounded by a pale cytoplasm) in CA1 hippocampal region. The results show that the dose which causes a higher number in normal cells was 1000 UI/kg and it could be used within the first 24 h after cerebral ischemia. Regarding to 500 UI/kg dose it remains efective just for the first two times (1 and 6 h), after that it seems to lose efficiency. And there was not any important change in number of normal cells by 2500 UI/kg dose administration within the three times used, compared to the ischemic group.

Title: Intraoperative monitoring of cerebral blood flow during brain tumor and cerebrovascular surgery by laser speckle flow imaging: Reliability and Practicality of measuring regional cerebral perfusion

Authors: *T. INOUE[1], M. IDEGUCHI[1], S. NOMURA[1], H. KOIZUMI[1], H. GOTO[1], Y. HIRAYAMA[1], E. SUEHIRO[1], F. OKA[1], K. SUGIMOTO[1], K. KAJIWARA[2], K. YOSHIKAWA[1], H. ISHIHARA[1], M. SUZUKI[1];

Abstract: Objective: To determine clinical utility of laser speckle flow imaging (LSFI), we used LSFI to monitor cerebral blood flow (CBF) as a complementary method for the management of during several kinds of neurosurgery. Methods: Intraoperative intensity of CBF by LSFI and pre- and postoperative CBF by 123I-iodoamphetamine single photon emission computed tomography (IMF-SPECT) were measured for 3 patients with internal carotid artery (ICA) aneurysms who were undergoing ICA-trapping surgery, for 16 patients with major cerebral artery occlusion who were undergoing EC-IC bypass surgery, and for 12 patients with mass lesion-related arteries and brain tumor or arterovenous malformation. LSFI device was centered over the surgical field, and the relative (CBF) before and after the temporary interruption of the arteries was measured through continuous recording. Results: The decrease in CBF (16.9% ± 2.3%) upon ICA interruption was equivalent to the decrease in CBF during the preoperative balloon test occlusion, as measured by IMP-SPECT (12.2% ± 4.4%). Whether preserved CBF in LSFI promised postoperative intact CBF was not determined, as no patient showed ischemic tolerance by ICA occlusion. The increase in CBF resulting from EC-IC bypass correlated moderately with the increase in postoperative CBF as measured by IMP-SPECT. However, the increase in CBF was too small to recognize intraoperatively by visual inspection. Good visualization of CBF in the surgical feld and relative CBF measurements in the regions of interest were achieved in real time with excellent spatiotemporal resolution. In 11 patients (92%) and 20 regions of interest, a decline in CBF was observed after temporary interruption of the feeding artery (n=8), passing artery (N=2), and both (n = 2) types. There was a signifcant average reduction in CBF of 15.3% ± 29.0%. There were no ischemic complications. Conclusion: Although LSFI clearly demonstrated a decrease in CBF, the information is taken only from the surface of the brain. LSFI was not sensitive enough to detect increased CBF by STA-MCA anastomosis, because CBF changes are minimized during anesthesia, probably owing to low metabolic activity. To recognition of mass lesion-related vasculature, however, LSFI can be used to avoid ischemic complications as procedure complementary to neurophysiological monitoring.

Title: Transfer of bacterial lipopolysaccharide-primed murine and human monocytes protects the brain from cerebral ischemic injury

Authors: *L. GARCIA-BONILLA, M. MURPHY, C. BENAKIS, D. BREA, C. IADECOLA, J. ANRATHER;
Feil Family Brain and Mind Res. Inst., Weill Cornell Med. Col., New York, NY

Abstract: Administration of a sub-lethal dose of the endotoxin lipopolysaccharide (LPS) renders the brain tolerant to a subsequent ischemic insult (preconditioning) [Nat Neurosci 14, 1363, 2011]. Given the prominent role of monocytes/macrophages as endotoxin sensors [Trends Immunol 30, 475, 2009], and as major players in regulating post-ischemic inflammation [Biochim Biophys Acta,1862, 329, 2016], we tested whether LPS is capable of inducing a protective phenotype in blood monocytes resulting in a reduction in ischemic injury. To this end, we evaluated if transferring of ex vivo LPS-primed monocytes into male C57Bl/6 mice confers protection after cerebral ischemia. Mouse monocytes were isolated from the bone marrow, 92±2% of which were $CD115^{+}Ly6C^{hi}$, and treated with saline or LPS (100 ng/ml). LPS stimulation of monocytes for 2 hours increased the expression of *Chi3l3* and *Retnla* mRNA, genes associated with an anti-inflammatory phenotype in monocytes/macrophages. Next, LPS-primed monocytes were injected ($5x10^5$ cells, i.v) into mice 7 hours after transient middle cerebral artery occlusion (MCAO; n=8-10 per group) and infarct volumes were assessed 72 hours later in cresyl violet-stained brain sections. Remarkably, mice receiving LPS-treated monocytes had a 56±10% reduction in infarct volume while no protection was observed in mice receiving saline-treated monocytes or if LPS stimulated monocytes were lysed before transfer (saline: 54±12 mm^3; LPS: 24±5 mm^3; $p<0.05$; LPS-lysed monocytes: 57±7 mm^3; mean±SE). To test whether this protective activity could also be elicited by human monocytes, we exposed purified human peripheral blood monocytes (79% $CD14^{+}CD16^{low}$) to saline or LPS and transferred them into mice that underwent MCAO as described above. Transfer of human monocytes that were exposed to LPS, but not saline, significantly reduced infarct volumes after MCA occlusion (24±5 vs. 45±8 mm^3; $p<0.05$). Immunohistochemical studies of adoptively transferred monocytes showed that both saline and LPS-primed monocytes were observed in the meninges but not in the brain parenchyma after stroke. Given that adoptively transferred

monocytes are localized to the meninges, a recently recognized gateway for immune cell infiltration into the ischemic brain, LPS primed monocytes might regulate leukocyte trafficking after stroke. In conclusion, our findings provide the rationale for new cell therapies based on the delivery of autologous or allogeneic protective monocytes into patients with ischemic stroke.

Title: A peptide disrupting kv2.1/syntaxin interaction is neuroprotective in cerebral ischemia

Authors: *C.-Y. YEH[1], A. M. BULAS[2], K. A. HARTNETT[2], C. T. ANDERSON[3], R. DI MAIO[4], T. TZOUNOPOULOS[3], D. SUN[4], R. KHANNA[5], E. AIZENMAN[2];
[2]Dept. of Neurobio., [3]Dept. of Otorhinolaryngology, [4]Dept. of Neurol., [1]Univ. of Pittsburgh, Pittsburgh, PA; [5]Dept. of Pharmacol., Univ. of Arizona, Tucson, AZ

Abstract: Neurodegeneration in the ischemic stroke penumbra involves caspase activation and represents an important target for therapeutic interventions. The voltage-gated potassium channel Kv2.1 has been shown to play an important role in programmed neuronal apoptosis. Previously, we have identified that Kv2.1 promotes caspase activation by generating a pronounced K^+ efflux through *de novo* channel insertion. This process is modulated by Zn^{2+}-dependent pathways leading to the phosphorylation of Kv2.1 at residues Y124 and S800, allowing interactions between the proximal Kv2.1 C-terminus (C1a) and the SNARE protein syntaxin 1A. Overexpression of the C1a decreases pseudo-apoptotic Kv2.1-S800E currents in CHO cells and improves neuronal survival after oxidative stress. Thus, suppressing apoptosis-permitting Kv2.1 currents through the competitive binding of syntaxin 1A represents a promising neuroprotective approach and is explored here through the evaluation of a peptide aptamer. Far-Western blot analysis of overlapping 15 a.a. segments of the C1a region found a 9 a.a. sequence with high binding affinity to syntaxin 1A. Conjugating the cell-permeable HIV trans-activator of

transcription domain (TAT) to the N-terminus of this sequence resulted in an administrable peptide construct (TAT-C1aB). *In vivo* two-photon imaging with FitC-tagged TAT-C1aB confirmed that i.p. administration of the peptide reaches brain vessels within minutes. Whole-cell patch clamp recordings demonstrated that incubation with 10 μM TAT-C1aB significantly reduces pseudo-apoptotic Kv2.1-S800E current density (vehicle vs TAT-C1aB: 267.2±22.03 vs 189.5±19.64, Mean±SEM pA/pF, n=11; p=0.0159) in CHO cells. Further, 1 μM TAT-C1aB treatment significantly decreased lactate dehydrogenase release in rat cortical neuron cultures after excitotoxic insult (2.45±0.24 vs 1.31±0.077, Mean±SEM normalized LDH readout, n=4 each group, p=0.0038). Proximity ligation assay revealed that post-injury TAT-C1aB incubation prevents the dramatic increase in Kv2.1/syntaxin interactions 3 hr after treatment with an apoptogen. Notably, in a mouse model of transient middle cerebral artery occlusion, injections of TAT-C1aB (i.p., 6nmol/g, at 1+6h reperfusion) significantly reduced infarct size (0.20±0.019 vs 0.12±0.016, Mean±SEM infarct ratio, n=10 and n=7 respectively, p=0.0053). In all above experiments, TAT-conjugated scramble control had no detectable effects. Together, these findings characterized a promising neuroprotectant prototype and established the Kv2.1/syntaxin interaction as a novel molecular target in ischemic stroke as well as other neurodegenerative diseases.

Title: Proportional stroke recovery in the rat: Evidence for a cross-species biological recovery process that incorporates initial impairment, infarct volume and rehabilitation intensity.

Authors: *M. S. JEFFERS, S. KARTHIKEYAN, D. CORBETT;
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Objective: Initial post-stroke impairment level and corticospinal tract lesion load have been identified as the most important predictors of functional recovery across time for human stroke. The present study sought to identify if similar biomarkers predict recovery of

post-stroke function in rats, indicating that an endogenous biological recovery process might be preserved across mammalian species. We then further investigated the roles of initial impairment, infarct volume and rehabilitation on this process. **Methods:** In a retrospective analysis of 593 male Sprague-Dawley rats we predicted post-stroke change in pellet retrieval (PR) in the Montoya staircase task based on the proportional recovery rule: $\Delta PR_{Predicted} = 0.7(PR_{Pre\text{-}stroke} - PR_{Initial})$. Stratification of the sample into "fitters" and "non-fitters" of this rule allowed identification of distinguishing characteristics using linear regression. **Results:** Approximately 30% of subjects were identified as "fitters" of the rule. Less severe infarct volumes and initial post-stroke impairments with a higher intensity of rehabilitation distinguished this group from "non-fitters". Interestingly, by using these characteristics to model recovery across the total sample we demonstrated that recovery could only be reliably predicted when rehabilitation is present. **Interpretation:** These findings suggest that proportional recovery is a cross-species phenomenon that can be modeled in Sprague-Dawley rats. Additionally, as infarct volume and initial impairment grow more severe, more intense rehabilitation is required in order to engage biological recovery processes.

Title: Effects of constraint-induced movement therapy (CIMT) and neural precursor cell (NPC) transplantation in the corpus callosum of the hypoxic-ischemic hemiplegic mouse model

Authors: ***P. RUMAJOGEE**[1], S. ALTAMENTOVA[1], J. LI[1], D. VAN DER KOOY[2], M. G. FEHLINGS[1];
[1]Genet. and Develop., Univ. Hlth. Network, Toronto, ON, Canada; [2]Mol. Genet., Inst. of Med. Sci., Toronto, ON, Canada

Abstract: BACKGROUND:
Cerebral palsy (CP) is the most common pediatric neurodevelopmental physical disability, with a prevalence of 2.3/1000 births, causing severe motor and developmental disturbances. Clinical

application of the Constraint-Induced Movement Therapy (CIMT) protocol shows functional benefits in hemiplegic CP. The usage of the child's "less-affected" arm is reduced in order to promote the overuse of the other, affected arm. CIMT has been suggested to trigger neural cell generation from endogenous neural precursor cell (NPC). However, the underlying mechanisms and optimal timing/mode of application remain poorly understood.
METHODS:
To investigate the hemiplegic CP, we use a Hypoxic-Ischemic model (HI) model. The right common carotid artery of post-natal day (PND) 7 C57Bl/6 mice is permanently occluded and, after 2 hours of recovery with the dam, the pups are exposed to hypoxic air (8% oxygen for 45 minutes).
The project has 3 major aspects: 1) Regeneration, which will focus on the effects of NPC transplantation in the corpus callosum (CC), known to be impacted early in the course of demyelinating conditions; 2) Rehabilitation, which will focus on the effects of CIMT; and 3) A third aspect is a combinatorial approach using NPCs and CIMT. NPCs are transplanted in the CC at PND21, while Botulinum toxin (Botox) is injected in 3 muscles of the right (unaffected) forelimb to mimic the CIMT protocol.
RESULTS:
Our results support the use NPCs and CIMT on the HI model. We have shown: A) Differences between HI and Control animals, as well as within HI groups (variability of injury): the CC morphology is affected; the HI mice use the unaffected forelimb with a clear preference (85% of the time); B) A good development and integration of NPCs in the CC, and co-localizations with neuronal, astrocytic as well as oligodendrocyte markers; C) A role of NPCs in functional recovery: after 1 month, some mice recover completely (50% use of the unaffected forelimb), while others recover only partially (78%); D) A recruitment of endogenous oligodendrocytes in the CC, most probably partially mediated by the transplanted NPCs; E) A potential synergistic effect between NPCs and CIMT.
CONCLUSION:
The variability of injury observed can recapitulate various aspects of clinical CP. This might be useful when developing translational treatment strategies. This work supports the use of NPC for CP treatment. However, while in our model direct re-myelination processes still remain to be demonstrated, significant recovery is observed after NPC and Botox treatments. Further investigation is needed in order to decipher the mechanisms of CIMT and a potential synergistic effect with NPCs.

Title: Docosahexaenoic acid provides neuroprotection by upregulating Iduna expression in the ischemic penumbra

Authors: N. G. BAZAN[1], P. K. MUKHERJEE[1], V. BALASZCZUK[1], A. OBENAUS[2], *L. KHOUTOROVA[1], S.-H. HONG[3], L. BELAYEV[1];
[1]LSU, New Orleans, LA; [2]Loma Linda Univ., Loma Linda, CA; [3]Baylor Col. of Medicine,, Houston, TX

Abstract: Ring finger protein 146, also called Iduna, has been identified as a neuroprotective protein. Iduna facilitates DNA repair and protects against cell death induced by NMDA receptor-mediated glutamate excitotoxicity or cerebral ischemia. Recently, we have shown that docosahexaenoic acid (DHA; 22:6n-3) therapy improves functional and histological outcomes following experimental stroke. This study evaluated the time course expression of Iduna in the ischemic penumbra and the role of DHA in cerebral ischemia and its potential mechanism. Thirty-six male SD rats were anesthetized with isoflurane and subjected to 2 h of middle cerebral artery occlusion (MCAo) by poly-L-lysine-coated intraluminal suture. DHA (5 mg/kg) or vehicle (saline) was administered IV at 3 h after the onset of MCAo, and animals were sacrificed on days 1, 3 and 7 (n=6 rats per group). Neurological function was evaluated during occlusion (60 min) and on days 1, 3 and 7 after MCAo; a grading scale of 0-12 was employed (0=normal and 12=maximal deficit). *Ex vivo* MRI, Western blot and immunohistochemistry (Iduna/NeuN and Iduna/GFAP) were conducted on days 1, 3 and 7. All animals showed similar values for rectal and cranial temperatures, arterial blood gases, and plasma glucose during and after MCAo. Behavioral deficit was significantly improved by treatment with DHA compared to vehicle on days 1 (by 30%), 3 (by 31%) and 7 (by 32%). DHA treatment rescued the ischemic core and penumbra, reduced T2 values (decreased edema) and cortical, subcortical, total lesion volumes (by 63-87%) on days 3 and 7. Western-blot analysis showed that DHA treatment increased Iduna expression in the ischemic penumbra compared to vehicle on days 1 (2.2±0.3 vs. 0.6±0.1) and 3 (0.44±0.05 vs. 0.3±0.01, respectively). There were no differences in Iduna expression on day 7 between DHA and vehicle-treated groups. Immunostaining revealed that Iduna expression was increased in the penumbra of DHA-treated rats. DHA protected the brain from severe damage caused by MCAo. This effect may be through upregulation of Iduna expression in the ischemic

penumbra. Thus, it is reasonable to hypothesize that DHA has potential for the effective treatment of ischemic stroke in patients.

Title: Differential analysis of oxygen radical formation in vasculature and parenchyma and its suppression by a nitrone (PBN) in an experimental model of ischemia/reperfusion by intravital fluorescence microscopy

Authors: *A. TASKIRAN SAG[1], M. YEMISCI[1], Y. GURSOY-OZDEMIR[1], E. S. ERDENER[1], D. YUCE[2], T. DALKARA[1];
[1]Hacettepe Univ. Inst. of Neurolog. Sci., Ankara, Turkey; [2]Hacettepe Univ. Cancer Inst., Ankara, Turkey

Abstract: Objective: Oxygen/nitrogen radicals are intensely produced on restoration of oxygen supply to the ischemic tissue and contribute to reperfusion injury and radicals reach to highest concentration on the microcirculation. N-tert-butyl-alpha-phenyl-nitrone (PBN), a superoxide scavenger, significantly decreases infarct volume when administered at the time of recanalization. Interestingly, its sulfo-derivative, S-PBN, which is blood-brain barrier impermeable, is equally protective to PBN, raising the possibility that the main site of action of PBN could be vasculature rather than the parenchyma. We investigated the cellular sources of oxidative stress during reperfusion and its suppression by PBN with intravital fluorescence microscopy.**Methods:** In mice under anesthesia, the distal middle cerebral artery was occluded by compression for 1 hour and then recanalized. For the following 1 hour, superoxide formation was monitored in the vasculature and parenchyma with topically applied dihydroethidium (DHE). Vessels with a diameter ranging from 20 to 60 μm were analyzed. PBN (100 mg/kg) was applied intraperitoneally 15 minutes before reperfusion and suppression of the arterial, venous, parenchymal DHE fluorescence was examined. Repeated measures designs in linear models were used for statistical evaluations.**Results:** We observed an intense increase in DHE fluorescence in vasculature as well as parenchyma during reperfusion. PBN significantly and

similarly suppressed DHE fluorescence in all compartments ($p<0.001$ for arterial and venous wall; $p=0.003$ for parenchyma).**Conclusions:** These data suggest that PBN's neuroprotective action is produced by suppression of radical toxicity in vascular as well as parenchymal compartments. However, the possibility that the vascular protection could secondarily reduce parenchymal radical stress should also be considered.

Title: Mechanisms of ischemic post-conditioning in the retina

Authors: ***S. KEIL**[1], B. MATHEW[2], L. TORRES[2], S. ROTH[3];
[1]Univ. of Illinois Chicago, Chicago, IL; [2]Anesthesiol., [3]Anesthesiol. and Ophthalmology, Univ. of Illinois, Chicago, IL

Abstract: We previously described the phenomenon of ischemic post conditioning in the in vivo retina. A brief period of ischemia following a prolonged damaging ischemia was capable of decreasing injury in the rat retina in vivo. We showed "delayed" post-conditioning, in which application of a brief ischemic stimulus as late as 24 h after damaging ischemia significantly improved functional recovery, and preserved structure. In the present study we examined the signaling mechanisms in delayed post conditioning (post-C). Rats were subjected to retinal ischemia by elevation of intraocular pressure. 24 h later, 8 min ischemia was applied, and retinae were harvested from the animals 24 h later. The retinal homogenates were applied to Kinexus antibody microarrays (over 800 proteins). The arrays were analyzed using a microarray analyzer. We compared results in ischemia + post-C to ischemia + sham post-C. Z scores were used to evaluate thresholds for significant increases or decreases in the phosphoproteins. Real time PCR was used to confirm results. We found significant increases in a group of proteins in the ischemia + post-C, which were decreased in ischemia + sham post-C. The proteins were: B23, 4EBP1, COX2, CDK7, LIMK1, Tau, Bcl, MST3, and VHR. These results indicate candidate proteins that may be involved in neuroprotection.

Title: Auraptene acts as an anti-inflammatory and neuroprotective agent in the mouse brain

Authors: ***S. OKUYAMA**, M. MORITA, M. KAJI, K. SHIMAMOTO, Y. OOKIDO, Y. AMAKURA, M. YOSHIMURA, M. NAKAJIMA, Y. FURUKAWA;
Col. of Pharmaceut. Sciences, Matsuyama Univ., Matsuyama, Ehime, Japan

Abstract: The anti-inflammatory activity of auraptene (AUR), a citrus coumarin, in peripheral tissues is well-studied. Our recent studies indicate the possibility that AUR exerts anti-inflammatory effects not only in peripheral tissues but also in the brain. In the present study, we investigated whether AUR directly exerts anti-inflammatory effects in the brain, and obtained the following results. (1) When a transient global cerebral ischemic mouse model was treated with AUR (25 mg/kg/day) for five days before and another three days after ischemic surgery, AUR suppressed neuronal cell death in the hippocampal CA1 region, microglia and astrocyte activation, and COX-2 mRNA expression in the hippocampus. (2) When cultured astrocytes were pretreated with AUR (25 μM) for 30 min before lipopolysaccharide (LPS)-treatment, AUR suppressed the LPS-induced expression of COX-2 mRNA and the mRNAs of pro-inflammatory cytokines. (3) When mouse was intraperitoneally administered with AUR (50 mg/kg), AUR was still detectable in the brain 60 min. These results suggested that AUR pass through the blood-brain-barrier and directly exerts anti-inflammatory effects on the brain, and that these effects were at least partly mediated by the suppression of inflammatory mediators derived from astrocytes.

Title: Establishment of the therapeutic window of the S-allylcysteine in an animal model to 1 hour of ischemia and 14 days of reperfution.

Authors: *C. A. ORTIZ, P. D. MALDONADO;
Patología Vascular Cerebral, Inst. Nacional De Neurología Y Neurocirugía, México, Mexico

Abstract: Background: It has been reported that the SAC is one of the biologically active compounds of aged garlic extract as it has shown to be a potent antioxidant in different models where oxidative stress plays a very important role. Specifically, in the model of cerebral ischemia, it is known that the SAC prevents edema formation because it inhibits lipid peroxidation and free radical production. Also recently in the laboratory was found that administration of SAC 1 h after the beginning of reperfusion decrease cerebral damage at 14 days of reperfusion. **Methods:** Wistar male rats were used with an initial weight between 280-320 g, randomly divided into five groups: the control group (CT); cerebral ischemia (1 h)/reperfusion (14 days) (IR) group; IR+SAC0 group; IR+SAC2 group; and IR+SAC4 group. Animals were anesthetized and underwent surgery to induce ischemic brain damage, temporarily occluding the middle cerebral artery (for 1 h) and allowing reperfusion of animals for 14 days. The SAC was administered orally at a dose of 100mg/kg at the following times: the beginning of reperfusion (time 0 h), 2 and 4 h after the beginning of reperfusion. The neurological deficit was evaluated in rats damaged by ischemia through 5 tests: spontaneous mobility, contralateral turns to injury, try hanging by the tail, ability to hold on to a cable and ability to attach to a cable. Quantification of the damage was made by a person blind to the treatment of samples. The mortality rate in this process is high **Results:** It was observed that the neurological deficits of animals after 14 days of reperfusion improvement SAC administration 2 h after reperfusion compared SAC administered at time 0 and at 4 h. Also a change was observed in the weight of the animals during the 14 days of reperfusion, in which it is noted that in the administration of the SAC at 2 h and 4 h after reperfusion produces greater protection since animals lose less weight and have a recovery after 7 days compared wiyh IR group. **Conclusions:** SAC treatment (100mg/kg) 2 h after onset reperfusion induces a neuroprotection in animals.

Title: Restoring cell surface expression of GABA (B) receptors: a potential strategy to limit neuronal death in cerebral ischemia

Authors: *K. BALAKRISHNAN[1,2], D. BENKE[1,2];
[2]Inst. of Pharmacol. and Toxicology, [1]Univ. of Zurich, Zurich, Switzerland

Abstract: Cerebral ischemia is a leading cause for long-term disability and mortality in adults due to prolonged massive neuronal death. One major mechanism behind ischemia-induced neuronal death is the excessive release of glutamate upon oxygen and glucose deprivation (OGD) occurring during ischemic stroke. Ischemic overexcitation of neurons downregulates GABA(B) receptors, which normally control excessive excitatory neurotransmission by mediating slow and prolonged neuronal inhibition. Sustained activation of glutamate receptors increases the intracellular Ca^{2+} concentration enhancing the activity of CaMKII, which leads to the phosphorylation of $GABA_B$ receptors at S867 in the C-terminal domain of the $GABA_{B1}$ subunit. This sorts the constitutively endocytosed $GABA_B$ receptors to lysosomal degradation instead of recycling them back to the cell surface. In this study we tested the hypothesis that restoring cell surface expression of $GABA_B$ receptors may prevent neuronal death under ischemic conditions. We identified a short synthetic peptide that prevents the interaction of CaMKII with $GABA_{B1}$ and consequently prevented the phosphorylation of $GABA_{B1}$ (S867). This short-interfering peptide prevented glutamate-induced downregulation of GABA(B) receptors in cultured cortical neurons and limited glutamate and OGD-induced neuronal death. Therefore, we expect that the preserved cell surface $GABA_B$ receptors levels under ischemic conditions counteract the excessive neuronal excitation and thus limit neuronal death in-vivo.

Title: CD38 knockout mice show significant protection against ischemic brain damage despite high level poly-ADp-ribosylation

Authors: A. LONG[1], J. H. PARK[1], N. KLIMOVA[2], D. J. LOANE[2], *T. KRISTIAN[2,1]; [1]Veterans Affairs Maryland Hlth. Ctr. Syst., Baltimore, MD; [2]Dept Anesthesiol, Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Several enzymes in cellular bioenergetics metabolism require NAD^+ as an essential cofactor for their activity. NAD^+ depletion following ischemic insult can result in cell death and has been associated with over-activation of poly-ADP-ribose polymerase PARP1 as well as an increase in NAD^+ consuming enzyme CD38. CD38 is an NAD^+ glycohydrolase that uses NAD^+ to generate second messengers cyclic ADP-ribose and ADP-ribose, playing an important role in inflammatory responses.

To determine the contribution of CD38 activity to the mechanisms of post-ischemic brain damage we subjected CD38 knockout (CD38KO) mice and wild-type (WT) mice to transient forebrain ischemia. The CD38KO mice showed a significant amelioration in both histological and neurologic outcome following ischemic insult. These mice exhibited only a 26% decrease in CA1 surviving neurons as compared to 50% in the WT. In general control CD38KO mice had significantly higher number of CA1 neurons when compared to control WT mice. Decrease of hippocampal NAD^+ levels detected during reperfusion in WT mice was only transient in CD38KO animals, suggesting that CD38 contributes to post-ischemic NAD^+ catabolism. Surprisingly, pre-ischemic poly-ADP-ribose (PAR) levels were 140% higher in CD38KO animals compared to WT animals and exhibited reduction post-ischemia in contrast to the increased levels in WT animals. The high PAR levels in CD38 mice were due to the reduced expression levels of poly-ADP-ribose glycohydrolase (PARG) in these animals. PARG catabolizes PAR and converts it to ADP-ribose. Thus, the absence of CD38 activity can not only directly affect inflammatory response, but also result in unpredicted alterations in the expression levels of enzymes participating in NAD^+ metabolism. Although the CD38KO mice showed significant protection against ischemic brain injury, the changes in enzyme activity related to NAD^+ metabolism makes the determination of the role of CD38 in mechanisms of ischemia-induced brain damage ambiguous.

Title: Ischaemia-induced erased perineuronal nets and damaged, but persisting GABAergic neurons in the nucleus reticularis thalami of wildtype and 3xTg mice

Authors: *W. HARTIG[1], S. APPEL[1], A. SUTTKUS[1], J. GROSCHE[2], D. MICHALSKI[3]; [1]Univ. Leipzig, PFI, Leipzig, Germany; [2]Effigos GmbH, Leipzig, Germany; [3]Univ. Leipzig, Dept of Neurol., Leipzig, Germany

Abstract: Treatment of ischaemic stroke is limited to intravenous thrombolysis and mechanical thrombectomy as recanalizing approaches. The urgently requested translation of further treatment options requires clinically relevant stroke models and should consider co-morbidities, age-dependency of neuropathological alterations and the complexity of the neurovascular unit (NVU). The NVU comprises not only neurons but also affected vessels, glial cells and the extracellular matrix (ECM) with perineuronal nets (PNs). These highly anionic, chondroitin sulphate proteoglycan-rich surroundings of certain neurons were comprehensively characterized in the naive brain. However, the role of PNs during ischaemia and as potential target for treatments is poorly understood. Therefore, this study is focused on stroke-induced alterations of PNs and GABAergic neurons with emphasis on the nucleus reticularis thalami (NRT). Mice underwent focal cerebral ischaemia by an occlusion of the middle cerebral artery, resulting in clinically relevant, predominantly striatal lesions. Experiments were performed with 3- and 12-month-old wild-type mice and co-morbid triple-transgenic (3xTg) mice displaying age-dependent Alzheimer-like alterations. One day after ischaemia onset, forebrain sections comprising the NRT were applied to double fluorescence labelling of biotinylated *Wisteria floribunda* agglutinin (WFA) as established marker for PNs and parvalbumin in fast-firing GABAergic neurons. Semiquantitative analyses revealed staining intensities, staining areas and cell counts for WFA and parvalbumin. The ischaemia-affected NRT displayed a drastic decline of WFA-staining compared with the contralateral, non-affected side. In parallel, parvalbumin-immunoreactivity was affected by ischaemia to a much lesser degree. Additional immunostaining detected the ischaemia-induced loss of aggrecan and neurocan in PNs and allocated neuropil. Further multiple immunofluorescence labelling demonstrated clearly

damaged GABAergic neurons in the ischaemic NRT, persistingly expressing the calcium-binding proteins parvalbumin and calbindin, the potassium channel subunit Kv3.1b and the glutamate decarboxylase isoforms GAD65 and GAD67 as their marker enzymes. In conclusion, our data show PNs as highly vulnerable constituents of the ECM under ischaemic conditions. Therefore, components of the extracellular matrix appear as promising targets of future neuroprotective strategies in acute ischaemic stroke which might also include ECM-degrading enzymes such as metalloproteinases, chondroitinases and aggrecanases.

Title: Neuroprotection by BDNF following OGD is higher in hippocampus than in cerebral cortex in an "*Ex vivo*" model of rat brain slices.

Authors: *P. GONZALEZ-RODRIGUEZ[1], E. FONT[1], B. ANUNCIBAY-SOTO[1], D. PÉREZ-RODRÍGUEZ[1], C. PÉREZ-GARCÍA[2], A. FERNÁNDEZ-LÓPEZ[1];

Abstract: Brain derived neurotrophic factor (BDNF) is a neurotrophin reported to present a neuroprotective effect on stroke. In this study, we analyze the effect of the presence of BDNF on slices of cerebral cortex (Cx) and hippocampus (Hp) in an "ex vivo" model, correlating the cell mortality and viability as well as the expression of some prosurvival genes. The study was carried out on 350 μm thick brain slices under oxygen and glucose deprivation (OGD) for 30 minutes followed by 60 and 180 minutes in normoxic solution (reperfusion-like condition). Hp and the Cx above it were analyzed independently. Mortality and viability were measured in BDNF dose-response curves by testing LDH and MTT respectively. Protein and mRNA levels of different AKT pathway markers were measured by Western blot and qPCR respectively. The

neuroprotective role reported for BDNF was consistent with the decreased mortality and increased survival observed in our "ex vivo" assays. In spite of its higher vulnerability, Hp presented a higher BDNF-response than Cx which could be related to the higher amount of the BDNF receptor, tropomyosin receptor kinase B (TrkB), in Hp. Furthermore BDNF significantly increased the expression of some genes in the AKT pathway, such as Nrf-2 induced genes, bcl-2 and c-fos in Hp but not in Cx. We conclude that the neuroprotective effect of BDNF can be already detected in the first hour of reperfusion. Furthermore this effect is stronger in Hp than in Cx.

Title: The impact of BDNF-Val66Met polymorphism upon GABAergic innervation of cortical pyramidal neurons and spiny striatal neurons in an animal model of ischemic stroke

Authors: H. ACTOR-ENGEL[1], B. S. RANA[1], Y.-W. CHEN[1], S. CHO[2], *C. J. AOKI[1]; [1]Ctr. Neural Sci., New York Univ., New York, NY; [2]Brain and Mind Res. Inst., Burke Med. Res. Inst., Weill Cornell Med. Coll, White Plains, NY

Abstract: Stroke induces structural plasticity and behavioral adaptation. Previously, it was shown that mice expressing the genetic variant of BDNF (Val66Met) exhibit greater acute motor deficits but unexpected enhancement of motor/gait function during the recovery phase, due to contribution by the intact hemisphere, when challenged by unilateral ischemic stroke (Qin et al., J Neurosci 34: 2493, 2014). We hypothesized that these bi-directional effects of BDNF-

Val66Met upon motor function recovery may be due to the multifaceted functions of BDNF: while BDNF is important for GABAergic synaptogenesis, it also reduces GABA release from mature synapses and supports LTP of excitatory synapses. Its bi-directional effect may additionally be due to the altered intracellular distribution pattern of BDNF within neurons: Val66Met SNP causes reduction in the intracellular trafficking of BDNF-mRNA and proteins, thereby reducing BDNF secretion from distal neurites but accumulating it within neuronal cell bodies. To test this hypothesis, we sought to determine whether ischemic stroke induced by 30 min occlusion of the middle cerebral artery (MCAO) leads to alterations in GABAergic synaptic inputs upon spiny neurons of cortex and striatum of the intact hemisphere, contralateral to ischemia, and whether this response differs across two genotypes of mice: $BDNF^{+/+}$ versus $BDNF^{Met/Met}$ (homozygous for the SNP). Mice of each genotype underwent MCAO at 3 months of age or were sham-operated. These and naïve animals were euthanized at 9 to 10 mo of age. Histology confirmed that MCAO caused drastic degeneration of the ipsilateral cerebral cortex and striatum, while sparing the contralateral hemisphere, thereby serving as a good animal model for studying the contribution made by the non-lesioned hemisphere in recovery from ischemic stroke. GABAergic innervation of neurons within these brains have begun to be assessed by quantifying the number and lengths of GABAergic synapses forming upon cell bodies and distal dendrites of neurons by EM-ICC, using anti-glutamic acid decarboxylase (GAD), the rate-limiting synthetic enzyme of GABA, to immunolabel GABAergic neurons. Details of the procedure are as described in a previous publication (Yi-Wen Chen et al., Cerebral Cortex, 2015). Based on data obtained from naive $BDNF^{Met/Met}$ brains analyzed at 2 months of age, we expect to observe decreased innervation of distal dendrites in both regions, which would be the cellular substrate for hyper-excitability within the striatum and of the cortico-striatal and striatal-nigral pathways.

Title: The glucagon like peptide 1 receptor agonist exendin4 ameliorates warfarin associated hemorrhagic transformation after cerebral ischemia

Authors: *M. CUI, F. Z. CHEN, W. F. WANG, H. Y. DING, Q. YANG, Q. DONG;
Fudan Univ. Huashan Hosp., Shanghai, China

Abstract: Background: As the number of patients with cardioembolic ischemic stroke is predicted to be double by 2030, increased burden of warfarin-associated hemorrhagic transformation (HT) after cerebral ischemia is an expected consequence. However, thus far, no effective treatment strategy is available for HT prevention in routine clinical practice. While the glucagon-like peptide-1 receptor (GLP-1R) agonist exendin-4 (Ex-4) is known to protect against oxidative stress and neuronal cell death caused by ischemic brain damage, its effect in preventing warfarin-associated HT after cerebral ischemia is yet unknown. Therefore, we hypothesized that Ex-4 would stabilize the blood-brain barrier (BBB) and suppress neuroinflammation through PI3K-Akt–induced inhibition of GSK-3β after warfarin-associated HT post-cerebral ischemia.
Methods: We used male C57BL/6 mice for all experiments. A 5-mg warfarin sodium tablet was dissolved in the animals' drinking water (effective warfarin uptake: 0.04 mg [2 mg/kg] per mouse). The mice were fed for 0, 6, 12, or 24 h with ad libitum access to the treated water. To study the effects of Ex-4, temporary middle cerebral artery occlusion (MCAO) was performed. Then, either Ex-4 (10 mg/kg) or saline was injected through the tail vein, and in the Ex-4 + wortmannin group, PI3K inhibitor wortmannin was intravenously injected, after reperfusion. The infarct volume, neurological deficits, and integrity of the BBB were assessed 72 h post MCAO. One- or two-way ANOVA was used to test the difference between means followed by Newman–Keuls post-hoc testing for pair-wise comparison.
Results: We observed that Ex-4 ameliorated warfarin-associated HT and preserved the integrity of the BBB after cerebral ischemia through the PI3K/Akt/GSK-3β pathway. Furthermore, Ex-4 suppressed oxidative DNA damage and lipid peroxidation, attenuated pro-inflammatory cytokine expression levels, and suppressed microglial activation and neutrophil infiltration in warfarin-associated HT post-cerebral ischemia. However, these effects were totally abolished in the mice treated with Ex-4 + the PI3K
inhibitor—wortmannin. The PI3K/Akt-GSK-3β signaling pathway appeared to contribute to the protection afforded by Ex-4 in the warfarin-associated HT model.
Conclusions: GLP-1 administration could reduce warfarin-associated HT in mice. This beneficial effect of GLP-1 is associated with attenuating neuroinflammation and BBB disruption by inactivating GSK-3β through the PI3K/Akt pathway.

Title: L Nio induced focal subcortical white matter stroke in mice

Authors: *Y. WANG, Z. ZHAO, A. MONTAGNE, B. ZLOKOVIC;
Zilkha Neurogenetic Inst., Keck Sch. of Medicine, USC, Los Angeles, CA

Abstract: Up to 30% of strokes in humans occur initially as silent infarcts in the white matter (WM), which increases risk for vascular cognitive impairment and dementia (VCID). Subcortical WM stroke model has been induced by vasoconstrictor N5-(1-iminoethyl)-L-ornithine, dihydrochloride (L-Nio). In this study, L-Nio (Calbiochem) was injected into subcortical WM of the anterior cingulum (AC) of the corticolimbic circuit using the Neurostar motorized ultra-precise small animal stereotaxic instrument (Model 963SD). The ischemic injury was verified by cresyl violet staining and MRI 24 h after L-Nio injection. Remote memory test and foot-fault test were performed two weeks after L-Nio injection in AC. The results showed that L-Nio can produce dose-dependent brain infarcts and focal mini-stroke confined to AC. The mice with L-Nio injection in AC developed impaired remote memory retrieval, a deficit of the corticolimbic circuit, but did not have deficits in motor function. These results demonstrated that L-Nio provided a reliable and reproducible model of focal stroke in WM.

Title: Pharmacologically induced hypothermia extends the therapeutic window for tpa to 6 hr after onset of embolic stroke in mice

Authors: *J. LEE, S. WON, L. WEI, S. YU;
Dept. of Anesthesiol., Emory Univ., Atlanta, GA

Abstract: Preclinical and clinical studies have shown therapeutic potential of mild-to-moderate hypothermia for treating stroke patients. Our recent studies showed that pharmacologically induced hypothermia (PIH) using our neurotensin receptor 1 (NTR1) agonists is effective in inducing therapeutic hypothermia and protecting the brain from ischemic and hemorrhagic stroke in mice and rats. We here tested the hypothermic and neuroprotective effect of HPI-363, a second-generation NTR1 agonist, in combination with delayed thrombolytic therapy in a mice model of embolic stroke. Adult mice subjected to embolic middle cerebral artery (MCA) occlusion were treated with HPI-363 at 0.5 hr after stroke and maintained hypothermia (31-33°C) until delayed treatment of tissue plasminogen activator (tPA) 4.5 or 6 hrs after stroke. In stroke mice the 4.5-6 hr-delayed tPA treatment caused significant increases in infarct volume and hemorrhagic transformation at 24 hr after stroke compared with saline-treated stroke mice. However, the HPI-363-induced hypothermic treatment significantly reduced infarct volume, hemorrhagic transformation, and the embolus volume at the site of the MCA occlusion at 24 hr after stroke compared with stroke plus tPA treatment alone. Furthermore, HPI-363 treatment with tPA reduced the expression and activity of matrix metalloproteinase-9 (MMP-9), improved microvascular density, and protective effects on BBB integrity. In conclusion, a combination of PIH early treatment with delayed tPA administration extended the therapeutic window for stroke to 6 hrs without increasing the incidence of hemorrhagic transformation. This combination approach may benefit clinical treatments of embolic strokes.

Council, Pisa, Italy; [5]Scuola Normale Superiore, Pisa, Italy; [6]EPFL, Lausanne, Switzerland

Abstract: Stroke affects 15 million people worldwide every year and is one of the leading causes of long-term disability. Neurorehabilitation protocols based on the use of robotic devices provide a highly repeatable therapy and have recently shown promising clinical results. Little is known about how rehabilitation molds the brain to promote motor recovery of the affected limb. We used a custom-made robotic platform that provides quantitative assessment of forelimb function in a retraction test. Complementary imaging techniques allowed us to access to the multiple facets of robotic rehabilitation-induced cortical plasticity after unilateral photothrombotic stroke in mice Primary Motor Cortex (Caudal Forelimb Area - CFA). First, we analyzed structural features of vasculature and dendritic reshaping in the peri-infarct area with two-photon fluorescence microscopy. Longitudinal analysis of dendritic branches and spines of pyramidal neurons suggests that robotic rehabilitation promotes the stabilization of peri-infarct cortical excitatory circuits, which is not accompanied by consistent vascular reorganization towards pre-stroke conditions. To investigate if this structural stabilization was linked to functional remapping, we performed mesoscale wide-field imaging on GCaMP6 mice while performing the motor task on the robotic platform. We revealed temporal and spatial features of the motor-triggered cortical activation, shining new light on rehabilitation-induced functional remapping of the ipsilesional cortex. Finally, by using an all-optical approach that combines optogenetic activation of the contralesional hemisphere and wide-field functional imaging of

peri-infarct area, we dissected the effect of robotic rehabilitation on inter-hemispheric cortico-cortical connectivity.

Abstract: Chronic cerebral hypoperfusion, among other pathophysiological processes, is a causal factor accounting for the development of cognitive decline and dementia in the elderly. Consequently, inhibition of several pathophysiological pathways of neuronal damage is an attractive neuroprotective strategy for the clinical management of these disorder. Melatonin, protects the brain against several insults through its antioxidant and anti-inflammatory properties. Sprague- Dawley rats with permanent bilateral common carotid artery occlusion (2VO), a well-established model of chronic cerebral hypoperfusion, were used. Melatonin 5mg/ml was administered to rats (2VO + MEL group) by continuous IV infusion from a subcutaneously implanted osmotic pump ALZET, Model 2ML1 (10µl/hr., 7 days, 2ml), or vehicle ethanol 15% in saline (2VO+VEH group),starting one day, after 2VO. A SHAM group was also included. Fifteen days after melatonin treatment, the neuroprotective effect of melatonin, was evaluated by means of spatial learning /memory tests performance (Morris Water Maze). In addition, the pyramidal neuron population of the CA1 segment of hippocampus was assessed at the end of the behavioral testing period. Impairment of place learning in the 2VO+VEH group, while a similar

performance of the 2VO + MEL group and SHAM group were observed. A significant loss of pyramidal neuron population in the CA1 segment of hippocampus (28.4 % less than in the SHAM group) was observed in the 2VO+VEH group. By contrast, a 95% pyramidal neuron population of the CA1 segment of hippocampus remained in the 2VO + MEL group. Overall these results emphasize the efficacy of melatonin in counteracting the pathophysiological processes induced by chronic cerebral hypoperfusion. Title: Hyaluronic acid hydrogel combined with cell therapy in experimental stroke

Authors: *L. SIMOES BRAGA BOISSERAND[1,2], J. PAPASSIN[2], N. COLLOMB[1], E. BARBIER[1], C. ROME[1], O. DETANTE[2];
[1]Grenoble Inst. Des Neurosciences, Grenoble, France; [2]Neurol., CHU Grenoble, Grenoble, France

Abstract: Introduction: Stroke is the leading cause of disability in adults, for which no effective treatment exists after the first 6 hours . Most evidences suggest that stem cell (SC) therapies have the potential to reduce post-stroke disability. Despite of beneficial effects, an important loss of grafted SC is reported when cells are administrated into infarct cavity. Development of biomaterials such as hydrogels in combination with stem cells (SC) or trophic factors can enhance brain remodeling after stroke. Hydrogels can be engineered to polymerize *in situ* allowing an *ex vivo* mixing with SC and an administration using a minimal invasiveness intracerebral (IC) injection.
Objective: Mesenchymal stem cells (MSC) were co-administrated with a hyaluronic acid hydrogel (Hystem, Sigma) with the aim to improve graft survival and potentiate their beneficial effects concerning functional outcome and brain remodeling after stroke.
Methods: 36 Sprague Dawley male rats, aged of 8 weeks were submitted to 90 minutes middle cerebral artery occlusion (MCAo) or sham surgery. One week later, rats were divided in 4 groups

1) IC injection of 10^5 human MSC mixed with hydrogel (n = 9); 2) IC MSC in Phosphate-buffered saline (PBS) (n=8); 3) IC PBS alone (n=2); 4) control group (sham for MCAo and treatment; n=6). The rats were followed during 4 weeks and assessed once a week by sensory-motor tests (n=36) (modified neurological severity score (mNSS) and adhesive removal test (ART)) and MRI (n=26 among the 36 rats). MRI scans were performed at D3, 9, 14, 21 and 28 on a 4.7T system (Bruker).
Results and discussion: Two days after MCAo, a mild neurological deficit was observed, without any significant difference among them. Combined MSC-hydrogel transplantation non significantly decreased neurological deficit from 28 days onward (mean +/- SD; mNSS: MSC-Hydrogel group 1.9 ± 1.8 vs. MSC group 2.9 ± 2.3; ART for left impaired forelimb 33.8s ± 35.2 vs. 45.1s ± 47.5 respectively). MRI analysis put in evidence an increase on Apparent Diffusion Coefficient (ADC) at day 29 for the ischemic groups: MSC+gel (1591±657 $\mu m^2/s$), MSC (1690±622 $\mu m^2/s$) in comparison with Sham (860±73 $\mu m^2/s$).
Conclusion: Hyaluronic acid hydrogel added to cell therapy presents no adverse effects after stroke. Longer follow-up will be required to determine if a synergic effect can be observed. Multiparametric MRI analysis is in progress and the number of animals per group will be increased.

Title: Impact of crhr1 blockade on the expression of bdnf, trkb, and th in the vta following global cerebral ischemia

Authors: *N. F. NARVAEZ LINARES, J. ISAA, P. BARRA DE LA TREMBLAYE, H. PLAMONDON;
Behavioral Neurosci., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: The ventral tegmental area (VTA) in the brain's reward circuitry is composed of a heterogeneous population of dopamine, GABA, and glutamate neurons that play important roles in mediating mood-related functions including depression. These neurons project to different brain regions, including the nucleus accumbens (NAc) and the medial prefrontal cortex (mPFC). Brain-derived neurotrophic factor (BDNF) protein and gene are upregulated in the NAc and VTA in rodents susceptible to depressive behaviors following chronic defeat stress. Corticotropin-releasing factor (CRF) plays a role in BDNF increase observed at the NAc. Moreover, blockade of CRH type 1 receptors (CRHR1) has been associated with anxiolytic and antidepressant effects in rodents. The current study assessed the role of CRHR1 in regulating expression of Tyrosine Hydroxylase (TH) and BDNF and its receptor, TrkB in the VTA after a global ischemia. Wistar male rats (N = 70) received an injection of antalarmin (Ant, 2µg / µl), a specific antagonist CRHR1, or a saline solution (Sal) before global ischemia. Expression of cerebral plasticity factors in the VTA was assessed 30 days following 10 min global ischemia. This study demonstrated that lasting dysregulation of neuroendocrine function following global cerebral ischemia could be blocked by the pre-ischemic administration of a CRHR1 antagonist, Antalarmin. Thereby, this research is one of the first assessing the role of CRHR1 signaling in regulation of BDNF and its receptor TrKB in dopaminergic neurons of the VTA following global cerebral ischemia.

Title: Nesting environment impacts hypoxic-ischemic injury in rodents

Authors: *B. M. MASON, V. ROMERO, L.-G. ROLLINS, S. LAMOUR, N. WALTON, P. LONDOÑO, S. DONALDSON, S. EID;
Univ. of Massachusetts, Boston, Boston, MA

Abstract: Hypoxic-ischemic encephalopathy (HIE) is a brain injury that follows difficult perinatal birth conditions and can lead to substantial white matter damage, neuron loss in motor and cognitive brain areas, motor impairment and cognitive decline. Adverse environments such

as poverty and stress may worsen these consequences. In rodent models, a strong link has been established between levels of maternal care-taking behavior (mCTB) and neurogenesis in neonatal pups, where high mCTB may decrease stress and promote neuroprotection. Therefore, we hypothesized that cage modification with a closed nestbox (CN) during pre-weaning would promote mCTB and pup weight gain, and in turn, protect again neuronal loss in HI injured postnatal day (PND) 7 Long Evans rats. Utilizing a cohort of both male and female pups (*N = 42 - 51*) under three conditions (control, sham, hypoxic-ischemic/HI injury) reared in CN or standard facility (SF), we recorded offspring weight and development through PND 60, tested anxiety-like behavior (elevated plus maze/EPM), and spatial learning (Morris Water Maze/MWM). Our findings show that CN rearing significantly increased weight gain for males [$F(13, 520)=4.818, p < 0.001$] and shifted the appearance of neurological characteristics (i.e., earlier eye opening, ear unfolding, and day of incisor eruption) for pups reared in CN versus those raised in SF. In addition, CN housing decreased anxiety-like behavior on the EPM by increasing the number of open-arm entries [$F(1,49)=4.191, p < 0.05$] and diminished mean latency to find the invisible platform in MWM trials for females and CN-reared HI pups. Finally, preliminary evidence from morphometry analysis shows that CN rearing altered HI injury infarct size and lead to greater retention of ipsilateral and contralateral hippocampus and cortex for both male and female pups. These results support our hypothesis that the CN environment would facilitate neurological development following HI, and highlight the importance of environment in mediating lifetime outcome following an early-life brain injury.

Title: DS-1040, a novel selective thrombin-activatable fibrinolysis inhibitor does not increase hemorrhagic risk in a mechanical model of stroke in rats.

Authors: T. ISHRAT[1,2], B. PILLAI[1,2], A. Y. FOUDA[1,2], W. ELDAHSHAN[1,2], H. AHMED[1,2], *K. NOGUCHI[3], S. C. FAGAN[1,2];

Norwood VA Med. Ctr., Augusta, GA; [3]End-Organ Dis. Labs., Daiichi Sankyo Co., Ltd., Tokyo, Japan

Abstract: **Background:** Activated form of thrombin-activatable fibrinolysis inhibitor (TAFIa) attenuates fibrinolysis and inhibition of TAFIa is a promising target for treatment of acute ischemic stroke. The aim of the present study was to elucidate the effect of DS-1040, a novel selective TAFIa inhibitor, on hemorrhagic risk in a mechanical model of stroke in rats.
Methods: Male Sprague-Dawley rats underwent a 3 hour-middle cerebral artery occlusion (MCAO) and were treated at reperfusion with tissue plasminogen activator (tPA, 10 mg/kg, bolus + infusion for 30 min), saline, or DS-1040 (1500 μg/kg injected intravenously, followed by subcutaneous infusion of 567 μg/kg/hour with micropump, SMP-200, for 21 hours). Behavioral outcome measures (Bederson, Beam walk, paw grasp) were obtained prior to sacrifice. The brains were evaluated for infarct size, cerebral hemorrhage (visual score and hemoglobin content) and edema. A separate set of groups of animals was used to determine the plasma concentration of DS-1040 at 24 hours post stroke.
Results: Treatment with tPA significantly ($p<0.05$) increased hemorrhagic risk and worsened functional outcome compared to the saline treated groups. DS-1040 treatment did not augment hemorrhagic risk or worsen outcome compared to saline. Mean plasma concentration of DS-1040 was 713 ng/mL, 10 x above the maximum effective concentration required for TAFI inhibition (ECmax, 64.7 ng/mL in a rat venous thromboembolism model).
Conclusion: These findings suggest that DS-1040, a TAFIa inhibitor, does not augment hemorrhagic risk compared to saline treatment at 24 hours after MCAO, and may be safer than tPA for acute ischemic stroke.

Title: Rescuing the ischemic retina

Authors: *B. MATHEW[1], L. TORRES[1], S. KEIL[2], S. ROTH[1];
[1]Anesthesiol., Univ. of Illinois At Chicago, Chicago, IL; [2]Neurosci., Univ. of Illinois, Chicago, IL

Abstract: We have previously shown that treatment 24 h after ischemia with conditioned media from bone marrow stem cells (BMSCs), as well as ischemic post-conditioning (Post-C) using a transient, non-damaging ischemic stimulus, significantly improved retinal function. Based upon these findings, we studied the effect of BMSCs delivered 24h after ischemia. Retinal ischemia was produced in adult Wistar rats by increasing intraocular pressure to 130-135 mm Hg for 55 min. BMSCs (approximately 130,000) were injected into the vitreous 24 h after the end of ischemia. Recovery was assessed 7 d after ischemia using electroretinography (ERG), at which time we euthanized the animals and then prepared cryosections of retina for TUNEL. We did Western blotting to evaluate inflammatory cytokines, autophagic and apoptosis proteins. Blood retinal barrier permeability was assessed with Evans Blue. Stem cells were localized in the retina using real time fundus imaging, retinal immunohistochemistry, and flat mounts. Intravitreal injection BMSCs 24 h after ischemia robustly improved retinal function, attenuated apoptosis, decreased blood retinal barrier leakage, decreased inflammatory cytokine levels, and maintained autophagic function compared to vehicle injected group. The BMSCs were found to penetrate into the retina and proliferate more effectively in ischemic vs normal retinae. These results are of relevance to rescuing retina from ischemia in conditions such as diabetic retinopathy.

Title: Protein synthesis inhibition in the peri-infarct cortex slows motor recovery in rats

Authors: *M. SCHUBRING-GIESE[1,2], J. HOSP[2], S. LEEMBURG[2], A. LUFT[2];
[1]Univ. of Zurich, Zurich, Switzerland; [2]Dept. of Neurol., Univ. Hosp. of Zurich, Zurich, Switzerland

Abstract: Neuroplasticity and reorganization of brain motor networks are thought to enable recovery of motor function after ischemic stroke. Especially in the cortex surrounding the

ischemic scar (i.e. peri-infarct cortex) evidence for lasting reorganization has been found at the level of neurons and networks. This reorganization depends on expression of specific genes and subsequent protein synthesis. To test the functional relevance of the peri-infarct cortex for recovery we assessed the effect of protein synthesis inhibition within this region after experimental stroke. Long-Evans rats were trained to perform a skilled-reaching task (SRT) until they reached plateau performance. A photothrombotic stroke was induced in the forelimb representation of the primary motor cortex (M1) contralateral to the trained paw. The SRT was re-trained after stroke while the protein synthesis inhibitor anisomycin (ANI) or saline were injected into the peri-infarct cortex through implanted cannulas. ANI injections reduced protein synthesis within the peri-infarct cortex by 69% and significantly impaired recovery of reaching performance through re-training. Improvement of motor performance within a single training session remained intact, while improvement between training sessions was impaired. ANI injections did not affect infarct size. Thus, protein synthesis inhibition within the peri-infarct cortex impairs recovery of motor deficits after ischemic stroke by interfering with consolidation of motor memory between training sessions but not short-term improvements within one session.

Title: Quantitative measurements of membrane-bound enzyme activity involved in ischemic damage and neuroprotection

Authors: ***Y. OU**, R. WILSON, B. YIN, S. G. WEBER;
Chem., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Ectopeptidases are membrane-bound enzymes whose catalytic domain faces the extracellular space (ECS). They hydrolyze and regulate the activity of neuropeptides. In recent years, these enzymes have been identified as important targets for drug development to treat neurological diseases, including ischemia[1-3]. We seek to understand whether the activity of these enzymes is involved in the mechanisms of ischemic damage and neuroprotection. Unfortunately, methods to measure their activity in intact tissues are lacking. We developed a method to determine the activity of these ectopeptidases by coupling electroosmotic push-pull perfusion

(EOPPP) with capillary liquid chromatography and mass spectrometry (cLC-MS). Substrate neuropeptides are hydrolyzed as they pass through hippocampal cultures during perfusion by EOPPP. Product concentration measured by cLC-MS yields estimates of enzyme activity. Computational simulations and *in vitro* experiments show that EOPPP causes little to no damage to surrounding tissue[4], has ~100 μm radial spatial resolution, can tune the residence time of substrates in the ECS to Michaelis-Menten kinetics, and can effectively perfuse and sample from severely ischemic regions. EOPPP-cLC revealed that hydrolysis of neuroprotective Leu-enkephalin by a bestatin-sensitive aminopeptidase (likely aminopeptidase N) is six times greater in CA1 than CA3 of the rat hippocampus. This is the first report of spatially resolved measurement of enzyme activity in live tissue. Inhibition of the aminopeptidase (100 μM bestatin) selectively protected the CA1 against ischemic damage from 40-min oxygen-glucose deprivation (OGD) (80 ± 2% cell death to 57 ± 3%, $p < 0.001$). Bestatin did not significantly change the cell death in the CA3 (58 ± 2% to 54 ± 4%), which is known to be more resilient. This neuroprotection occurs as early as 2-hours post-OGD and was selectively reversed by the addition of 10 μM naltrindole, a selective δ-opioid receptor (DOR) antagonist (86 ± 8%, $p < 0.001$). Thus, we conclude that selective neuroprotection in CA1 resulting from aminopeptidase inhibition was due to extended lifetime of Leu-enkephalin in the ECS, which reduced cell death via activation of DORs. Title: Effects of intranasal Orexin-A treatment on neuroinflammation in an asphyxial cardiac arrest rodent Model

Authors: ***H. R. MODI**[1], Q. WANG, 21210[2], E. GREENWALD[3], A. SAVONENKO[3], R. GEOCADIN[3], N. THAKOR[3];
[1]Biomed. Engin. Dept., [2]Biomed. engineering, [3]Johns Hopkins Univ., Baltimore, MD

Abstract: Introduction: Resuscitation after cardiac arrest (CA) entails significant risk of coma and disorders of consciousness resulting in poor neurological outcome. The hypothalamic orexinergic pathway is responsible for arousal in general. We hypothesized that targeting the orexinergic pathway via intranasal orexin-A treatment may improve arousal by decreasing neuroinflammation from post-CA coma. **Methods**: We assessed effects of intranasal orexin-A (50μM) on neuroinflammatory markers on post-CA rat brains region (prefrontal cortex, caudal cortex, hippocampus, striatum, hypothalamus, medulla and cerebellum) at 4 hrs in a blinded post CA rodents. Male Wistar rats (300-350 g) were subjected to 7 minutes of asphyxial CA. All animals received either intranasal vehicle or orexin-A treatment at 30 minutes post-resuscitation. **Results**: Inflammatory markers (mRNA levels) showed selective vulnerability in brain region specific manner following CA. Orexin-A (50μM) treatment showed rescue of inflammation and reduce selective vulnerability by reducing inflammatory markers post-CA. Neural Deficit Score (NDS) and Sub-score showed significant improvement with orexin-A treatment group. With orexin-A treatment, mRNA levels of orexin 1 receptor (OX1R) did not change much while OX2R showed change with orexin-A treatment compare to sham group and CA vehicle treated group. Microglial activation marker Cd11b and proinflammatory makers IL1b, iNOS, tumor necrosis factor alpha (TNFα) were found to be increased significantly in most of brain regions as result of CA whereas they were ameliorated with orexin-A treatment. **Conclusion**: Intranasal Orexin-A treatment attenuated neuroinflammatory response and simultaneously improved arousal and neurological outcomes of CA. This research is supported by NIH grant R01 HL071568.

Title: Role of intracellular calcium receptor inositol 1,4,5-triphosphate type 1 (IP3R1) in rat hippocampus after neonatal anoxia

Authors: *J. M. IKEBARA[1], D. S. CARDOSO[1], B. C. V. DE CAMPOS[1], T. A. S. BRETHERICK[1], N. M. M. DIAS[1], G. S. V. HIGA[2], S. H. TAKADA[1], A. H. KIHARA[1]; [1]Univ. Federal Do ABC, São Bernardo do Campo, Brazil; [2]Univ. de Sâo Paulo, São Paulo, Brazil

Abstract: Anoxia is one of the most prevalent causes of neonatal morbidity and mortality, especially in preterm neonates, constituting an important public health problem due to permanent sequelae observed in patients. Oxygen deprivation triggers a series of simultaneous cascades, culminating in cell death, mainly in more vulnerable metabolic brain regions, such as the hippocampus. In the process of cell death by oxygen deprivation, calcium plays a crucial role, since its massive entry into the cell due to activation of glutamatergic receptors results in cell death by excitotoxicity. Considering that calcium participates in various cellular processes, this study focused on intracellular calcium receptor inositol 1,4,5-trisphosphate type 1 (IP3R1) role in cell death after oxygen deprivation. Real-time PCR gene expression analysis revealed a decrease of IP3R1 gene expression 24 hours after neonatal anoxia. A semi quantitative analysis of IP3R-positive cells was performed and we were not able to observe alterations between control and anoxia animals. However, we observed that anoxia animals present a higher colocalization of IP3R1 and nucleus marker (DAPI). This result suggests that neonatal anoxia may cause IP3R1 translocation to the nucleus in hippocampal cells. Futhermore, to analyze the functional role of IP3R1, a blocker of the receptor, 2-aminoethoxydiphenyl borate (2-APB), was injected in hippocampus and staining neurodegeneration tecniques were performed. In this way, this study may contribute to new perspectives in the investigation of neurodenegeration mechanisms triggered by oxygen deprivation.

Title: Polyunsaturated fatty acids potentiates the neuroprotective effect of Cop-1 in a cerebral ischemia/reperfusion model.

Authors: *E. E. GARCIA-VENCES, K. CANTÚ SALDAÑA, Y. CRUZ MARTINEZ, V. GALVEZ SUSANO, R. DE JESUS BENAVIDES, D. LOERA, C. MORENO, A. IBARRA; Univ. Anahuac Mexico Norte, Mexico city, Mexico

Abstract: An ischemic stroke occurs as a result of a disturbance or interruption of cerebral blood flow that significantly reduces the supply of oxygen and glucose to the neural tissue. Consequently, several cell death mechanisms such as necrosis, excitotoxicity, free radical production and inflammation are triggered. Protective autoimmunity (PA) a physiological phenomenon that develops after central nervous system (CNS) damage- might have beneficial effects over the secondary mechanisms of stroke and cerebrovascular diseases. Nevertheless, in order to exert these effects, it must be modulated with neural derived peptides. Copolymer-1 (Cop-1) is a synthetic polypeptide that increases Th2 cytokine secretion patterns and inhibits the production of inflammatory cytokines after cerebral ischemia. On the other hand, the supplementation with polyunsaturated fatty acids (PUFA) have beneficial effects on neuronal function, as well as anti-inflammatory and antioxidant activities. Furthermore, PUFAs improve membrane fluidity, enhance neurotrophic support and their mediators are responsible for certain processes within the CNS: modulation of neuroinflammatory mechanisms, cell survival, structure and function of neurons, glial and endothelial cells. Therefore PUFAs may be novel targets of interest for therapy of several neurodegenerative process like ischemic stroke. The addition of PUFAs to the therapy with Cop-1 could potentiate the neuroprotective effects. Therefore, our group decided to investigate the effect of these combination therapy in a focal cerebral ischemia/reperfusion model. In order to evaluate this approach, 24 rats were randomly allocated into 4 groups (6 rats per group): Group 1, Cop-1 + Complete Freund's Adjuvant (CFA) + PUFAs; Group 2, Cop-1+ CFA; Group 3, PUFAs and Group 4, non-treated animals. All groups were subjected to cerebral ischemia. PUFAs (Omegas 3, 6 and 9) were administered through an orogastric cannula (40/mg/kg/d/) 4 weeks before the ischemic event (groups 1 and 3). Cop-1 was subcutaneously administered (200 μg) at the interescapular space immediately after reperfusion. Neurological deficit was evaluated at 24 hours and 7 days after ischemia using the Zea Longa scale. Infarcted area was revealed by the triphenyl tetrazolium chloride and quantified using an image analysis software (Image J), 7 days after ischemia. Results showed a significant reduction of neurological deficit in rats treated with Cop-1+ CFA+ PUFAs as compared with Cop-1 + CFA. In the same way, the addition of PUFAs reduced the infarct size. This work demonstrated that the use of PUFAs as supplementation potentiates the neuroprotective effect of Cop-1+ CFA.

Title: Differences in the unfolded protein response (UPR) between astroglia and microglia following cerebral global ischemia

Authors: *E. FONT BELMONTE, B. ANUNCIBAY-SOTO, M. SANTOS-GALDIANO, P. GONZALEZ-RODRIGUEZ, M. REGUEIRO-PURRIÑOS, A. FERNANDEZ-LOPEZ;
Univ. de Leon, Inst. de Biomedicina, Leon, Spain

Abstract: We have recently demonstrated that the post-ischemic treatment with salubrinal presents a neuroprotective effect decreasing the neuronal demise and modifying differentially the ER stress in different cell types in the neurovascular unit. Salubrinal inhibits the GADD134, a phosphatase of the eIF2α thus enhancing one of the unfolded protein response (UPR) pathways (PERK-ATF4 pathway). In this study we analyzed the effects of the ischemic injury and the post-ischemic treatment with salubrinal in microglia and astroglia (including the eIF2α phosphorylation as a marker of PERK-ATF4 pathway activation) in a rat global cerebral ischemia model (2 vessel-occlusion) following 48 h of reperfusion. Ischemia-induced astrogliosis is reverted by salubrinal but eiF2α phosphorylation in this cell type is very scarce at this reperfusion time. Microglia is also modified by ischemia and the treatment with salubrinal but, in contrast with astroglia, presents a robust eIF2α phosphorylation. We conclude that neuroprotective effect of salubrinal involves a decrease in the reactive gliosis, and hypothesize differences in UPR between microglia and astroglia following global ischemia. Title: Unfolded protein response (UPR) and autophagy are involved in the neuroprotection after focal cerebral ischemia mediated by 2-hydroxyarachidonic acid.

Authors: *I. F. UGIDOS[1], P. GONZÁLEZ-RODRÍGUEZ[1], B. ANUNCIBAY-SOTO[1], D. PÉREZ-RODRÍGUEZ[1], M. SANTOS-GALDIANO[1], X. BUSQUETS[2], A. FERNÁNDEZ-LÓPEZ[1];

Abstract: Endoplasmic reticulum (ER) stress is a hallmark of many cell homeostasis imbalances, including those derived from cerebral ischemia. In this study, we measured a number of parameters that mirror ER stress levels, mainly the unfolded protein response (UPR) and their link to autophagy. The effect of the neuroprotective agent 2-hydroxyarachidonic acid (2OAA) on these responses was also analyzed. The study was performed in a rat model of transient (1 hour) focal cerebral ischemia by middle cerebral artery occlusion (MCAO) followed by a single oral dose (1 g/kg) of 2OAA, or vehicle, 1 hour after ischemia. Samples from damaged and not damaged hemispheres were collected at 6 h and 24 h after ischemia and protein and mRNA were quantified by Western blot and qPCR respectively. Phosphorylation of eIF2α, as well as GRP78 levels indicates that ischemia induces the increase of ER stress. The treatment with 2OAA increases the phosphorylation of eIF2α, and decreases GRP78 levels indicating that this agent counteracts ER stress. Autophagy markers (Beclin-1, LC3B, p62) were measured indicating that ischemia increases autophagy 24 h after injury, while the treatment with 2OAA modifies the expression of autophagy markers. We conclude that, 24 h after ischemia, the neuroprotective effect of 2OAA involves both the UPR and autophagy homeostatic mechanisms. Title: The treatment with the neuroprotective agent, 2-hydroxyarachidonic acid, after transient focal cerebral ischemia restores the ischemia-induced increases in free fatty acid levels.

Authors: ***A. FERNANDEZ-LOPEZ**[1], I. F. UGIDOS[1], M. IBARGUREN[2], D. J. LÓPEZ[2], M. PADILLA-MARCOS[2], C. JAUME-BOUZÁ[2], P. V. ESCRIBÁ[2];

Abstract: We have previously reported that 2-hydroxyarachidonic acid (2OAA), an inhibitor of cyclooxygenases COX1 and COX2, exerts neuroprotective effects in a focal cerebral ischemia model of middle cerebral artery occlusion (MCAO). We analyzed here, in the same MCAO model, the lipid modifications that occur 24 h after ischemia as well as the effects of a single oral dose (1 g/kg) of 2OAA administered 1 hour after ischemia. We observed significant increases in both COX2 expression and relative concentration of free fatty acids (nmol lipid/mg protein) comparing the injured hemisphere with the corresponding contralateral hemisphere. The

treatment with 2OAA induced significant decreases in free fatty acid levels in pyriform cortex and striatum. Transcript levels of COX2 in the injured hemisphere were not decreased by the 2OAA post-insult treatment. Since arachidonic acid (AA) is a free fatty acid and substrate of COX2, we hypothesize that ischemia induces an increase of AA, which in turn promotes COX2 activity and the ensuing production of proinflammatory mediators. The similar response in the contralateral hemispheres treated and non treated with 2OAA indicates that COX2 blockade does not involve changes in its expression. On the other hand, the increases in COX2 expression in both treated and non treated damaged hemispheres suggest increased levels of AA in the damaged areas of treated animals. Additional studies on the ratio of AA in the free fatty acids seem necessary to elucidate the relevance of AA in the total amount of free fatty acids following ischemia.

Title: Chronic anemia is associated with significant white matter atrophy.

Authors: S. CHOI[1], J. COLOGNIER[2], A. D. BUSH[3], T. D. COATES[2], *R. I. WOOD[4], J. C. WOOD[2];
[1]Neurosciences Grad. Program, [2]Dept. of Pediatrics, [3]Dept. of Bioengineering, USC, Los Angeles, CA; [4]Keck Sch. Med. USC, Los Angeles, CA

Abstract: Silent strokes and white matter atrophy are common in patients with sickle cell anemia, but the mechanism is unknown. We have previously shown that resting blood flow is

increased in these patients such that oxygen delivery is preserved under unstressed conditions. However, resting hyperemia results in blunted vasodilatory reserve, potentially leaving patients at risk for cerebral ischemia in response to desaturation events, acute anemia, or increased metabolic demands. To remove the confounding influence of sickle hemoglobin, we measured grey and white matter volumes and cerebral blood flow in 14 thalassemia major patients (hemoglobin level 10.3 ± 0.9 g/dl, age 24.2 ± 6.8 yrs, 36% male) and 37 African-American subjects without sickle cell disease (hemoglobin level 13.5 ± 1.3 g/dl, age 27± 10.6 yrs, 26% male). 3D T1-weighted MR images (1 mm^3 isotropic resolution) were processed using BrainSuite (brainsuite.org) in a semi-automated fashion to extract, classify tissue types, and calculate brain volumes, with manual correction as needed. 3D T2-weighted MR images (1.2 mm x 1.2 mm x 1.2 mm) were collected to quantify number and volume of white matter strokes. Total cerebral blood flow was measured using phase contrast imaging of the carotid and vertebral vessels in a single axial slice placed 5 mm above the carotid bifurcation. Total brain blood flow was normalized to brain volume x an assumed density of 1.05 g/cm^3. Cerebral blood flow was reciprocally related to blood oxygen content (1.34 x Hb x Oxygen Saturation + 0.3) with an r^2 of 0.54, $p<0.0001$, such that resting oxygen delivery was normal in all subjects. Age and sex-corrected white matter volume had a reciprocal relationship with baseline cerebral flow ($r^2 = 0.24$, $p=0.0002$) and a linear relationship with hemoglobin ($r^2 = 0.17$, $p = 0.003$). White matter Z-score was – 0.7 ± 0.7 compared with 0.0 ± 1.0 for the control group, $p=0.007$. Rare white matter hyperintensities were seen in both groups with no significant differences. Taken together, these data indicate the white matter volume is decreased in anemic subjects, proportionally to their hemoglobin levels, independent of silent stroke. We postulate that the increased resting hyperemia observed in these patients limits their vasodilatory reserve, leaving them vulnerable to acute interruptions in oxygen delivery or increased brain metabolic needs.

Title: Leukocyte response is regulated by microRNA let7i in patients with acute ischemic stroke

Authors: ***G. JICKLING**, B. P. ANDER, N. SHROFF, B. STAMOVA, C. DYKSTRA-AIELLO, X. SHAN, D. LIU, F. R. SHARP;
Neurol., Univ. of California Davis, Sacramento, CA

Abstract: Objective: The immune system responds rapidly following ischemic brain injury and can contribute to the final extent of brain damage. microRNA are differentially expressed in leukocytes following ischemic stroke and may regulate the immune response to ischemic brain injury. In this study we evaluate microRNA let7i-5p in ischemic stroke and its regulation of leukocytes.
Methods: A total of 212 patients were studied; 106 with acute ischemic stroke and 106 risk factor matched controls. Let7i-5p miRNA expression was assessed by Taqman qRT-PCR. Target gene expression was assessed by whole genome HTA Affymetrix microarray. Let7i-5p post-transcriptional regulation of target genes was evaluated by 3'UTR luciferase assay. Target protein expression was assessed by ELISA.
Results: Let7i-5p was decreased in patients with acute ischemic stroke (fold change -1.4, $p<0.00001$). Let7i-5p inversely correlated with NIH Stroke Scale at admission ($r= -0.32$, $p=0.02$), infarct volume ($r= -0.21$, $p=0.04$) and plasma MMP9 ($r= -0.46$, $p=0.01$). The decrease in let7i-5p was associated with increased expression of several of its messenger RNA targets including CD28/CD86, CXCL8 and HMGB1. *In vitro* studies confirm let7i-5p post-transcriptional regulation of target genes CD86, CXCL8 and HMGB1. Functional analysis predicted let7i-5p regulates pathways involved in leukocyte activation, recruitment, proliferation including canonical pathways CD28 signaling in T helper cells, HMGB1 signaling, and CXCL8 signaling.
Conclusions: Let7i-5p is decreased in circulating leukocytes of patients with acute ischemic stroke. Mechanisms by which let7i-5p regulates inflammatory response post-stroke include targeting CD28 / CD86, CXCL8 and HMGB1.

Title: Effect of light-dark cycle on stroke lesion size and motor deficit in a mouse photothrombosis model of stroke

Authors: A. GOWER[1,2], B. LIANG[1,2], D. LAGACE[1], *M. TIBERI[1,2];
[1]Neurosci., Univ. of Ottawa, Ottawa, ON, Canada; [2]Neurosci., Ottawa Hosp. Res. Inst., Ottawa, ON, Canada

Abstract: Mice and rats are nocturnal animals, yet in many preclinical studies on stroke recovery ischemia, behavioural testing and treatment occurs during the animal's inactive period. Rates of ischemic stroke rise in the mornings in humans, corresponding to circadian increases in blood pressure, activity levels and a myriad of other factors. It is unclear whether there is a difference in the qualities or severity of awake or asleep ischemic stroke in humans, although some studies suggest this. Furthermore, the impact of dark-period stroke induction on animal models of stroke has not been fully examined. The objective of this study is to determine if there are any differences in the outcomes of photothrombotic strokes induced during a mouse's active (dark) period or inactive (light) period, with an aim to better model the majority of human ischemic strokes. 32 ten week old, male C57BL6 mice underwent photothrombosis stroke. Prior to photothrombosis, mice acclimated for two weeks in either Light-Dark(LD) 12h:12h or reverse LD 12h:12h housing and underwent training and prestroke measurements on 3 motor-behavioural tasks, the adhesive removal test, the horizontal ladder test and the cylinder test. After stroke, lesions were confirmed with Magnetic Resonance Imaging. Animals underwent testing on the three behavioural tasks at 2-4 days post stroke and 20-22 days post stroke. At study completion brains were collected and infarct size was determined. Results from our 3 behavioural tests suggest that mice who underwent stroke induction and testing during their dark period have greater motor deficits following stroke, when compared to their pre-stroke performance, which tends to be better than mice tested during their light period. Infarct sizes showed a non-significant tendency to be larger in dark-period mice in our first cohort (n=16). Our second cohort (n=15) is in the analysis stages to confirm our findings. Our data points to a potential difference in stroke outcome when stroke is induced during the animal's dark period. This suggests that using reverse light-dark housing conditions can improve our model of human stroke and stroke recovery. These results will inform the methods of our next goal, to investigate the efficacy dopamine receptor (DAR) agonists, delivered with aerobic exercise, on motor recovery from stroke. This work is prompted by previous work suggesting a role for dopamine receptors when in stroke recovery, such as those studies which have found levodopa improves stroke recovery, and by the link between DARs and plasticity as well as DARs and the growth factors, BDNF and GDNF. This study, will similarly employ the photothrombosis model and the same behavioural tests.

Title: Cellular mechanisms underlying the ischemic damage in area CA3 of the hippocampus

Authors: *C. TECUATL TOLAMA, E. J. GALVAN ESPINOSA;
Farmacobiologia, CINVESTAV Sede Sur, Distrito Federal, Mexico

Abstract: The cellular mechanisms underlying ischemic damage in area CA3 of the hippocampus are explored in the present study. Extracellular recordings (Population Spikes, PS and Mossy fibers fEPSPs) on acute slices (30-40 days old) were performed, and controlled exposure to Oxygen-glucose deprivation (10 min), followed by 2 h reperfusion of ACSF was used to assess the alterations of evoked responses after an ischemic insult. OGD suppressed both PS and MF fEPSPs without signs of recovery at 2 hr post-OGD exposure; Input-Output curves at 2.5 h post-OGD confirmed the lack of electrophysiological responsiveness. Similar results were found when the glutamatergic transmission was blocked with Kynurenic acid. When slices were preincubated with BAPTA (n=8) or when sodium was replaced with N-methyl-D-Glucamine (n=8), PS and MF fEPSPs exhibited a partial recovery. Then, we investigated the role of Transient Receptor Potential Cation Channels (TRPVs) as a contributor of Na^+ and Ca^{2+} influx mediating CA3 responses. Slices preincubated with capsazepine (n=8) showed a significant recovery of PS and MF fEPSPs during reperfusion post-OGD. To further investigate the individual contribution of different TRPVs during the ischemic insult, slices were preincubated with AMG9810 or HC-067047 (antagonist for TRPV1 and TRPV4, respectively). Slices preincubated with AMG 9810 show a strong recovery (n=8), whereas blockade of TRPV4 with HC-067047 partially reverts the deleterious effect of OGD (n=8). These results indicate that ischemic damage involves strong cationic influx, independent of ionotropic glutamatergic receptors activity. We also show that TRPVs plays a critical role in the ischemic damage, as blockade of these receptors revert the deleterious effects of OGD on area CA3.

Title: *In situ* expression of pluripotency factors improves functional recovery by hippocampal neurogenesis and synaptic plasticity in hypoxic-ischemic brain injury.

Authors: *S. WI[1,2], J. SEO[1,2], J. YU[1,2], Y. SHIN[1,2], M. KIM[1,2], S.-R. CHO[1,2];
[1]Dept. and Res. Inst. of Rehabil. Med., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of;
[2]Brain Korea 21 PLUS Project for Med. Science, Yonsei Univ. Col. of Med., Seoul, Korea, Republic of

Abstract: Introduction: The resident stem/progenitor cells can be stimulated in vivo by injuries such as stroke, hypoxic-ischemic(HI) brain injury, and traumatic brain injury. Since stem/progenitor cells present in the adult brain and the production of new neurons occurs at specific sites, there is a possibility for the treatment of incurable neurological diseases. Understanding of the molecular control of endogenous neural stem cell (NSC) activation and progenitor cell mobilization will likely provide many new opportunities as therapeutic strategies. Pluripotency factors such as Klf4, Sox2, Oct4, and c-Myc can be used to convert one cell type to another directly. These factors can stimulate proliferation from NSCs to mature neurons in subgranular zone (SGZ) of the dentate gyrus in the hippocampus. In this study, we focused on *in situ* transient expression of pluripotency factors would facilitate endogenous NSC activation, cell proliferation, a critical and essential process for recovery of injured tissue.
Methods: HI brain injury was induced CD-1® mice at 1 week of age by unilaterally right carotid artery ligation and exposure to hypoxia (8% O_2 for 60 min). At six weeks of age, the mice were randomly injected either GFP as control group or four pluripotency factors with GFP as treated group into the right side of the lateral ventricle. Passive avoidance test(PAT) and openfield test were performed before the treatment and 8 weeks after the treatment to evaluate neurobehavioral function. We confirmed the endogenous cell fate of SGZ of the dentate gyrus in hippocampus using immunohistochemistry. To identify hippocampal synaptic plasticity, we conducted western blot and immunohistochemistry.
Results: The number of $BrdU^+$/βIII-tubulin+ neurons was significantly higher in the treated group compared than the control group. Treated group also increased $BrdU^+$/$nestin^+$ and $BrdU^+$/$NeuN^+$, but not $BrdU^+$/$GFAP^+$ cells in the SGZ. Hippocampal synaptic plasticity also increased, and it was confirmed by a synaptic marker, post-synaptic density 95(PSD-95).

Importantly, neurobehavioral evaluations such as PAT and openfield test showed that the treated group improved long-term memory and decreased anxiety in HI brain injury.
Conclusion: *In situ* transient expression of pluripotency factors improved long-term memory and decreased anxiety. The underlying mechanisms of these repair processes increased endogenous neurogenesis of SGZ and increased hippocampal synaptic plasticity.

Title: Quality and quantity mononuclear cells rescue peri-infarct lesion during acute stroke phase

Authors: *T. NAKAYAMA;
Tokai Univ., Isehara, Japan

Abstract: *Background:* Recently, many studies with iPS or stem cells have published for ischemic stroke. Some studies tried to engraft iPS or stem cells to the brain directly; however, due to lack of neurovascular unit, those were not perfectly succeeded. Previously we reported higher grade quality EPCs (JAHA, 2014) and we investigate therapeutic window and those effects with using those cells for ischemic stroke model mice. We investigated the vasculogenesis around peri-infarct lesion. *Materials and methods:* We made 69 ischemic stroke model mice (10 weeks male C57BL/6 mice) with permanent middle cerebral artery occlusion (MCAO). We injected PBS, PBMNCs, and QQMNCs into external carotid artery at each 1 day (n=37), 3 days (n=23), and 5 days (n=15) after MCAO. At 3 weeks after MCAO, we took the brains and investigated time-lapse physiological parameters including cerebral blood flow and immunohistochemistry against some anti-vasculogenetic factor antibodies. Also, we injected PBS, PBMNCs, and QQMNCs at 1 day (n=27) and sacrificed at 1 week after MCAO.Western bolting was performed to measure the anti-inflammatory cytokines. We injected ink-urethane into untreated mice (n=5) and QQMNCs-treated mice (n=5), due to evaluate vasculogenesis. *Results:* In the stroke model mice at 1 day and 3 days MNCs injections after MCAO, the stroke volume was decreased; however, the positive cells were increased with immunochemistry of IL10 at 1 week after MCAO and VEGF at 1 and 3 weeks after MCAO. The vascular numbers

increased at peri-infarct lesion with treated mice. *Conclusions:* Those results indicate that QQMNCs could repair and regenerate neurovascular units after ischemic stroke, and the better MNCs injection timings might be 1 day and 3 days after MCAO. Vasculogenesis may occur at 1 week after MCAO with QQMNCs-treated mice.

Title: Post-stroke intranasal (+)-naloxone reduces microglial activation and improves behavioral recovery in rat model of stroke

Authors: *J. E. ANTTILA[1], K. ALBERT[1], E. S. WIRES[2], K. MÄTLIK[1], L. LORAM[3], L. WATKINS[3], K. RICE[2], Y. WANG[2], B. K. HARVEY[2], M. AIRAVAARA[1];
[1]Inst. of Biotechnology, Univ. of Helsinki, Helsinki, Finland; [2]Intramural Res. Program, Natl. Inst. on Drug Abuse, NIH, Baltimore, MD; [3]Univ. of Colorado, Boulder, CO

Abstract: Inflammation has a major role in the pathophysiology of ischemic stroke. Microglia are the brain resident immune cells that are activated after ischemia but it is still unclear whether microglial activation is harmful or beneficial to the recovery. Both stereoisomers of naloxone, the (+) and (-) enantiomer, have been shown to decrease microglial activation. (-)-naloxone is an opioid receptor antagonist while (+)-naloxone has only very low affinity for opioid receptors. Here we tested post-stroke delivery of (+)-naloxone for the ability to promote functional recovery after cortical stroke in rats. By using (+) enantiomer the possible side effects caused by opioid receptor antagonism can be avoided.
A unilateral cortical infarction was induced in adult male Sprague Dawley rats by transiently ligating the distal branch of the right middle cerebral artery with 10-0 suture and occluding both common carotid arteries for 60 minutes. At post-stroke day 1, the rats were balanced into groups based on neurological deficits and either (+)-naloxone, vehicle or no treatment was given intranasally to the rats twice daily for the next 7 days. The behavioral recovery of the rats was followed for 2 weeks by biased swing activity, Bederson's score as well as horizontal and

vertical activity. Immunohistochemical staining for microglia was carried out with Iba1 and CD11b antibodies from coronal brain sections.
(+)-naloxone decreased biased swing activity and Bederson's score in dose-dependent manner starting from post-stroke day 10. In addition, (+)-naloxone increased horizontal activity on day 14 post-stroke. As measured with unbiased stereology, (+)-naloxone decreased the number of Iba1+ cells by 50% in the striatum compared to the vehicle treatment. The data suggests that post-stroke intranasal (+)-naloxone decreases microglial activation and simultaneously promotes recovery from ischemic brain injury.

Title: Chronic cerebral hypoperfusion rodent model by bilateral ICA ligation in different species for hemodynamic assessment of human moyamoya disease

Authors: *K.-E. LEE, Y. KWON, G. PARK, E. CHOI, B. YUN, J. LEE, J. HONG;
Dept. of Neurology, Ajou Univ. Sch. of Med., Suwon, Suwon, Korea, Republic of

Abstract: ***Background:*** Moyamoya disease is a rare but common in Asian, which manifests a chronic blood flow shrinkage due to a progressive occlusion of the proximal intracranial arteries around the circle of Willis. To evaluate the hemodynamic status of such a clinical entity in experimental situations, we intended to establish an appropriate rat model which represents chronic cerebral hypoperfusion by completely ligating bilateral internal carotid arteries (ICA). We analyzed the changes of sequential flow and respective arterial size around the circle of Willis in different rat species. ***Methods****:* Chronic hypoperfusion models were made by bilateral ICAs' ligations (BICAL) in the Wistar and Sprague-Dawley (SD) rats. *Step 1:* Changes of cerebral blood flow (CBF) after bilateral ICA ligations were sequentially observed at different times (D0, 1, 3, 7, 14 and 21) for 3 weeks by the laser Doppler flow measuring device (PIM3). *Step 2:* Arterial changes around the Willisian circle were compared in bilateral ICA ligation and sham operation (without ICA ligation) models after the fixation with blue latex infusion after BICAL operation 21 days in the same species. *Step 3:* To make a mimicking condition for clinical moyamoya patients, sudden cerebral infarction using a permanent middle cerebral artery

(MCA) thread occlusion was induced in an aforementioned set-up model representing ischemic preconditioned properties with different periods (7, 14, and 21 days) of the BICAL, and the infarctions were observed on triphenyl tetrazolium chloride (TTC) stains in different rat species and time-points. ***Results****:* Wistar rat [vs. baseline CBF values (D0)] did not reach the baseline CBF during whole study period, but SD rat did not reflect the chronic hypoperfusion status since 7 days because it exceeded the baseline CBF after 7 days since BICAL. Wistar rat (vs. SD rat) after BICAL is significantly thinner in arterial diameters (internal carotid artery, posterior communicating artery, posterior cerebral artery, and basilar artery, $p < 0.05$ respectively) despite no difference of MCA diameters ($p = 0.35$). Permanent MCA occlusion with a thread insertion in Wistar rat reduced infarction size and mortality according to an increase of BICAL duration. ***Conclusion****:* Our data suggest that Wistar rat using permanent MCA occlusion model after BICAL might be appropriate for a hemodynamic evaluation of moyamoya disease with our observations of less infarct volume and mortality compared with SD rat. This phenomenon can be explained by a cerebral ischemic precondition due to less compensation by thinning Willisian collaterals especially in the Wistar.

Title: Acute but not delayed caffeine administration offers neuroprotection in a mouse model of neonatal hypoxic ischemic brain injury.

Authors: *E. DI MARTINO[1], M. WINERDAL[1], M. E. WINERDAL[2], B. B. FREDHOLM[3], O. WINQVIST[2], U. ÅDÉN[1];
[1]Dept. of Women's and Children's Hlth., [2]Dept. of Med., [3]Dept. of Physiol. and Pharmacol., Karolinska Institutet, Stockholm, Sweden

Abstract: Hypoxic ischemic (HI) brain injury remains an important cause of brain damage in the neonate with potentially life long consequences. It is now acknowledged that perinatal HI triggers a broad inflammatory reaction in the brain. Caffeine, which is a competitive inhibitor of adenosine receptors, is commonly used as treatment for apnea in prematurity. In addition, caffeine treatment is associated with decreased incidences of cerebral palsy and cognitive delay in children born preterm. In this study we investigated the effects of caffeine in a neonatal HI

murine model. Wild type C57BL/6 mice were subjected to HI by unilateral ligation of the common carotid artery under isoflurane anaesthesia at postnatal day (pnd) 10 and then exposed to 10% oxygen for 60 min. A single dose of 5mg/kg caffeine or phosphate buffered saline (PBS) was administered i.p. directly after HI (0h). Open field and rotarod behavioral tests were performed at pnd 24 and the mice were subsequently sacrificed. Infarction size was calculated by loss of MAP-2 staining while immune response was studied by flow cytometry of brain infiltrating cells at 24h, 72h and two weeks after caffeine administration. In a second set of animals, a single dose of caffeine or PBS was administered at 6, 12 or 24 hours after HI. Behavioral tests were performed and infarction size calculated in accordance to first group of mice. An atrophy reduction of 44% ($p<0.05$) was shown only in the group that received an acute administration of caffeine compared to the PBS one, no protection was shown in later treatments. In the open field test, lower locomotor activity was seen in the 0h caffeine group than the PBS one, indicating enhanced learning. No significant difference was shown in the later treatments. A significant reduction of CD8+/CD69 positive cells was detected in the caffeine treated group at 24h but not at 72h and two weeks after the lesion. Our data indicates that an acute single dose of caffeine is a possible neuroprotective treatment after neonatal HI without serious immunological side effects or discernible immunological long-term consequences if administered soon after HI. Later treatments do not show any beneficial effect in mice.

Title: Anti-neuroprotective effects on neuronal damage following transient forebrain ischemia by garlic extract treatment

Authors: *S. YI[1], D. YOO[2], I. HWANG[2];
[1]Dept. of Biomed. Lab. Sci., SoonChunHyang Univ., Asan, Korea, Republic of; [2]Dept. of Anat. and Cell Biol., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: In the present study, we investigated neuroprotective effects of oil-macerated garlic products (Z- or E-ajoene) against neuronal damage after transient forebrain ischemia. Male

Mongolian gerbils were divided into 4 groups: sham-operated, ischemia-operated (vehicle), E-ajoene treated, and Z-ajoene treated groups. E- or Z-ajoene (25 mg/kg) was orally administered 30 min prior to the induction of transient forebrain ischemia. One day after ischemia/reperfusion, locomotor hyperactivity significantly reduced in the E- and Z-ajoene- treated groups, compared to that in the vehicle-treated group. Five days after transient ischemia, the number of cresyl violet-positive neurons in the E- and Z-ajoene-treated groups increased, compared to that in the vehicle-treated group. Reactive gliosis in the CA1 region of E- and Z-ajoene- treated groups reduced, compared to that in the vehicle-treated group. These neuroprotective effects were more prominent in animals treated with Z-ajoene, than in those treated with E-ajoene. In addition, Z-ajoene significantly decreased lipid peroxidation, as indicated by 4-hydroxy- 2-nonenal levels in hippocampal homogenates, compared to that observed in the vehicle-treated group at a range of time points after ischemia. These results suggest that Z-ajoene protects I/R-induced delayed neuronal death and gliosis by reducing lipid peroxidation in the gerbil hippocampal CA1 region.

Title: Identification of new chemical drugs to protect ischemic brain injury based on the inhibition of AMP-activated protein kinase

Authors: J.-W. EOM[1], T.-Y. KIM[2], B.-R. SEO[2], J.-Y. KOH[2], *Y.-H. KIM[1];
[1]Sejong Univ., Seoul, Korea, Republic of; [2]Univ. of Ulsan Col. of Med., Seoul, Korea, Republic of

Abstract: We recently reported that AMP-activated protein kinase (AMPK) contributed to zinc-induced neuronal death through the induction of Bim, pro-apoptotic Bcl-2 homology domain 3 (BH3)-only protein in an LKB1-dependent manner. Since many reports showed that AMPK plays a key role in excitotoxicity and ischemic brain injury, and zinc neurotoxicity is one of underlying neuronal death mechanism after ischemic brain injury, we thought that the inhibition

of AMPK could be a therapeutic target for Stroke diseases. Therefore, we tried to find a new chemical drug to reduce the activity of AMPK, zinc-induced neuronal death in mouse cortical cultures, and brain injury after middle cerebral artery occlusion (MCAO) in the mouse to develop the candidate drugs for Stroke. First, by using structure-based virtual screening, we selected 208 chemicals which could bind to the active site of the alpha subunit of AMPK as the putative inhibitor for AMPK. And then we examined whether these chemicals indeed inhibit AMPK activity using *in vitro* AMPK enzyme activity assay. 40 chemicals showed the stronger inhibition of AMPK activity in comparison with compound C, the well-known AMPK inhibitor. Next, we tested the possibility that these 40 chemicals may attenuate zinc-induced neuronal death in mouse cortical neuronal cultures. As a result, 7 chemicals were selected. Since ischemic brain injury has diverse types of neuronal death including excitotoxicity, apoptosis, and oxidative stress, we next examined whether these selected chemicals may also attenuate other types of neuronal death. Among them, 2 chemicals attenuated NMDA-induced excitotoxicity, iron-mediated oxidative stress, and etoposide-induced apoptosis as well as zinc neurotoxicity in mouse cortical cultures. However, one candidate compound showed toxicity at more than 60 microM in the mouse cortical cultures, so we finally chose only one as a candidate compound for brain ischemia. The selected chemical (2G11) was next tested *in vivo* effect on focal cerebral ischemia through permanent middle cerebral artery occlusion. The critical reduction of infarct volume was observed by 2G11. Thus, we suggested that AMPK could be a therapeutic target for Stroke and a new chemical compound having the inhibitory effect of AMPK as the candidate drug for Stroke.

Title: Therapeutic potential of a STEP-derived peptide in cerebral ischemia

Authors: S. RAJAGOPAL[1], R. PODDAR[1], L. WINTER[1], A. M. ALLAN[2], *S. PAUL[3]; [1]Dept. of Neurol., [2]Dept. of Neurosci., Univ. of New Mexico, Albuquerque, NM; [3]Dept Neurol, Univ. New Mexico, Albuquerque, NM

Abstract: Despite advances in understanding the pathophysiology of acute ischemic stroke, successful treatment remains a major challenge in clinical medicine. Reperfusion with recombinant tissue plasminogen activator remains the only pharmacologic therapy. Rapid reperfusion, although necessary for restoration of brain metabolic activity, is also associated with additional risks. The development of neuroprotection strategies, to protect the brain from both ischemia and reperfusion injury is therefore an important goal. Emerging evidence indicate that the brain-enriched and neuron-specific tyrosine phosphatase (STEP) that is activated following glutamate-mediated NMDA receptor stimulation may play a role in neuroprotection against cerebral ischemia. During a transient ischemic insult (middle cerebral artery occlusion or MCAO for 90 min) in Wistar rats activation of STEP promotes neuronal survival by down regulating several detrimental cascades, while degradation of active STEP over time leads to loss of its neuroprotective effects that allows the progression of ischemic brain damage. Maintaining STEP availability through intravenous administration of a brain permeable and constitutively active STEP-derived peptide significantly reduces ischemic brain damage observed 24 hours after the onset of the insult. Conversely, deletion of STEP gene in mice (STEP knockout mice) exacerbates brain injury following a mild ischemic stroke as observed 24 hours after the onset of the insult. Based on these findings the current study evaluated the temporal profile of pathological changes in the brain, by magnetic resonance imaging, over a period of 30 days in Wistar rats subjected to MCAO and treated with the STEP-derived peptide either at the onset of reperfusion or 6 hour after the onset of the insult. Functional assessment was performed throughout the time course to determine alterations in sensorimotor and cognitive functions. The analysis of the long-term pathological changes and behavioral outcome following restoration of the STEP signaling pathway could establish the potential benefit of this approach for stroke therapy.

Title: Newborn piglet brain slices for studying cellular mechanism in cerebral palsy

Authors: *V. RANCIC[1], A. RUANGKITTISAKUL[1], B. RAWAL[1], J. TURNER[2], P.-Y. CHEUNG[2], K. BALLANYI[1];
[1]Physiol., [2]Pediatrics, Univ. of Alberta, Edmonton, AB, Canada

Abstract: Cerebral Palsy (CP) and related encephalopathies develop when the brain suffers from insufficient oxygen and/or blood supply before or during birth. Such hypoxia/ischemia (HI) insults can cause brain damage (HI-BD) leading to CP for which no effective treatment is available. Therefore, animal research is needed with an increasing number of in vivo studies using newborn piglets because their gyrencephalic brain is similar to that of humans including perinatal development. To analyze at the cellular level how HI-BD affects neural networks in a CP-proned brain area, we have developed somatosensory cortex (SSC) brain slices from 0-18 days-old piglets. These slices show spontaneous extracellular electrical early network oscillations (ENOs) that can be monitored simultaneously with membrane potential and cytosolic calcium dynamics in visualized SSC neurons. Using two-photon microscopy, we found that a single sodium action potential already triggers a transient cytosolic calcium rise whereas multiple action potentials cause a major calcium elevation. By incubating slices with fluorescent SR-101, the soma and processes of either SSC neurons (165 μM, 20-23 ^{o}C, 30 min) or SSC astrocytes plus white matter oligodendrocytes (1 μM, 36 ^{o}C, 40 min) were labeled, while only astrocytes were selectively immunostained with S100b, thus enabling quantification of HI-BD. Our preliminary findings indicate that blockade of ENOs with cyanide-induced 'chemical anoxia' is followed by long-lasting seizure-like hyperexcitability during the recovery phase that is depressed by activation of A1-type adenosine receptors. Mechanisms of such in vitro 'reperfusion' hyperexcitability will be compared with those in seizure-like hyperexcitability likely occurring in SSC slices from piglets exposed to HI in vivo. The findings indicate that our novel piglet SSC slices are a potent in vitro model to identify mechanisms in hypoxic/ischemic brain damage leading to CP and related encephalopathies and may thus be instrumental for developing effective treatment.

Title: B cell-neuronal interactions induce neuroprotection in an in-vitro stroke model.

Authors: *V. TORRES, S. B. ORTEGA, X. KONG, A. M. STOWE;
Neurol. and Neurotherapeutics, UT Southwestern, Dallas, TX

Abstract: Background: Regulatory B and T cells are thought to play a protective role in the central nervous system by suppressing the inflammatory response and damage, including after stroke onset. Transferred B cells also inhibit leukocyte migration and preserve blood brain barrier integrity during stroke. The direct neuroprotective effects B cells potentially exert on neurons, however, remain unclear. Therefore, by utilizing an *in-vitro* ischemia model, oxygen glucose deprivation (OGD), **we hypothesize that direct B cell and neuronal interactions promote neuronal protection following ischemia.** Methods: Cortical and hippocampal cells were isolated from postnatal day 0-2 pups and cultured until confluent (minimum 7 days). B cells were isolated via negative selection EasySep magnetic beads from spleens of adult 8-12 week old male C57BL/6 mice. For B cell pre-treatment, B cells were co-cultured for 4 days prior to OGD in 1:1, 1:10, and 1:20 B cell:neuron ratios. In B cell post-treatment, B cells were co-cultured for 4 days immediately after OGD. OGD was induced for 2h by exposure to 0.1% O_2 in a hypoxic chamber with serum/glucose-free HBSS. Following a 3-day post-OGD recovery, neuronal protection was assessed using MAP2+ immunofluorescent staining, and confocal microscopy (10x, 4 images/well). Cells were quantified using the counter tool in Photoshop, normalized to non-B cell control, and analyzed by one-way ANOVA, Bonferroni post-hoc (Graphpad Prism). Significance was $p<0.05$. Results: 4-day pre-treatment with B cells at a 1:1 ratio significantly protected neurons with 128±23% increased survival, and preserved dendritic arborization of 423±372%, over non-B cell control. However, a lower 4-day post stroke B cell treatment at a ratio of 1:10 significantly preserved dendritic arborization at 67±32% over non-B cell control, without altering overall cell number. Conclusions: Our pre-treatment condition suggest that B-cells promote neuroprotection, while our post-treatment condition still need further dissection in order to understand the dynamic interplay between B-cells and neurons. Nonetheless, these results are the first to indicate a direct B cell function in neuronal survival following ischemia. Future experiments will aim to elucidate the mechanism(s) of action through ELISA and downstream signaling assays.

Title: Activated protein C (APC) in the acute phase suppresses the development of cerebral infarction after focal cerebral ischemia

Authors: *K. YAMATO[1], Y. NAKAJO[1,4], H. YAMAMOTO–IMOTO[2], K. KOKAME[2], T. MIYATA[2], H. KATAOKA[3], J. C. TAKAHASHI[3], H. YANAMOTO[1,5];

Laboratory, Rakuwa–kai Otowa Hosp., Kyoto, Japan; [5]Dept. of Cardiovasc. Science, Div. of Surgical Med., Osaka Univ. Grad. Sch. of Med., Suita, Japan

Abstract: Despite years of research and efforts to translate stroke research into clinical therapy, ischemic stroke remains a major cause of death, disability, and diminished quality of life. Recombinant tissue-type plasminogen activator (tPA) is the only approved therapy for acute ischemic stroke. Although more aggressive thrombolysis was expected to be more beneficial, higher doses of tPA are associated with an increased risk of hemorrhagic transformation and neurotoxicity. In this study, we used activated protein C (APC), a serine protease found in the human blood with anticoagulant activity. APC has also been reported to possess potent cytoprotective activities. We used our original three-vessel occlusion (3-VO) ischemia mouse model (15-minute focal ischemia limited to the cortex), recently reported. Mice received either APC (2, 4 or 8 mg/kg; supplied by The Chemo-Sero-Therapeutic Research Institute), or human albumin as vehicle control, or saline, intravenously, five minutes after the induction of ischemia (N=7-13). The second injection of the same drug or control was performed three hours later. The regional cerebral blood flow was monitored before (control), during, and after ischemia using laser Doppler flowmetry. We evaluated neurological deficit using our original tail suspension test or bar-balance test, at 24 hours after ischemia. Each brain was cut into 1 mm-thick slices, and the volumes of infarcted lesions and edema were analyzed using 2% TTC. The results showed that, APC (2 mg/kg) significantly suppressed infarcted volumes (adjusted by edema) compared to albumin or saline (APC: 14.3±4.7 mm^3, albumin: 19.6±4.8 mm^3, saline: 21.7±6.6 mm^3; $p<0.05$). In the functional analysis, the neurological deficits were less in APC compared to the saline. In the dose-escalation test on the APC-treatment, infarcted volumes in APC (4 or 8 mg/kg) or saline were relatively or significantly larger compared to APC (2 mg/kg) ($p<0.05$). It had been reported that protein C (PC) levels under normal condition were inversely associated with incidence of ischemic stroke but not coronary heart disease, suggesting that PC or APC may be an endogenous brain-protectant. In the present study, APC, when administered after the

induction of focal ischemia (five minutes in mice is regarded as the equivalent of 40 minutes in humans according to the physiological time scale), damage of the brain was significantly reduced, when the dosage of APC was appropriate, along with a trend towards improved neurological deficit at 24 hours after ischemia. The administration of APC for the treatment of ischemic stroke in the acute phase to protect the brain is a promising candidate for a future clinical trial.

Title: Spatiotemporal synchrony predicts brain viability in a rodent model of ischemic stroke

Authors: *E. G. WANN, N. S. JACOBS, R. D. FROSTIG;
Neurobio. and Behavior, Univ. of California Irvine Dept. of Neurobio. and Behavior, Irvine, CA

Abstract: Stroke is the fifth leading cause of death in the United States, and the majority of these cases are due to Middle Cerebral Artery (MCA) ischemia (Mozaffarian et al., 2016). Improved treatments for MCA ischemia are necessary as current therapeutic strategies are only effective for a subset of stroke patients and only reduce damage or its functional consequences. Previous studies from our laboratory have demonstrated that sensory stimulation delivered within 2 hours (‘early treatment’) after permanent MCA occlusion (pMCAO) completely protects the cortex from impending stroke damage, whereas the same intermittent sensory stimulation results in exacerbated damage if delivered 3 or more hours after ischemic onset (‘late treatment’) (Frostig et al., 2012). The interaction between sensory stimulation treatment and the post-ischemic (0-5 hours) neuronal network state is unknown but may be important for understanding the efficacy of sensory stimulation treatment. Using multisite local field potential (LFP) recordings across horizontal locations of S1 and all cortical depths, this research generates for the first time a continuous spatiotemporal profile of neuronal activity from the MCA territory during the acute post-ischemic period. Spatiotemporal synchrony, a measure of coordinated neuronal activity

across recording locations, is increased primarily in the delta band directly after pMCAO and is persistently high throughout the acute post-pMCAO period in pMCAO alone animals. Our data further indicate that high post-pMCAO spatiotemporal synchrony is reduced and baseline spatiotemporal synchrony is reestablished in early treated but not late treated animals. As synchrony is known to be fundamental for cortical function and relevant to many pathological brain states, enhanced spatiotemporal synchrony may be a signature of cortical network dysfunction after pMCAO and predictive of whether damage is incurred after pMCAO and sensory stimulation treatment.

Title: Association between diabetes < chronic cerebral hypoperfusion induces cognitive impairments < enhances microglia expression in the hippocampus of middle aged rats.

Authors: *A. N. HUBNER, E. D. F. FERREIRA, R. M. M. W. OLIVEIRA, H. MILANI; Pharmacol. and Therapeut., State Univ. of Maringa, Maringa, Brazil

Abstract: Introduction: Vascular dementia (VD) is a progressive disease, caused by reduced blood flow to the brain that affects cognitive abilities. Diabetes has been established as a risk factor for VD and reported to almost double the risk of VD. The vascular damages caused by hyperglycemia induces a chronic cerebral hypoperfusion (CCH) state. Experimentally, the permanent four vessel occlusion/internal carotid artery model (4-VO/ICA) in rats reproduces some behavioral and cellular aspects of VD, such as memory impairment and hippocampal neurodegeneration. **Aim:** To investigate the behavioral outcomes of the association between hyperglycemia and 4-VO/ICA in middle-aged rats. The expression of microglia in the hippocampus was also evaluated. **Methods**: The Ethical Committee on Animal Research of State University of Maringá approved all experimental procedures (CEUA 15/2014). Male 12 months old Wistar rats received a single dose of streptozotocin (35 mg/Kg, i.v.) to induce diabetes condition. Animals with glycemia values > 250mg/dl were considered hyperglycemic. The animals were trained in the aversive radial maze (AvRM), during 15 days. After, the animals were submitted to sham or 4-VO/ICA surgeries. Four experimental groups were generated:

sham+hyperglycemia; sham+normoglycemia; 4VO/ICA+normoglycemia and 4VO/ICA+hyperglycemia. The animals were assessed for memory performance in the AvRM at 7, 14, 21 days after the surgeries. The following parameters were registered: (i) latency, (ii) number of reference memory errors and (iii) number of working memory errors. The animals then had their brains removed for immunohistochemical analysis of microglial ionized calcium-binding adaptor molecule-1 (Iba-1) expression. Behavioral data were analyzed by two-way ANOVA followed by the *post hoc* Bonferroni test. Histological data were normalized to the meanvalues of the sham group and analyzed by the Student *t* test. **Results**: Significant differences in the latency ($F_{1.60}$ = 15.44; p= 0.0005), reference errors ($F_{1.60}$= 4.313; p = 0.0465) and working errors ($F_{1.60}$= 10.55; p=0.0029) were detected when comparing 4-VO/ICA+normoglycemia *versus* 4-VO/ICA+hyperglycemia groups. The 4-VO/ICA+hyperglycemia group presented increase in the Iba-1 expression compared with the 4-VO/ICA+normoglycemia (t_{10}=3.00;p=0.013), sham+hyperglycemia (t_{10}=4.49;p=0.012) and sham+normoglycemia (t_9=4.14;p=0.0025). **Conclusion:** Association of hyperglycemia and 4VO/ICA induces cognitive impairments and enhances the microglial expression in the CA1 hippocampal subfield of middle-aged rats.

Title: Inhibiting post-stroke neuroinflammation by ischemia-targeted complement modulation limits acute injury and promotes motor and cognitive recovery after murine stroke

Authors: *A. ALAWIEH[1], F. LANGLEY[1], L. KULIK[2], M. HOLERS[2], S. TOMLINSON[1,3]; [1]Microbiology and Immunol., Med. Univ. of South Carolina, Charleston, SC; [2]Med. and Immunol., Univ. of Colorado Sch. of Med., Denver, CO; [3]Ralph H. Johnson VA Med. Ctr., Charleston, SC

Abstract: Ischemia leads to the cellular expression of damage-associated molecular patterns (DAMPS) and their recognition by natural IgM antibodies that subsequently activate complement and propagate inflammation. We previously isolated two natural IgM monoclonal antibodies (mAbs) from un-manipulated mice: B4 that recognizes modified annexin-IV, and C2 that recognizes a subset of phospholipids. Both B4 and C2 mAbs specifically recognized ischemic cells and reconstituted cerebral ischemia reperfusion injury in otherwise protected antibody-deficient Rag1-/- mice. Therefore, we developed a novel strategy of site-targeted complement inhibition by fusing a single chain antibody (scFv) derived from the B4 mAb to the complement inhibitor, Crry. We show that the fusion construct, B4scFv-Crry, inhibits complement activation in-vitro and specifically targets the ischemic brain in-vivo following 60 min transient middle cerebral artery occlusion (MCAO). A single dose of B4scFv-Crry administered 5 hr. after reperfusion inhibited IgM and complement deposition in the ischemic brain, and significantly reduced infarct volume and neurological deficit scores in both young and aged mice as measured 24 hr. after ischemia. B4scFv alone provided similar levels of improvement at 24 hr. after ischemia, but only B4scFv-Crry provided protection into the chronic phase (15 days), yielding significant reduction in cell death and tissue scarring, and significant improvement in gross motor deficits, forelimb asymmetry and cognitive performance. Following MCAO, we observed a sustained neuro-inflammatory response manifesting as continuous IgM and complement deposition and robust M1 (pro-inflammatory)-type activation of microglia lasting beyond 15 days after reperfusion. However, acute administration of B4scFv-Crry after stroke interrupted the inflammatory neurodegenerative cycle by significantly inhibiting complement and IgM deposition, and shifting microglial polarity to resting and M2-polarized phenotypes in the chronic phase. Finally, we demonstrated that both B4scFv and B4scFv-Crry bound specifically within the ischemic core and penumbra of brain samples obtained from patients who died after acute stroke. No binding was observed in sections prepared from normal brain tissue from the same patient, or from age-matched controls. These data indicate a similar DAMP recognition system occurs in the brains of mouse and man, and that B4scFv-targeted complement inhibition has translational potential for inhibiting inflammatory neurodegenerative cascades after stroke in order to improve motor and cognitive outcomes.

Title: Modeling upper extremity impairments after subcortical white matter stroke in rats: forelimb strength and skill decrements in an isometric pull task after focal infarcts of the posterior limb of the internal capsule

Authors: *E. NUDI[1], B. R. BARKSDALE[2], S. K. YOUNG[1], T. A. JONES[3];
[2]Inst. for Neurosci., [3]Dept. of Psychology and The Inst. of Neurosci., [1]Univ. of Texas at Austin, Austin, TX

Abstract: Stroke affects around 800,000 people in the United States each year and is the fifth leading cause of death. It is common for stroke survivors to experience lasting upper limb motor impairment and many of these have damage only to subcortical white matter. Upper limb impairments after strokes involving the posterior limb of the internal capsule are especially common. However, most animal stroke models do not specifically target the posterior limb of the internal capsule. This study aims to characterize forelimb motor function over time following focal ischemic damage to the posterior limb of the internal capsule, induced via slow microinfusion of the vasoconstricting peptide, endothelin-1. An angled infusion approach was used to minimize direct damage to motor cortex. Male Long-Evans rats were pre-trained on an isometric pull task (Vulintus, Mototrak) until proficiency on the task was reached (~90% success rate). In this task, rats in a chamber reach through a window to grasp and pull a lever. Pulls that are made with sufficient force are rewarded by release of a banana flavored food pellet into the chamber. The success rate and force generation during the pull are measured. After lesion induction, animals were then given a 4-5 day recovery period, followed by periodic retesting on the same task. As measured on the first post-infarct testing day, there was a more than 50% reduction in success rate and pull force, which subsequently partially improved towards baseline. The assessment period is ongoing with behavioral testing being conducted weekly for at least 3 months. These preliminary results support that this model of subcortical white matter stroke results in weakness and impaired motor skill, reproducing important clinical characteristics of upper extremity motor impairment after stroke.

Title: Optogenetic stimulation improves iPS-NPCs transplantation therapy after ischemic stroke

Authors: D. CHEN[1,2], Z. Z. WEI[1,2], K. BERGLUND[3], X. GU[1,2], M. SONG[1], O. MOHAMAD[1], *S. YU[1,2], L. WEI[1,2,3];

Abstract: Stroke remains a leading cause of human death and long-term disability with very few effective treatments. Stem cell transplantation therapy provides the possibility to regenerate and repair damaged brain tissues after ischemic stroke. In this study, we tested the hypothesis that a combination strategy of iPS-NPCs transplantation and optogenetic manipulation could enhance regenerative properties of transplanted cells, resulting in better tissue repair and functional recovery after stroke. The blue light sensitive channelrhodopsin 2 (ChR2) channel was expressed in iPS cell-derived neural progenitor cells (iPS-NPCs). These optogenetic-engineered iPS-NPCs could differentiate to functional neurons that fire action potentials evoked by current injection or blue light stimulation. Light stimulation increased mRNA levels of synaptic markers Synapsin-1 and PSD95, and growth factors FGF, BDNF and SDF-1 in differentiated neurons. Light stimulation also increased the axonal outgrowth of iPS-NPCs derived neurons. ChR2-engineered iPS-NPCs were transplanted into the ischemic core and penumbra 7 days after focal ischemic stroke in mice. One day after cell transplantation, blue light stimulation (10 Hz, 15 min) was performed 3 times daily until 14 days after stroke. Immunochemistry staining results showed that light stimulation of grafted iPS-NPCs resulted in higher level of Synapsin-1 in the peri-infarct region compared to animals received iPS-NPC transplantation but without stimulation. The adhesive removal test revealed that iPS-NPC transplantation plus optogenetic stimulation

significantly promoted sensorimotor function and whisker touching behavior 14 days after stroke compared to no stimulation controls. These results suggest that optogenetics can be used to promote the iPS-NPCs transplantation therapy after stroke for tissue repair and functional recovery.

Title: Ripk mediates outcome after intracerebral hemorrhage in mice

Authors: ***S. LULE**[1], L. M. MCALLISTER[1], Y. ZHENG[1], L. WU[1], J. BERTIN[2], M. J. WHALEN[1];
[1]Mgh/Harvard Med. Sch., Charlestown, MA; [2]Pattern Recognition Receptor DPU, GlaxoSmithKline, Collegeville, PA

Abstract: Intracerebral hemorrhage (ICH) results in high mortality and severe neurological deficits in survivors. ICH lacks specific therapy in part because mechanisms of cell death after ICH are incompletely understood. Necroptosis is a form of programmed necrosis mediated by receptor interacting protein kinases (RIPK) 1 and 3. Our previous report suggested a role for RIPK3 in plasmalemma damage typical of necrosis in a collagenase ICH model (Zhu et al, 2012). Here, we used RIPK1 kinase dead mutant mice to test the hypothesis that necroptosis is a predominant mechanism of cell death after ICH in mice. We induced ICH in mice using stereotactic injections of 30µl autologous blood into the right striatum (0.1mm anterior, 2.5mm lateral, 3mm ventral to bregma). Propidium iodide (PI) was injected intraperitoneally to label brain cells with plasmalemma damage. Fluoro Jade B was used to label degenerating neurons. Cell counts were performed blindly in 8 core and 8 peripheral regions of the ICH. Grid walk, wire grip, context fear conditioning, and Morris water maze (MWM) were used to assess sensorimotor and cognitive function after ICH. Mice containing loss of function point mutations in the RIPK1 kinase domain (D138N or K45A) were used to assess RIPK1 function in the ICH model. RM ANOVA was used to analyze weight loss, motor and MWM data and cell count data were analyzed by ANOVA/t-test. Plasmalemma damage was an early and persistent feature of

neuronal and non-neuronal cellular injury. PI+ cells were identified at 6 h, peaked at 24-48 h ($p<0.05$ vs. sham ICH 24 h), and few were detected at 7 d. At 24 h, over 90% of FJB+ cells colocalized PI+, with over 75% of FJB+ cells co-localizing PI at 48 and 72 h. In pulse labeling experiments, the majority of PI+ cells disappeared from injured brain between 1 and 6 h of labeling. $Ripk1^{D138N/D138N}$ mutant mice had significantly reduced PI+ cells at 24 h (Core: 19±3, Periphery: 20±4) compared to WT (Core: 120±29, Periphery: 51±10/x200 field, $p<0.01$) and 50% less FJB+ cells in core and periphery regions ($p<0.05$). Both $Ripk1^{D138N/D138N}$ and $RIPK1^{K45A/K45A}$ mutant mice had significantly improved postinjury weight gain ($p<0.05$) and improved postinjury MWM performance ($p<0.01$ RM ANOVA) but no differences in swim speeds, corner turn, foot fault, wire grip, Y-Maze, and contextual fear learning. The data suggest a predominant role for necrosis in autologous blood ICH-induced cell death. RIPK1 appears to play a significant role in neuronal and non-neuronal cell death as well as in recovery of weight gain and cognitive function after ICH. The data suggest that RIPK1 may be a novel therapeutic target to improve outcome after ICH.

Title: BMP-4 expression by pericytes after ischemia aggravates white matter damage.

Authors: *M. UEMURA;
Kyoto Univ., Kyoto, Japan

Abstract: ***Objective*** Dysregulated transforming growth factor beta (TGFβ) signaling is considered to play a detrimental role in pathogenesis of cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL), a hereditary type of vascular cognitive impairment (VCI). However, the largest group of TGFβ superfamily members, bone morphogenetic proteins (BMPs), has not been explored in dementing disorders. The aim of this study was therefore to characterize signaling abnormalities of BMP family in VCI. ***Methods*** To investigate the role of BMPs in VCI, we performed an immunohistochemical study using post-mortem frontal lobe tissues from 6-7 cases of VCI, Alzheimer's disease, and age-matched controls. Brain sections were immunostained with antibodies against TGFβ1 and BMPs (BMP-2/4/6/7/9), as well as two pericyte markers and an oligodendrocyte precursor cell (OPC) marker.

We subsequently tested oxygen-glucose deprivation (OGD) in cultured pericytes to simulate ischemia, and also investigated effects of BMP-4 on cultured vascular cells and myelin related cells. ***Results*** Among the TGFβ superfamily members, BMP-4 was highly expressed in pericytes in the white matter of VCI, and its expression correlated with the degree of myelin loss. The number of OPC was fewer in the subventricular zone with higher BMP-4 expression. In cultured pericytes, continuous OGD induced BMP-4 expression. Recombinant BMP-4 induced tube formation of endothelial cells and proliferation of pericytes. Meanwhile, BMP-4 suppressed maturation of OPCs and strongly induced conversion of OPCs to astrocytes. ***Conclusions*** Our findings suggest that ischemic myelin damage evolves in parallel with BMP-4 upregulation in pericytes. BMP-4 expression promotes angiogenesis but induces astrogenesis at the expense of OPC maturation and proliferation, which may aggravate myelin damage. These results may explain why white matter is particularly vulnerable to chronic hypoperfusion. Regulation of BMP-4 signaling has the potential as treatment strategy for VCI.

Title: Post stroke dietary supplementation of omega3 polyunsaturated fatty acids combined with docosahexaenoic acid treatment promote neurological recovery in aged mice after cerebral ischemia

Authors: *X. JIANG[1,2], J. SUENAGA[3], H. PU[3], Z. WENG[3,4], Y. SHI[3], X. HU[2,3,4], J. CHEN[2,3,4]; [1]Univ. of Pittsburgh Sch. of Med., Inst. of Brain Disorders & Recovery, Pittsburgh, PA; [2]State Key Lab. of Med. Neurobio. and Inst. of Brain Sciences,Fudan Univ., Shanghai, China; [3]Inst. of Brain Disorders & Recovery, Univ. of Pittsburgh Sch. of Med., Pittsburgh, PA; [4]Geriatric Research, Educational and Clin. Center, Veterans Affairs Pittsburgh Hlth. Care Syst., Pittsburgh, PA

Abstract: Stroke is a leading cause of serious long-term disabilities in adults in the US. Nowadays, treatment to ischemic stroke is largely limited to tPA thrombolytic therapy. Previous studies have demonstrated that prophylactic food supplement of omega-3 polyunsaturated fatty acids (n-3 PUFAs) and docosahexaenoic acid (DHA) could ameliorate brain injury after ischemic stroke. However, the therapeutic effect of post-stroke n-3 PUFA or DHA supplementation in aged mice is not well characterized and is what we aimed to find out in this study. 18 months old C57BL/6J mice induced with distal middle cerebral artery occlusion (dMCAO) were randomly assigned to 4 groups: 1) vehicle, 2) DHA, 3) n-3 PUFAs and 4) DHA+n-3 PUFAs groups. All measurements were made by investigators blinded to experimental groups. DHA (10mg/kg) was given intraperitoneally 24h after dMCAO and then once daily until 10 days after dMCAO. Dietary n-3 PUFA supplementation (50 mg in every gram of regular diet) started from 5 days after dMCAO until sacrificed. Neurological deficits and brain tissue loss, neurogenesis, angiogenesis and oligodendrocyte regeneration were assessed up to 35days after dMCAO. The results show that n-3 PUFA or DHA treatment did not reduce brain tissue loss (n=8-10 per group, $p>0.05$ vs. vehicle by ANOVA). Although the infarct volume was limited to

the cortex and showed no difference among groups, rotarod test and adhesive removal test indicated significant sensorimotor deficits which last up to 35 days after injury. Aged mice which received n-3 PUFA with combined DHA demonstrated significantly attenuated deficits (n=6-8 per group, $p<0.05$ vs. vehicle by ANOVA and *post hoc* turkey test). In the Morris water maze test, DHA alone or combined with n-3 PUFAs promoted the learning and memory ability in aged mice, reflected by decreased latency to find the hidden platform and increased time in the goal quadrant (n=9-11 per group, $p<0.05$ vs. vehicle by unpaired t-test). Further immunostaining show that angiogenesis was enhanced in n-3 PUFAs alone or combined with DHA treatment group as demonstrated by increased number of $BrdU^+CD31^+$ vessels in both cortex and striatum at 35 days post injury (N=8 per group, $p<0.01$ vs. vehicle by ANOVA and *post hoc* turkey test). Interestingly, newly proliferated neurons ($BrdU^+NeuN^+$ cells) and oligodendrocytes ($BrdU^+APC^+$ cells) were seldom found in all the groups. Our results suggest that n-3 PUFAs dietary supplementation combined with DHA treatment showed beneficial effects in the aged mice after dMCAO by attenuating neurological deficits and promoting angiogenesis. Also, it may be a clinically translatable treatment for ischemic stroke in the aged population.

Title: Lacunar stroke in the rat using an optrode and rose bengal causes selective lesion of the forelimb representation of the internal capsule

Authors: *T. WEN[1], A. SINDHURAKAR[1], V. CONTRERAS[1], H. PARK[1], J. B. CARMEL[1,2]; [1]Burke Med. Res. Inst., White Plains, NY; [2]Brain and Mind Res. Inst. and Departments of Neurol. and Pediatrics, Weill Med. Col. of Cornell Univ., New York, NY

Abstract: Subcortical stroke leads to significant neurological impairment and represent an important public health challenge. Available animal models are limited in the variability of the targeting and the size of the stroke. The aim of this study was to use the combination of an optic fiber and an electrode to establish a reproducible lacunar stroke in the rat. We first performed tract labeling and electrophysiological motor mapping of the rat IC to better characterize the IC

somatotopy. For tract labeling, we injected AAV2 viruses expressing green and red fluorescent protein into the forelimb and the hindlimb areas of the cortex, respectively. For mapping, we used a microelectrode to stimulate the IC and characterized the responses as forelimb, hindlimb, or both. From both anatomy and physiology, we found largely separate representations of the forelimb and hindlimb in the IC. We used this map to target the forelimb representation at 7.0-7.5 mm ventral to the dura mater. The electrode was used to locate the hot spot of the forelimb representation, where forelimb movements could be elicited at low stimulus intensity. At this location, the optic fiber was used to activate systemically administered rose bengal using green wavelength light to cause the lesion. The lesion was selectively confirmed in the target posterior limb of the IC by TTC (2,3,5-triphenyltetrazolium chloride) staining and cresyl violet staining 48 hours after lesion. We compared our new method against local injection of the vasoconstrictor endothelin-1. Endothelin injection caused more widespread damage to the cortex and the corpus callosum of the injected hemisphere. In sum, the new method is both highly reproducible and selective for the forelimb representation of the IC. Thus, we can use this model to mimic the human clinical condition and to study which circuits help mediate functional recovery after subcortical stroke.

Title: Effect of systemic hemopexin therapy after intracerebral hemorrhage

Authors: Y. CAO, Z. YAN, J. CHEN-ROETLING, *R. F. REGAN;
Dept Emergency Med., Thomas Jefferson Univ., Philadelphia, PA

Abstract: Erythrocyte lysis after intracerebral hemorrhage (ICH) exposes adjacent cells to toxic concentrations of hemoglobin, which rapidly oxidizes to methemoglobin and releases its heme moieties. Experimental evidence suggests that heme and its degradation products initiate oxidative and inflammatory injury cascades that may be amenable to targeted therapies. The

primary defense against heme toxicity is provided by hemopexin, a glycoprotein that binds it with extraordinary affinity and mitigates its pro-oxidant and pro-inflammatory effect. A prior study demonstrated that hemopexin knockout increased striatal injury in both the collagenase and blood injection ICH models. The present study tested the hypothesis that exogenous human hemopexin protected wild-type mice in these models. Pharmacokinetic studies demonstrated that 70 mg/kg hemopexin i.p. daily maintained serum human hemopexin concentrations at 0.9-1.2 mg/ml, a range similar to human physiologic levels, and had no sustained effect on mouse hemopexin levels. Injection of collagenase into the right striatum of Swiss-Webster mice reduced perihematomal cell viability to 50±6% of contralateral, as measured by MTT assay after striatal dissociation. Treatment with 70 mg/kg human hemopexin i.p. daily beginning two hours after collagenase increased striatal cell viability to 85±9% (P= 0.013). Hemopexin at this dose also provided significant blood-brain barrier protection, with leakage of Evans blue decreasing from 71±7 to 40±8 ng/striatum. However, a lower hemopexin dose (35 mg/kg) provided no benefit. A more variable effect was observed using C57BL/6 mice expressing the red fluorescent protein dTomato in neurons, with significant protection observed at 8 days after collagenase injection, but not at 3 days. The blood injection model produced somewhat less injury, reducing striatal cell viability to 67±2% of contralateral at three days in control mice, increasing to 84±4% with 35 mg/kg hemopexin treatment ($P < 0.05$). These results indicate that systemic therapy with human hemopexin may mitigate perihematomal cell loss after experimental ICH, and suggest that further investigation of its therapeutic potential is warranted.

Title: Quantifying deficits in forelimb force generation using an automated skilled reaching task after middle cerebral artery occlusion in rats

Authors: *K. S. VALENZUELA, N. MITTAL, T. A. JONES, T. SCHALLERT;
Psychology, The Univ. of Texas At Austin, Austin, TX

Abstract: Reaching tasks are commonly used to assess various facets of forelimb function following stroke in rat models. These tasks provide valuable information about skilled forelimb performance and movement quality, although they do not directly quantify the strength of movement. The Isometric Pull Task (MotoTrak, Vulintus), a fairly new behavioral neuroscience task, is a fully automated system that incorporates reach-to-grasp motion and provides quantitative data on forelimb force generation. Furthermore, forelimb force generation in clinically relevant stroke models such as middle cerebral artery occlusion (MCAo) has not been examined. Male Long Evan rats (n=8) were trained with their preferred limb to reach outside a chamber, grasp a handle attached to a stationary force transducer, and pull with a predetermined amount of force to receive a banana flavored food pellet. Transient focal ischemia was induced in the hemisphere contralateral to the preferred limb by an intraluminal middle cerebral artery occlusion suture method. Focal ischemic time was 60 mins and was confirmed via Laser Doppler flow. Animals were then probed for deficits of forelimb strength during 30 min probe sessions with the Isometric Pull Task on days 5, 10, 15, 21, and 28 post-MCAo. An adaptive setting on MotoTrak was used post-MCAo to accommodate for the severity of the impairments. Additionally, an arm barrier was inserted in order to prevent compensation with the unimpaired limb. Average forelimb force dropped from 189 grams at pre-MCAo baseline to 40g on Day 5 post-MCAo. At Day 28 post-MCAo, average forelimb force was only 75g. Additionally, the average number of pull attempts per session was 188 at pre-MCAo baseline and dropped to 5 at Day 5 post-MCAo. The average number of pull attempts at Day 28 was 67. Forelimb weakness is often seen in stroke patients. We demonstrated that the Isometric Pull Task is sensitive to robust deficits in forelimb force generation following MCAo. This task provides an additional measure that can be used to evaluate motor dysfunction that is characteristic of upper extremity impairments in clinical stroke populations.

Title: Learned-subordinate use of the paretic forelimb after motor cortical infarcts in rats: effects of prior task experience

Authors: *D. MILLER[1,2], K. V. TRUONG[3], E. T. NUDI[4], T. A. JONES[1,4];
[1]Inst. of Neurosci., [2]Biochem., [3]Publ. Hlth., [4]Psychology, Univ. of Texas At Austin, Austin, TX

Abstract: The impact of stroke on the performance of unimanual tasks with the paretic side has been extensively studied in animal models and clinical populations. Its impact on bimanual coordination has not received as prominent attention, though both hands are normally used together for most manual tasks. We recently developed a bimanual skill task, the popcorn retrieval task, which rats perform using coordinated asymmetrical reach and grasp movements with both forelimbs (Dutcher et al., 2013). In rats that are skilled in unimanual reaching, *de novo* training on the popcorn retrieval task after unilateral motor cortical infarcts results in a progressive shift from dominant use of the paretic (uni-manually trained pre-infarct) to the nonparetic forelimb over weeks of training. That is, the task revealed practice-dependent learned subordinant-use of the paretic limb. The present study aimed to characterize (1) how intact animals learn the popcorn retrieval task and (2) how, once established, the bimanual reaching skill is affected by unilateral infarcts of the caudal forelimb area (CFA) of motor cortex. After a shaping period, rats were trained for 20 days (1 session/day) on the popcorn retrieval task, followed by ischemic (endothelin-1 induced) CFA lesions contralateral to the dominant-for-task limb and 20 additional days of testing on the same task. Limb dominance was defined by asymmetries in the number of reach attempts and reach initiations made by each limb. Before the lesions, limb asymmetries progressively increased over the first 11 days of training and then plateaued, suggesting the establishment of a stable inter-limb coordination strategy. This was followed by peak performance (12-14 days), as measured by successful retrievals. After the lesions, the proportions of reaching movements made with either limb converged over the first 2 days, with approximately symmetrical proportions thereafter. There were reductions in reach initiations with the paretic (previously dominant limb), but this limb continued to initiate most reaches. These effects contrast with the complete reversal of limb dominance that was observed with *de novo* post-lesion training on the task. Thus, the pattern of change in bimanual coordination strategies after CFA infarcts varies between a newly learned versus well-established skill.

Title: Cerebral blood flow is impaired in concussed rugby players immediately following injury and affected by previous concussion history

Authors: *J. M. SERRADOR, M. FALVO;
Pharmacology, Physiol. & Neurosci., Rutgers, Newark, NJ

Abstract: Increasing evidence is suggesting that concussions are a possible significant cause of long term cognitive and health problems among athletes. Despite this increasing evidence, there is a lack of data on the physiological effects of a concussion on cerebral blood flow regulation. The goal of this work was to determine if concussions cause impairment of cerebral blood flow regulation in the first few hours after injury. In addition we were interested if history of previous concussions affected the response.

During a recreational rugby tournament a total of 91 players were recruited. Of these players, 59 were recruited as controls (12 females) and 34 had suffered a concussion (8 females). All testing was performed on the field to assess cerebral blood flow using Doppler, beat-by-beat blood pressure, and end-tidal CO_2. Subjects performed three sit to stand maneuvers. Data was collected 131±23 min following the head trauma.

We had previously found that concussed players demonstrated greater mean arterial pressure than controls and this was associated with significantly lower internal carotid blood flow. Examining history of concussion, we found that concussed rugby players with a history of concussion had significantly higher mean arterial pressures than those without (No H_x: 93.5±11.9 vs H_x: 102.1±14.9 mmHg, P=0.03). In contrast there was no difference in blood pressure in the non-concussed group. Examining internal carotid flow in the non-concussed group there was a tendency for flow to be lower in players with a history of concussions (Controls: No H_x: 515±186 vs H_x: 450±165 mL/min) but not in players who had just suffered a concussion (No H_x: 309±168 vs H_x: 330±101 mL/min). Surprisingly, players with a current concussion but no history had greater drops in blood pressure when standing than those with a history of concussion (No H_x: -23.4±12.1 vs H_x: -17.5±7.6 mmHg, P=0.016). They also demonstrated greater drops in middle cerebral artery flow velocity when standing (No H_x: -19.2±5.6 vs H_x: -15.0±6.7%, P=0.031)

These data suggest that while cerebral blood flow is impaired immediately following concussion, a previous history of concussion may also be associated with lower cerebral blood flow at baseline. Surprisingly previous history of concussion seemed to be protective to maintaining blood pressure and cerebral blood flow when standing, following a concussion. Further work is needed to determine how previous history of concussion may affect both blood pressure and cerebral blood flow regulation. This work was supported by the War Related Illness and Injury Study Center within the Department of Veteran Affairs.

Title: The effects of concussion-prone athletics on the brain: A comparison of football, cross-country, and socioeconomically matched non-athletes using diffusion-imaging.

Authors: B. A. CARON[1], D. A. KELLAR[2], F. PESTILLI[2], H. CHENG[2], S. D. NEWMAN[2], *N. L. PORT[3];
[1]Program in Neurosci., [2]Psychological and Brain Sci., [3]Indiana Univ., Bloomington, IN

Abstract: With the upward trend in early deaths and retirements by American football players, the topic of behavioral and structural deficits caused by concussion is an increasingly important one in the related research fields. With an incidence rate of 2.9 competition concussions per 1,000 athlete exposures (NCAA 2013) in collegiate football, the concussion risk to athletes is significant. However, even subconcussive blows, or blows that do not lead to a concussion diagnosis, appear to create health risks for athletes. On average, non-concussed Division 1 football players experience 503 impacts at 54G's or above (McAllister et al., 2014). These subconcussive blows appear to lead to significant neural changes, the severity of which may depend on the number of hits. In a study of non-concussed high school football players, Talavage et al (2014) found that athletes with a higher number of subconcussive blows were significantly different in fMRI and neurocognitive testing paradigms than athletes with a lower number of subconcussive blows. Similarly, McAllister et al (2014) demonstrated that white matter measures both FA (fractional anisotropy) and MD (mean diffusivity) correlated with neurocognitive test scores and head impact exposure. The present study attempted to replicate previous studies measuring changes in white matter measures (FA and MD) of 19 Division I upperclassmen football players, a group that we hypothesized experiences a high number of subconcussive blows, with 16 male cross-country athletes and 12 socioeconomically matched male non-athlete undergraduates using diffusion-weighted MRI and tract-based spatial statistic analyses. The present study went furthered established findings by measuring white matter tissue changes using advanced microstructural metrics, such as neurite-orientation dispersion and density (Zhang et al., 2012). No statistical differences were found between the football players and the other groups in regards to FA, statistical differences were found instead for MD, with football players having lower values than either control group. Importantly, football players showed higher neurite-orientation dispersion and density in the thalamus and extending through the frontal

cortex. No significant differences were found between the cross-country and the non-athlete control groups for any of the measures tested. These results support the hypothesis that multiple subconcussive blows result in microstructural white matter tissue changes. Future research is needed to determine a causal relationship between subconcussive blows and white matter tissue changes, and the mechanism/s by which these changes are produced.

Title: Resting-state MEG reveals different patterns of aberrant functional connectivity in combat-related mild traumatic brain injury

Authors: *M. HUANG[1,5], D. L. HARRINGTON[1,5], A. ROBB SWAN[5], A. ANGELES[5], S. NICHOLS[6], A. DRAKE[7], T. SONG[2], M. DIWAKAR[2], C. W. HUANG[3], V. B. RISBROUGH[5,4,8], A. DALE[2], H. BARTSCH[2], R. LEE[5,2], D. G. BAKER[5,4,8]; [2]Radiology, [3]Bioengineering, [4]Psychiatry, [1]UCSD, San Diego, CA; [5]Radiology, Research, and Psychiatry Services, VA San Diego Healthcare Syst., San Diego, CA; [6]Neurosci., Univ. of California San Diego, San Diego, CA; [7]Naval Med. Ctr., San Diego, CA; [8]VA Ctr. of Excellence for Stress and Mental Hlth., San Diego, CA

Abstract: Blast mild traumatic brain injury (mTBI) is a leading cause of sustained impairment in military service members and Veterans. However, the mechanism of persistent disability is not fully understood. In the present study, disturbances in brain functioning were investigated in mTBI participants using a source-imaging-based approach to analyze functional connectivity

(FC) from resting-state magnetoencephalography (rs-MEG). Study participants included 26 active-duty service members or Veterans who had blast mTBI with persistent post-concussive symptoms and 22 healthy control active-duty service members or Veterans. The source time-courses from gray-matter regions of interest (ROIs) were then used to compute ROI to whole-brain (ROI-global) FC for two different measures: 1) time-lagged cross-correlation and 2) phase-lock synchrony. FC analyses were conducted for different frequency bands. Compared with the controls, participants with blast mTBI showed increased gray-matter ROI-global FC in beta, gamma, and low-frequency bands, but not in the alpha band. Sources of abnormal increases in FC were from the: 1) prefrontal cortex (right ventro-medial prefrontal cortex, right rostral anterior cingulate cortex), left ventro-lateral and dorsolateral prefrontal cortex; 2) medial temporal lobe (bilateral parahippocampal gyri, hippocampi, and amygdala); and 3) right putamen and cerebellum. In contrast, the blast mTBI group also showed decreased FC of the right frontal pole. Group differences were highly consistent for the two different FC measures. FC of the left ventro-lateral prefrontal cortex correlated with cognitive functioning in mTBI participants. Altogether, our findings of increased and decreased regional-patterns of FC suggest that disturbances in the intrinsic organization of the brain may be due to multiple mechanisms.

Title: Melatonin attenuates traumatic brain injury induced inflammation

Authors: ***J. JI**;
Dept. of Neurosurg., Nanjing Med. Univ., Nanjing, China

Abstract: Melatonin functions as a crucial mediator of inflammation; however, the underlying mechanisms of this process remain poorly understood. Dysfunctional mitochondria, a main

source of reactive oxygen species (ROS), are impacted in inflammation activation. Herein, inhibition of mitophagy, the selective degradation of damaged mitochondria by autophagy, enhanced inflammation induced by traumatic brain injury (TBI). Melatonin treatment activated mitophagy via the mTOR pathway, to attenuate TBI-induced inflammation. Furthermore, treatment with melatonin significantly ameliorated neuronal death and behavioral deficits after TBI, while 3-methyladenine reversed this effect by inhibiting mitophagy. Taken together, these results highlight a role for melatonin in protecting against virally TBI-triggered immunopathology, which is accomplished by negatively regulating inflammation activation and IL-1β production via the autophagy of damaged mitochondria.

Title: Speech comprehension in patients with persistent vegetative state : a neuroimaging approach

Authors: *Y. OKAHARA[1,2], K. UTSUMI[1,3], K. TAKANO[1], K. ODAKA[4], Y. UCHINO[4], K. KANSAKU[1,5];
[1]Systems Neurosci. Section, Dept. of Rehabil. for Brain Functions, Res. Inst. of NRCD, Tokorozawa, Japan; [2]Dept. of Neurolog. Surgery, Chiba Univ. Grad. Sch. of Med., Chiba, Japan; [3]Dept. of Neurol., Brain Res. Institute, Niigata Univ., Niigata, Japan; [4]Chiba Ryogo Ctr., Chiba, Japan; [5]Brain Sci. Inspired Life Support Res. Ctr., Univ. of Electro-Communications, Tokyo, Japan

Abstract: Patients who represent no evidence of awareness of self and environment, and no evidence of volitional response to passive stimulus like an auditory, visual, and tactile have been diagnosed as persistent vegetative state (PVS), or recently as unresponsive wakefulness syndrome. Previous reports, by using fMRI, suggested that some patients in PVS have preserved cognitive function in imagery tasks (Owen, et al., 2005) and a language task with intelligible speech and unintelligible noise stimuli (Coleman, et al., 2007). In this study, we applied another language task, which employed passive listening to spoken narrative with a global language structure (Kansaku, et al., 2000; Kansaku and Kitazawa, 2001), to access cognitive state in PVS. Three PVS patients participated in this fMRI experiment (one male, mean: 33.6 years old). In the task, each experiment consisted of 8 epochs: 4 narrative epochs alternating with 4 control epochs. Two types of experiments were carried out. In experiment 1, to observe the whole extent of activation elicited by listening to a narrative, the narrative (80 s) was delivered during the four test epochs (epochs 1, 3, 5 and 7) and no sound was delivered during the control epochs. In experiment 2, to exclude activation elicited by processing of auditory voice in general, the narrative was delivered during the test epochs and the preceding test epochs were replayed in reverse during each control epoch. SPM12 (Wellcome Trust Centre for Neuroimaging, London, UK) was used for the analyses.
In experiment 1, significant activation distributed over the primary auditory cortex and the superior temporal gyrus (STG) was found bilaterally in 2 out of 3 subjects. In experiment 2, a patient (female, 20 years old) showed significant activation in the left middle temporal gyrus (MTG) and the temporo-parietal cortex (TPC), which agreed with a language study that investigated the posterior language areas (Kansaku, 2000).
The results suggest that the language task is useful to evaluate the level of speech comprehension; the patient who did not show activation in both experiments may not recognize human voice, the patient who showed activation only in experiment 1 may recognize human voice, and the patient who showed activation in both experiments may comprehend speech.

Title: Returning to form: factors affecting sleep disturbance duration and recovery following traumatic brain injury

Authors: *N. R. GRIFFIN[1], E. WICKWIRE[2], G. T. MANLEY[3], P. MUKHERJEE[3], J. YUE[3], M. VASSAR[3], W. A. GORDON[4], D. O. OKONKWO[5], A. B. VALADKA[6], D. M. SCHNYER[1]; [1]The Univ. of Texas At Austin, Austin, TX; [2]Univ. of Maryland, Baltimore, MD; [3]Univ. of California, San Francisco, San Francisco, CA; [4]Icahn Sch. of Med. at Mount Sinai, New York, NY; [5]Univ. of Pittsburgh, Pittsburgh, PA; [6]Virginia Commonwealth Univ., Richmond, VA

Abstract: Traumatic brain injuries are known to cause a range of physiological disturbances, including disturbances in sleep behaviors, which may extend for prolonged periods after injury. The majority of TBI patients suffer from sleep disturbances post-injury in one or more forms including nocturnal insomnia, daytime hypersomnia, frequent awakening from sleep, and delayed sleep onset (Parcell et al., 2006). Although sleep disturbances following TBI are common, the mechanisms underlying the source, duration, and recovery from sleep disturbances is unclear. Potential contributing factors including depression and anxiety, which like sleep disturbances, commonly increase following TBI (Shekleton et al, 2010). Further, while most individuals who experience an increased sleep disturbances, anxiety, and/or depressive symptoms improve during the year following injury, a considerable subset of individuals do not see significant improvement after over a year post-injury (Williams, Lazic, & Ogilvie, 2008). Data collected from the Transforming Research and Clinical Knowledge in Traumatic Brain Injury (TRACK-TBI) pilot study, with follow-up intervals at three months and six months after injury, allows for a more thorough investigation of the pattern of sleep disturbance following TBI and the potential interaction with depressive symptoms more comprehensively than much of the existing research. To examine effects of TBI-related disturbances on sleep, we performed regression analyses on two composite scores of sleep disturbance measures: sleep deficits (trouble falling asleep and sleeping less than usual), and sleep increases (sleeping more than usual and diurnal insomnia). The Brief Symptom Inventory 18 (BSI-18), intake Glasgow Coma Scale, Glasgow Outcome Scale – Extended, age, and sex were used as predictors in our models of sleep disturbance. Consistent with the literature, we found a significant correlation between BSI-18 depression and anxiety scores in our sample ($r = .75$, $p < .001$). Interestingly, both sleep disturbance composites *increased* at the 6-month follow-up relative to the 3-month follow up, and physical outcomes did not significantly improve across follow-ups. Using stepwise regression, we found that anxiety scores and declines in physical outcome best predict both sleep increases and sleep deficits at 6 months. Although depression alone predicts sleep disturbances at 6 months, the model including physical recovery and anxiety provides significantly stronger fit. This suggests that although depression affects sleep abnormalities, lack of physical recovery and increasing anxiety more strongly drive enduring sleep disturbances post-TBI.

Title: An arterial spin labeling demonstration of decreased functional connectivity following mild traumatic brain injury

Authors: *N. M. WISEMAN[1], A. IRAJI[2], E. HAACKE[3], Z. KOU[4];
[1]Dept. of Psychiatry and Behavioral Neurosciences, [2]Dept. of Biomed. Engin., [3]Dept. of Radiology, Dept. of Biomed. Engin., [4]Dept. of Biomed. Engineering, Dept. of Radiology, Wayne State Univ., Detroit, MI

Abstract: Mild traumatic brain injury (mTBI) acutely disturbs both cerebral blood flow (CBF) and functional connectivity in intrinsic brain networks (IBNs). However, the relationship between these, and their relationship to brain recovery, still requires further investigation. While IBNs are usually studied with blood-oxygen-level dependent (BOLD)-based resting state functional magnetic resonance imaging (rsfMRI), recent work has shown that they can be identified with an arterial spin labeling (ASL) method, which is usually performed to obtain information about CBF. Because ASL is more directly related to blood flow than BOLD, it may be better suited for assessing changes in blood flow related to changes in metabolism and therefore more reliably identify IBNs. Additionally, by using one sequence to assess both IBNs and CBF at the same time, we can better identify the relationships between changes in IBN connectivity and CBF. In this study, we performed pulsed ASL (PASL) and rsfMRI in 13 healthy controls and 13 mTBI patients at the acute stage after injury and again one month later. A 20-component independent component analysis (ICA) performed on both the PASL and rsfMRI data revealed 4 IBNs with high similarity between the two methods, including the default mode network (DMN), motor network, subcallosal network, and frontal DMN, as well as similar vascular and cerebrospinal fluid non-network components. The connectivity within the DMN, a network commonly seen to differ in mTBI patients as compared to controls, was compared between patient and control groups and across time points. The only significant between-group results after family-wise error (FWE) correction were found at the second time point, with 108 mm^3 in the right precuneus detected by rsfMRI analysis and 64 mm^3 in the left precuneus and 576 mm^3 in the left angular gyrus detected by PASL as having decreased involvement in the

DMN in patients as compared to controls. Each of these regions was substantially larger before FWE correction, which is known to be very conservative, suggesting that a less conservative method of multiple comparisons correction may better identify the extent of the affected regions. Neither group showed any significant differences between time points after FWE correction. The voxel-wise CBF data was analyzed in the same fashion and revealed no significant differences after FWE-correction. These results suggest that PASL-based functional connectivity analysis can detect similar alterations as rsfMRI-based connectivity analysis and further support the use of ASL for identification of IBNs and associated CBF changes.

Therapy, Univ. of Western Ontario, London, ON, Canada; [6]Primary Care Sport Med., Fowler Kennedy Sport Med., London, ON, Canada; [7]Paediatrics Critical Care Med., London Hlth. Sci. Ctr., London, ON, Canada

Abstract: Objective: To determine longitudinal changes in MRI parameters, clinical cognitive measures and blood markers in concussion-naive athletes participating in a contact sport. **Methods:** We followed a female university-level rugby team (n = 54, age 18-23) over a three-year period. Players were evaluated during intense pre-season tryouts and practices and again

after a period of relative rest 2-3 months post-season. Players did not experience a diagnosed concussion during the season or 10-months before the pre-season scan. Diffusion tensor imaging (DTI) was used to quantify white matter structural integrity and resting state fMRI (RS-fMRI) was used to examine functional connectivity between 136 brain regions. Hematology and flow cytometry were used to mechanistically interpret imaging changes, along with Sport Concussion Assessment Tool (SCAT) and Immediate Post-Concussion Assessment and Cognitive Testing (ImPACT) clinical measures. **Results:** After 2-3 months of post-season recovery, there were significant increases in fractional anisotropy and decreases in mean and radial diffusivities along a number of white matter tracts. Decreased RS-fMRI functional connectivity was observed amongst brain regions involving those same tracts. Total leukocyte populations decreased and lymphocytes increased following the 2-3 months of recovery, along with improved verbal, visual, and immediate memory composite scores. Subsequent pre-season data in a subset of returning players did not rebound completely, and exhibited aggregate changes by the next post-season scan. **Conclusions:** The structural and functional MRI changes observed here over single and multiple seasons of contact play suggest transient changes in myelin, a possible neuroreparative mechanism given the recovery of blood inflammatory biomarkers. Future studies are required to investigate the longevity of this structural repair.

Title: Cognitive function in contact sport: effects of cumulative head impact exposure and chronic athletic involvement

Authors: *D. BREWER DELUCE[1,2], T. D. WILSON[2], A. M. OWEN[1];
[1]Brain & Mind Inst., [2]Anat. & Cell Biol., The Univ. of Western Ontario, London, ON, Canada

Abstract: Repetitive sub-clinical head impacts (SHI) are linked to progressive cognitive decline and post mortem chronic traumatic encephalopathy (CTE) diagnoses in pro contact-sport athletes. Additionally, chronic physical activity seems to provide a neuroprotective benefit

throughout life, and in recovering from concussion. Given this two-pronged interaction we sought to measure the influence of SHI on cognitive function while accounting for long-term athletic participation with non-contact athletic controls.
From 2014-2016 we assessed the cognitive function of 42 male varsity football athletes in the pre- and post-season as well as 13 male varsity rowing athletes on a similar time scale. Cognitive battery scores (www.cambridgebrainsciences.com) were assessed in terms of season-long changes, and in comparison to controls as a representation of career-long SHI and athletic exposure. In the pre-season, there were no significant differences between footballers and rowers, or between rowers and sedentary controls on any metric. In comparison with controls, footballers had impaired scores on 3 tests despite no recent concussion. Importantly, across the season, footballer's demonstrated a decrease in score on a single test of executive function suggesting that a season of SHI exposure may cause measurable cognitive decline.
It is well established that exercise training, while neuroprotective, does not afford robust benefits unless abilities are first compromised by injury or disease. As such, given their chronic SHI exposure, footballers may demonstrate a beneficial effect of exercise allowing them to match the performance of rowers which may be capped by a healthful ceiling effect.
With the addition of post-season rowing scores, we aim to further explore the modulatory effect of exercise on cognition in order to better understand the behavioural representation of cognition in chronic SHI exposure, which is important for developing better assessments of SHI-related cognitive decline and rehabilitative strategies.

Title: Frontal pole cortical deficits in mild, moderate, and severe traumatic brain injuries

Authors: *C. EIERUD[1,2], D. E. NATHAN[1,2], T. TESLOVICH[1,3], G. RIEDY[1], G. BONAVIA[1], J. OLLINGER[1];
[1]Neuroimaging, Natl. Intrepid Ctr. of Excellence, Bethesda, MD; [2]North Tide LLC, Dulles, VA; [3]Sage Consulting, Alexandria, VA

Abstract: Approximately 320,000 service members from Operation Iraqi Freedom/Operation Enduring Freedom have suffered a Traumatic Brain Injury (TBI). Even mild traumatic brain injury (mTBI) may cause chronic disabilities and blast is a common mechanism of TBI. Currently, there are no clear neuroimaging indicators of blast effects.
The following 7 groups (N=620 males) were used in this study: $control_1$ (n=60, age=33.7, SD=8.3), $mTBI_1$ (n=240, age=33.7, SD=8.3), $control_2$ (n=27, age=33.0, SD=8.6), nonblast-mTBI (n=60, age=33.1, SD=7.6), blast-mTBI (n=180, age=33.0, SD=4.9), moderate TBI (N=41, age=33.4, SD=7.8), and severe TBI (n=12, age=32.9, SD=7.1). Patients had chronic TBI symptoms (at least 3 months) before imaging using a 3T Discovery 750 MRI. Individual surface-based cortical thickness maps were generated in FreeSurfer and smoothed using a 10 mm kernel. The first-level analysis calculated a two-sample ($control_1$, $mTBI_1$) cluster based permutation test. It detected a significant cluster (mTBI-mask) in which decreased thickness was seen in mTBI subjects relative to the control group. Regions identified within the mTBI-mask included right-lateralized frontal pole, rostral middle frontal gyrus and sulcus, pars orbitalis, lateral orbitofrontal cortex, superior frontal cortex, and medial orbitofrontal cortex.
Second-level analyses were conducted, comparing cortical thickness values within the mTBI-mask between the remaining groups. Targeted two-sample t-tests resulted in following: $control_2$ > blast-mTBI ($p < 0.004$, d=0.61), $control_2$ > moderate TBI ($p < 0.06$, d=0.41), and $control_2$ > severe TBI ($p < 0.05$, d=0.66). Interestingly, nonblast mTBI > blast-mTBI ($p < 0.03$, d=0.29), which may indicate that the mTBI-mask is sensitive to the blast mechanism as well. P-values are one-sided since the mTBI mask assumes cortical thinning in TBI and blast.
In conclusion, regional decreases in cortical thickness may be used to differentiate between controls and TBI subgroups. Within mTBI, these effects may be further modulated by blast exposure.

Title: The accuracy of head impact sensors and concussion assessment tools in collegiate football players

Authors: *A. D. REBCHUK[1], H. J. BROWN[1], G. P. SIEGMUND[2,1], J.-S. BLOUIN[1,3,4]; [1]Kinesiology, The Univ. of British Columbia, Vancouver, BC, Canada; [2]MEA Forensic Engineers & Scientists, Vancouver, BC, Canada; [3]Djavad Mowafaghian Ctr. for Brain Hlth., Vancouver, BC, Canada; [4]The Inst. for Computing, Information, and Cognitive Systems, Vancouver, BC, Canada

Abstract: Prior research suggests that repetitive head impacts (RHI) in sport correlate with neurological deficits later in life (Bailes et al., 2014; Montenigro et al., 2016). To better establish this relationship, we need sensors that accurately detect head impacts and clinical tools that accurately diagnose concussions. Here, we performed a field study with two objectives: i) to validate a head impact sensor and ii) to explore the diagnostic accuracy of two clinical tools: the Sport Concussion Assessment Tool – 3rd Edition (SCAT3; McCrory et al., 2012) and the King-Devick Test (KDT). Male collegiate football players (n=35) wore the xPatch, a wireless sensor that adheres to the mastoid process and records head impact kinematics, for 1 or 2 football seasons. We collected weekly neurocognitive data and observed 8 concussions (diagnosed by the team physician). Using video, we classified all head impacts detected by the sensor during games as true positives, true negatives, false positives and false negatives and then calculated the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV) of the xPatch's impact classification algorithm. We also correlated the cumulative peak head kinematics to the number of impacts detected. Receiver operator characteristic (ROC) curves were generated and the area under the curve (AUC) for each component of the SCAT3 and KDT was calculated using both the absolute score and change from pre-season baseline. The xPatch's algorithm had a sensitivity of 82.2%, specificity of 74.9%, PPV of 80.6%, and NPV of 76.8%. Cumulative head impact kinematics correlated strongly with the number of head impacts (r^2=0.76-0.88) when including all impact events detected by the sensor (true and false positives). These correlations improved (r^2=0.98-0.99) when only true positive and false negative impacts were included. The AUCs for change scores were higher ($p<0.05$) than for absolute scores for the Balance Error Scoring System (BESS; foam trials), Standardized Assessment of Concussion (SAC) and KDT. Using change scores we saw an AUC of 0.91 for the Graded Symptom Checklist (GSC), 0.80 for KDT, 0.65 for BESS and 0.64 for SAC. These findings suggest that a simple measure of RHI (number of impacts) can accurately predict the head's cumulative biomechanics. They also emphasize a need to develop more reliable tests of balance and executive function in concussed patients. Improved impact sensors and concussion assessment tools will allow us to better understand the link between RHI and later-life neurological deficits.

Title: The effects of concussion-prone athletics on brain function: A comparison of football, cross-country, & socioeconomically matched non-athletes using fMRI

Authors: D. A. KELLAR, 47405[1], B. A. CARON[1], N. PORT[1], F. PESTILLI[1], H. CHENG[1], *S. D. NEWMAN[2];
[2]Dept. of Psychological and Brain Sci., [1]Indiana Univ., Bloomington, IN

Abstract: Concussion is prevalent in many of the most popular sports. Awareness of the potential negative impact of participation in concussion-prone sports has led to increased research on the topic, including examining the risks of subconcussive impacts. Recent research has shown that sustaining multiple blows to the head, even at subconcussive levels, may affect white matter integrity (McAllister et al., 2014). Whereas concussions are defined by the American Association of Neurological Surgeons as “a clinical syndrome characterized by immediate and transient alteration in brain function” which can be diagnosed with some degree of certainty, multiple high frequency subconcussive blows could result in less overt and immediate behavioral deficits. For example, Talavage et al. (2014) showed fMRI and neurocognitive differences between high-school football athletes that sustained a low number compared to a high number of subconcussive blows throughout a season. To explore the potential long-lasting effects of playing contact sports, the current study recruited 19 college upperclassmen from the Indiana University football team prior to the start of their season and prior to contact practice; therefore none of the athletes reported having a recent concussion. Two control groups were also examined - non-contact sport athletes, cross-country runners, and non-athletes who were socioeconomically matched to the football players. Both groups were recruited from Indiana University. Participants performed an ocular-motor smooth pursuit task during fMRI acquisition. Football players showed significantly increased activation in the occipital cortex and the cerebellum compared to both control groups. Additionally, when comparing the two control groups, they showed no differences in activation. These results suggest that football players require increased effort to perform the ocular-motor task. Further

research is required to determine whether and to what degree subconcussive impacts contribute to such differences, and how long lasting those changes might be.

Title: Effects of caffeine and hypothermia on neuropathology in P6 rats with experimentally induced hypoxic ischemic brain injury

Authors: ***A. L. SMITH**[1], M. POTTER[1], H. M. CONTRERAS-MORA[1], T. S. ROSENKRANTZ[2], R. H. FITCH[1];

Abstract: Neonatal hypoxic ischemic (HI) injury reflects reductions in blood and/or oxygen supply, as often seen preterm/low-birthweight infants. Neural HI injuries in this populations stem from hemorrhagic or ischemic vascular events, and/or or systemic hypoxia, and typically manifest as white matter damage (with more subtle gray matter damage in older preterms). HI injuries are associated with later deficits in cognition and behavior, including motor skills, memory, and language. To improve long-term outcomes, various neuroprotective interventions have been explored. In term infants with HI stemming from birth complications, the primary intervention is hypothermia (aka "cooling"). Mechanistically, hypothermia hinders aspects of apoptosis and thus reduces downstream tissue loss. We recently reported beneficial effects of even brief and subtle intra-insult hypothermia (i.e., during insult) in a postnatal day 7 (P7) HI rat model. More recently, putative benefits of extended hypothermia (3 hours) in a late preterm HI model (P6 HI) were also examined, to assess whether benefits of hypothermia might transfer to a late preterm population. We were surprised to find that hypothermia failed to rescue behavior in P6 HI subjects, and even appeared detrimental to shams (Contreras-Mora et al., 2015). Other therapies under study include caffeine, a non-selective adenosine antagonist used as a respiratory stimulant in ventilated preterm infants. Previous studies in our lab showed a protective behavioral benefit from caffeine when HI injury was induced on postnatal (P) day 7 in rats (Alexander et al., 2013), and more recently, on P6 (Contreras-Mora et al., 2015). Importantly, this protection was optimal when caffeine was administered immediately following the HI insult. The current study sought to investigate the potential combined beneficial effect of caffeine and hypothermia on neuropathology in a P6 HI model. To accomplish this, subjects who had received P6 HI along with either caffeine treatment, extended hypothermia, or no treatement were compared to respective shams. Specifically, we assessed volumes of the cortex, hippocampus, internal capsule, lateral ventricles, and corpus callosum. Measures were quantified *post-mortem* to determine whether caffeine and/or hypothermia was able to ameliorate brain injury. Volumetric measures were also correlated with behavioral measures, to determine whether gross
neuropathology was able to provide an accurate prediction for long-term behavioral outcomes. Results offer important information to aid clinicians in determining the most optimal neuroprotective strategy for at-risk infants with HI.

Title: Metal-metal interactions in zinc-induced neurotoxicity: the possible involvements in the pathogenesis of vascular dementia

Authors: *M. KAWAHARA[1], D. MIZUNO[2], K.-I. TANAKA[1];
[1]Musashino Univ., Nishitokyo, Japan; [2]Dept. of Forensic Med., Yamagata Univ., Yamagata, Japan

Abstract: Zinc (Zn) is accumulated in the synaptic vesicles and co-released with glutamate during the neuronal excitation. It is widely accepted that excess Zn released into the synaptic clefts under the condition of transient global ischemia plays central roles in the neurodegeneration in vascular dementia. We have investigated the molecular mechanism of Zn-induced neurotoxicity using immortalized hypothalamic neurons (GT1-7 cells). Zn^{2+} caused apoptotic death of GT1-7 cells after 24h. We found that carnosine (beta-alanyl histidine) and anserine (1-methyl carnosine) protected against Zn-induced neurotoxicity. Furthermore, our results demonstrated that carnosine and anserine protected against Zn-induced neurotoxicity not by preventing increases in intracellular Zn^{2+} but by participating in the regulation of the endoplasmic reticulum (ER) stress pathway and the activity-regulated cytoskeletal protein (Arc). We also investigated the role of other metal ions including Cu^{2+}, Mn^{2+}, Fe^{2+}, Fe^{3+}, Ni^{2+}, and Al^{3+} in Zn-induced neurotoxicity. Although the co-existence of Fe^{2+}, Fe^{3+}, or Ni^{2+} did not influence Zn neurotoxicity, Al^{3+} attenuated Zn-induced neurotoxicity in a dose-dependent manner. Meanwhile, Cu^{2+} or Mn^{2+} remarkably enhanced the neurotoxicity of Zn. Carnosine did not attenuate Cu-induced neurotoxicity nor Mn-induced neurotoxicity. Considering that Cu is also accumulated in the synaptic vesicles and released into the synaptic clefts, it is possible that Zn and Cu interact in the synaptic clefts and plays essential roles in the pathogenesis of vascular dementia or other neurodegenerative diseases. Furthermore, given advantageous properties of carnosine and anserine (relatively nontoxic, heat-stable, and water-soluble), dietary supplementation with them may be an effective strategy for the preventionor treatment of neurodegenerative diseases such as ischemia induced neuronal death and VD. Based on this idea, we have developed a convenient system for the quantitative analysis of carnosine and analyzed their amounts in various foods.

Title: Could sildenafil repair hippocampal brain injuries in term neonatal encephalopathy?

Authors: *A. A. YAZDANI[1], P. BALIAN[1], Z. KHOJA[1], K. CUI[2], G. LUHESHI[2], P. WINTERMARK[1];
[1]Newborn Med., Montreal Childrens Hosp., Montreal, QC, Canada; [2]Douglas Mental Hlth. Univ. Inst., Montreal, QC, Canada

Abstract: INTRODUCTION: Neonatal encephalopathy remains a major cause of mortality and morbidity worldwide. Neonatal encephalopathy often leads to chronic activation of inflammatory cascades that hinders repair of the developing brain. Microgliosis and astrogliosis are activated in the rat model of hypoxia-Ischemia (HI). Hippocampus in particular is a well documented site of neuronal injury in neonatal HI. Sildenafil has been shown to reduce neuroinflammation in rat models of multiple sclerosis and Alzheimer disease, and it is already used safely to treat persistent pulmonary hypertension in human newborns. It may thus also be useful in newborns to modulate neuroinflammation following hypoxia-ischemia.
OBJECTIVE: To determine how hippocampal brain injury develops and neuroinflammation is activated after neonatal hypoxia-ischemia (HI) at term-equivalent age and whether sildenafil may modulate this activation and impact neuronal number and vascular density.
METHODS: Neonatal HI was induced in male Long-Evans rat pups at postnatal day 10 (P10) by left common carotid ligation followed by 2-hour exposure to 8% oxygen. Sham operated rat pups served as control. Both groups were administered 0 (vehicle), 2, 10 or 50 mg/kg of sildenafil twice daily by oral gavage, starting from 12 hours post-HI for 7 consecutive days. At P30, rats were sacrificed and their brains extracted. CA1, CA3 and dentate gyrus (DG) areas of the ipsilateral hippocampus were analyzed for microgliosis (Iba1) and astrogliosis (GFAP), neuronal number (NeuN), and vascular density (collagen IV).
RESULTS: HI caused a significant increase in the number of microglia and astrocytes in CA1, CA3 and DG regions of the hippocampus, compared to sham vehicle rat animals. There were no significant changes in neuronal number or vascular density in the hippocampus of HI vs sham

animals. Higher doses of Sildenafil (10mg/kg and 50mg/kg) significantly reduced the number of activated microglia and reactive astrocytes in CA1 and dentate gyrus of the hippocampus in HI animals. The highest dose of Sildenafil (50mg/kg) significantly increases neuronal number in the dentate gyrus of HI animals compared to sham vehicle animals. There were no changes in vascular density between the treatment groups and the control group.
CONCLUSION: Oral Sildenafil, especially at higher dosage, may reduce neuroinflammation following neonatal hypoxic-ischemia and increases neuronal number in the hippocampus.

Title: Inhibition of sustained TRPM2 channel activity represents a novel neuro-restorative strategy to improve memory function after global cerebral ischemia

Authors: *R. M. DIETZ[1], J. E. ORFILA[2], G. DENG[2], P. S. HERSON[2];
[1]Dept Neurosciences, Neuronal Injury Program, Univ. of Colorado, Aurora, CO; [2]Neuronal Injury Program, Univ. of Colorado, Denver, CO

Abstract: Introduction: Cardiac arrest (CA) is a major cause of mortality and morbidity and results in global cerebral ischemia and hypoxic-ischemic injury. The consequent neuronal damage results in long-term cognitive impairments, including memory disturbances and more general executive disorders. Memory disorders commonly observed following CA are readily explained by the selective vulnerability and dysfunction of CA1 pyramidal cells of the hippocampus. This study investigated the role of the non-selective cation channel TRPM2 on ischemia-induced synaptic dysfunction.
Methods: Male and female C57Bl/6 mice (20-25g) underwent 8 min CA and cardiopulmonary

resuscitation (CA/CPR). Hippocampal CA1 function and synaptic plasticity were evaluated using acute brain slices 7 days after CA/CPR or sham controls. Synaptic plasticity was measured by long term potentiation (LTP) of synaptic signals following theta-burst stimulation (TBS). Increase in field excitatory post-synaptic potential slope 60 min after TBS was analyzed to measure LTP. Slices or mice were treated with our novel peptide inhibitor of TRPM2, termed tatM2NX, as indicated below.
Results: Recordings obtained in slices from male mice 7 days after CA/CPR exhibited impairment of LTP when cells were exposed to the same TBS stimulation that stimulates robust LTP in sham control mice (161±9%, n=6 in sham compared to 105±9%, n=8 on day 7). Remarkably, bath application of the TRPM2 channel inhibitor tatM2NX (1μM) for 2 hours reversed the CA/CPR-induced loss of LTP, recovering to 149.8±26% (n=3; $P<0.05$ compared to paired 7 day CA/CPR slices recorded from the same animal). In vivo administration of tatM2NX (20 mg/kg administered ip on day 6 after CA/CPR) reversed CA/CPR-induced impairments in LTP, recovering to 171±11% (n=6 recordings from 4 mice treated with peptide; $P<0.05$ compared to 7 day CA/CPR slices). Similar data was observed in female mice (data not shown). Finally, memory function was measured using a well-established hippocampal-specific memory task, contextual fear conditioning. CA/CPR causes a decrease in freezing behavior, indicating lack of memory. This was reversed in CA/CPR mice given tatM2NX (20 mg/kg, single ip injection 24 hr before testing) on day 7 post-CPR compared to vehicle-injected mice
Conclusions: These data indicate that following global cerebral ischemia synaptic TRPM2 channels are chronically activated, contributing to long-lasting impairments of the remaining hippocampal network. Therefore, inhibition of TRPM2 channels at chronic timepoints following ischemia may represent a novel strategy to improve functional recovery after cerebral ischemia.

Title: Vasodilatory regulation failure in transient postischemic hyperperfusion in rats

Authors: *K. NAKAMURA[1,2], T. MUTOH[2,1], K. SASAKI[3,1], Y. TAKI[2], T. ISHIKAWA[1], T. KINOSHITA[1];
[1]Res. Inst. For Brain & Blood Vessels Akita, Akita-Shi, Japan; [2]Nuclear Med. and Radiology, [3]Preclinical Evaluation, Inst. of Development, Aging and Cancer, Tohoku Univ., Sendai, Japan

Abstract: [Introduction] Post-ischemic hyperperfusion was observed in transient ischemic tissue 48 hours after middle cerebral artery (MCA) occlusion [1,2]. A possible physiological mechanism would be vasodilatory regulation failure with full relaxation of resistance vessels in ischemic tissue. To confirm the physiological reason, we have performed two photon microscopy observation and experiments for revealing vasodilatory response with carbon dioxide (CO_2) inhalation. [Methods] Six male Sprague-Dawley rats were used. Transient ischemic regions were induced by modified model of MCA occlusion [3]. The model of twisting the monofilament at the left MCA for temporally interruption of blood flow and the right and left common carotid arteries with temporally clipping in thirty minutes. Before the transient ischemic operation, a cranial window (diameter of 2 mm) was prepared for optical access to the cortical vasculature in left hemisphere. We have confirmed the post-ischemic hyperperfusion in continuous arterial spin labeling in 4.7 tesla magnetic resonance image 24 hours after the operation. Then we observed two-photon microscopy with intravenously injected rhodamine-dextran two days after the operation. In the microscopic observation, each animal was mechanically ventilated under paralyzed condition with rocuronium bromide and isoflurane anesthesia. [Results and Discussion] Arterial blood CO_2 tension was increased from 38.0±4.5 to 44.5±3.8 mmHg with 0.4 % CO_2 in anesthetic carrier gas and increased to 52.0±2.8 mmHg with 0.8% CO_2. Vessel image was reconstructed by maximum intensity projection from images acquired from cortical surface to the depth of 0.5 mm. Subtracted image obtained from hypercapnia and normocapnia was evaluated for vasodilatory regulation. Arterial diameter was almost same between CO_2 inhalation and normo-capnia condition. The arterial vasodilated response to hypercapnia in the ischemic tissue was not observed in this study. The post-ischemic hyperperfusion might be related to the vasodilatory regulation failure. Title: Chronic MRI abnormalities in adult rats following *In utero* insult: modeling the brain injury associated with chorioamnionitis

Authors: *T. R. YELLOWHAIR[1], S. ROBINSON[2], L. L. JANTZIE[1];
[1]Dept. of Pediatrics and Neurosciences, Univ. of New Mexico Sch. of Med., Albuquerque, NM;
[2]Dept. of Pediatric Neurosurg., Johns Hopkins Univ., Baltimore, MD

Abstract: Preterm infants are prone to numerous neurological deficits including cerebral palsy, epilepsy, sensory processing impairment and intellectual disability. Improved understanding of chronic microstructural brain abnormalities in preterm infants using complex diffusion imaging will facilitate development of biomarkers and new therapeutic strategies for this vulnerable patient population**.** Here, using our established rat model that combines *in utero* placental perfusion deficits and intra-amniotic inflammation consistent with chorioamnionitis, we hypothesized prenatal injury would induce significant white and gray matter microstructural and diffusion abnormalities on magnetic resonance imaging (MRI). On embryonic day 18 (E18), under anesthesia, laparotomy was performed on pregnant Sprague-Dawley dams with transient (1hr) uterine artery occlusion (TSHI) and intra-amniotic injection of lipopolysaccharide (LPS, 4 μg/sac). Shams had anesthesia with laparotomy for 1hr. Laparotomy was then closed, and rat pups were born at term (E22). *Ex vivo* MRI occurred on postnatal day 35 (P35, n=7-11/group) on a 4.7T scanner. Compared to shams, TSHI+LPS animals have significantly decreased fractional anisotropy (FA) in the corpus callosum (t test, p=0.007), and increased axial diffusivity (AD, p=0.03) and radial diffusivity (RD, p=0.004). Also, TSHI+LPS animals have decreased FA in the external capsule (p=0.0001), striatum (p=0.04), hippocampus (p=0.02) and thalamus (p=0.0004), with concomitant abnormalities in AD and RD. In sum, prenatal hypoxia-ischemia and intra-amniotic LPS yields significant, widespread diffusion abnormalities and impaired microstructural coherence in adult rats. These preclinical data corroborate regional diffusion and microstructural brain abnormalities observed in children with deficits from preterm birth complicated by chorioamnionitis. Sophisticated imaging analyses will define radiological biomarkers of chronic brain injury associated with complications from preterm birth and refine the development and indications for emerging therapeutic interventions.

Title: Microrna-210/iscu axis mediates neuronal cell death in neonatal hypoxic-ischemic brain injury

Authors: *Q. MA, Y. LI, C. DASGUPTA, L. ZHANG;
Loma Linda Univ., Loma Linda, CA

Abstract: Perinatal hypoxia-ischemia (HI) is a leading cause of acute mortality and chronic brain injury in newborns with a high risk of hypoxic-ischemic encephalopathy. MicroRNA-210 (miR-210) is "*the Master Hypoxamirs"* that are regulated by hypoxia. A key target of miR210 is iron-sulfur cluster scaffold protein (ISCU) and the miR-210/ISCU axis has been reported to be involved in pathological processes in response to hypoxia. Our recent study demonstrated that inhibition of miR-210 provided neuroprotection in neonatal HI brain injury; however, the underlying mechanisms remain elusive. Postnatal day 7 (P7) Sprague Dawley rat pups were subject to ligation of right common carotid artery followed by hypoxic (8% O2) treatment. At 4 hours after HI, miR-210 inhibitor, complementary locked nucleic acid oligonucleotides (LNA-miR-210) was administered intracerebroventricularly into ipsilateral hemisphere of rat brains. The results showed that neonatal HI insult significantly reduced ISCU protein levels and respiratory chain complex I activity in isolated brain mitochondria and increased 3-nitrotysine levels in the brain tissue, which were blocked by LNA treatment. In addition in P5 rat pups, miR-210 mimic or ISCU siRNA was injected into right hemisphere of rat brains, 48 hours after injection neonatal HI insult was conducted. The results showed that miR-210 mimic or ISCU siRNA injection resulted in downreguation of ISCU protein levels and increased susceptibility of the neonatal brain to HI brain insult. To investigate the role of miR-210/ISCU axis in intracellular ROS generation and neuronal cell death, primary cortical neurons were isolated and treated with oxygen-glucose deprivation (OGD) at DIV7. Consistent with the *in vivo* findings, OGD induced upregulation of miR-210 in primary cortical neurons, increased caspase 3 and 9 activities and reduced cortical neuron viability by increasing LDH release. In addition, OGD significantly reduced ISCU protein levels and complex I activity and increased intracellular ROS, which were revered by LNA treatment. Thus, the results demonstrate that miR-210/ISCU axis mediates oxidative stress and neuronal cell death in neonatal HI brain injury.

Title: Inflammation and vulnerable blood vessels aggravate ischemic injuries in a mouse model of Type 1 diabetes

Authors: *A. C. LO, A. K. W. LAI;
Dept. of Ophthalmology, The Univ. of Hong Kong, Hong Kong, Hong Kong

Abstract: PURPOSE: Patients with type 1 diabetes are more prone to cerebrovascular mortality after stroke and display a more severe post-ischemic outcome. Their median survival is only half when compared with those in the general population. In the current study, we aim to elucidate the potential mechanisms contributing to the exacerbation.
METHOD: $Ins2^{Akita/+}$ mice, a type 1 diabetic mouse model, and their wildtype ($Ins2^{+/+}$) littermates at 12 weeks of age were challenged with experimental stroke by middle cerebral artery occlusion (MCAO) for 2h followed by 2h of reperfusion. Survival rate and neurological deficits were assessed at the end of reperfusion. Their brain slices were stained with 2, 3, 5-triphenyltetrazolium chloride for estimation of the infarction, hemispheric swelling and hemorrhagic area. Western blot analysis was used to compare levels of ZO-1, VEGF and pErk for assessment of blood vessel integrity and inflammation. ER-stress (ATF6, BiP, CHOP, PERK and IRE-1α) and autophagy (Atg12, Bcn1, LC3-a, LC3-b and p62) response were also assayed using real-time PCR.
RESULTS: Decreased survival rate, increased neurological deficits as well as increased infarct and hemorrhage after MCAO were observed in $Ins2^{Akita/+}$ mice. There were also significant down-regulation of ZO-1 protein and remarkable up-regulation of VEGF and pErk protein. mRNA expression of CHOP was further augmented in $Ins2^{Aktia/+}$ mice.
CONCLUSION: $Ins2^{Akita/+}$ mice displayed high mortality after MCAO, similar to that in type 1 diabetic patients upon stroke. Augmented cerebral hemorrhage and decreased ZO-1 expression indicated a lower blood vessel integrity in $Ins2^{Akita/+}$ mice. Provoked inflammatory response and ER-stress may play important roles in the exacerbation of the ischemic brain, which was evidenced in increased infarction in $Ins2^{Akita/+}$ mice.

Abstract: It is increasing evidences that transplantation of human mesenchymal stem/stromal cells (hMSCs) suppressed neuronal cell death after several central nervous system damages such as stroke and trauma. We have reported that transplanted hMSCs modified microglial state to alternative activating phenotype with suppressing inflammatory cytokines after the damages. However, it is still unclear hMSCs' responses in the tissues after the transplantation because the number of hMSCs was obviously smaller than the recipient cells and the responses were masked by the recipient tissues. The purpose of the present study is to understand the reaction of hMSCs in the brain. We exposed condition medium of mouse hippocampal homogenate which obtained from 1day after transient forebrain ischemia (ischemic brain condition medium: ibCM) to mimic hippocampal state after ischemia and surveyed the transcriptome in comparison with non-ischemic hippocampal homogenate (brain condition medium: bCM). Moreover, the hMSCs were exposed by ibCM of different ischemic region to determine the relation of ischemia and the responses. Finally, the hMSCs were exposed ibCM in cytokines knockout (KO) mice. The hMSCs exposed by ibCM increased 98 genes >2-fold more and decreased 78 genes <2-fold more to compare with those by bCM. Up-regulated genes included chemokines and CCL2 was the highest expression. The CCL2 increased in the media after hippocampal ibCM, but not cortical and cerebellar ibCM by ELISA. Moreover, the increase of CCL2 was suppressed by the ibCM in IL-1 and TNF-alpha KO mice. These results suggest that transplanted hMSCs responded to pro-inflammatory cytokines in the ischemic brain and released several chemokines.

Title: Synaptic and glial modifications induced by perinatal asphyxia

Authors: *F. CAPANI[1,2], M. HERRERA[2], A. GONZALEZ[3], C. QUARRACINO[1], S. MUCCI[1], R. KOLLIKERS-FRERS[1];
[1]Inst. Inv. Cardiológicas, UBA-CONICET, Capital Federal, Argentina; [2]Univ. Católica Argentina-CIPP, Buenos Aires, Argentina; [3]Univ. Maimonides , Facultad de Farmacia y Bioquimica, Buenos Aires, Argentina

Abstract: Perinatal asphyxia (PA) induces short and long term synaptic and cytoskeleton alterations that have been associated with neuronal cell death following hypoxia. The aim of this study was to elucidate the mechanisms underlying this dysfunction. We used a well-established murine model of PA, which was modified in our laboratory. After one and 2 months of the PA insult, an increase in the F-actin staining in neostriatum and hippocampus synapses was observed using correlative fluorescent electron microscopy for phalloidin-eosin. Mushroom-shaped spines showed the most consistent staining. Strong alterations in the dendrite and astroglial cytoskeleton organization were found at 4 months of PA. After 6 months of PA, we observed an increase in ubiquitination level and an increment of rat neostriatum post synaptic densities (PSDs) thickness, which was related to the duration and severity of the hypoxic insult. Using 3-d reconstruction and electron tomography we observed clear signs of damage in the asphyctic PSDs. These changes were correlated with intense staining for ubiquitin. Finally, in 18 months old rat we encountered a reduction in the number of synapses in the PA animals related with a decrease in BDNF staining. Overall, these results demonstrate that synaptic dysfunction following PA might be produced by early changes in the actin organization and long-term misfolding and aggregation of proteins in the PSDs.

Abstract: Cerebral Ischemia results from occlusion of a major cerebral artery and involves a sequence of molecular events that induce cell death. Decrease of cerebral blood flow restricts the delivery of substrates predominantly oxygen and glucose with consequent decline in the metabolism of energy. Interestingly, neuronal cell death can be prevented by modulating the energetic state of the cell. Antioxidants such as resveratrol (RSV) exert a neuroprotective effect after ischemia through mechanisms closely associated with activation of ATP generating pathways in which AMP-activated kinase (AMPK) is involved. **Objective**. We investigated the effect of RSV treatment on AMPK activation on ischemia-induced cellular damage. **Methods.** Male Wistar rats (280 to 350 g) were subjected to 2 h of middle cerebral artery occlusion (MCAO) followed by 24 h of reperfusion. RSV was administered (1 mg/kg; i.v; diluted in 50% ethanol) at the onset of reperfusion. Damage to the brain tissue was evaluated by the technique of 2,3,5-Triphenyltetrazolium chloride (TTC) dye. Rat primary neuronal culture (E17) was used at 7 - 8 days in vitro. Cultures were stimulated with glutamate (100 μM) for 10 min and were evaluated after 20 min and 24 h of recovery. Resveratrol (100 μM) was administered at the start of recovery. In cultures, cell viability was assessed by MTT, LDH release and Trypan blue exclusion. Mitochondrial calcium buffer capacity was analyzed with the fluorescent probe Fluo-4 AM. Western blotting was used to evaluated AMPK activation through phosphorylation. **Results.** Administration of RSV to rats subjected to MCAO/reperfusion reduced the infarct area and increased the survival rate. In neuronal cultures, excitotoxicity increased cellular death. This effect was reversed by RSV and restored after AMPK inhibition with compound C. Western Blotting results indicated that excitotoxicity increases AMPK phosphorylation after 20 min of recovery. RSV induced an additional increase on the levels of pAMPK, effect that was diminished with compound C. Excitotoxicity increased the number of cells unable to buffer the cytoplasmic calcium, suggesting that mitochondrial function was altered. RSV partially prevented mitochondrial losing buffer capacity. **Discussion.** We observed that the use of the natural antioxidant RSV at the onset of reperfusion has a beneficial effect against cerebral

ischemia through activation of cell survival pathways dependent on AMPK activation. Our results suggest that the neural activation of AMPK may be an important mediator in the neuroprotective activity of RSV, probably through the restoration of energy metabolism of the cell.

Title: Alternative splicing of leukocyte mRNAs differs after intracerebral hemorrhage and ischemic stroke of different etiologies

Authors: *C. J. DYKSTRA-AIELLO, G. C. JICKLING, B. ANDER, X. ZHAN, D. LIU, H. HULL, M. ORANTIA, C. HO, F. R. SHARP, B. S. STAMOVA;
Neurol., Univ. of California, Davis, Sacramento, CA

Abstract: Background: Previous transcriptome research in blood of ischemic stroke (IS) patients has used 3'-biased microarrays, which are unable to capture changes in a majority of alternatively spliced transcripts. Alternative splicing (AS) has been implicated in many diseases, but its role in IS and intracerebral hemorrhage (ICH) is a new domain. Thus, we hypothesized that AS differs among 1) IS, ICH and vascular risk factor controls (VRFC), and 2) three main IS causes (Cardioembolic, Large Vessel and Lacunar), ICH and VRFC.
Methods: We studied differential alternative splicing (DAS) in whole blood of IS, ICH and VRFC males using Affymetrix Human Transcriptome Arrays 2.0 which probe exon junctions (n=36, 12 per group). To study DAS between IS causes, ICH and VRFC, we used RNA-seq (Illumina, 200M 2X100bp reads/sample) on 20 whole blood samples (n=4 males per group). We assessed DAS with ANOVA (FDR $p<0.05$) and calculated differential exon-usage between each group ($p<0.0005$; fold change>|1.2|). We compared the results of RNA-seq-determined differentially expressed exons to a separate set of ICH and VRFC subjects (n=48, 24 per group) using HTA arrays. We evaluated group separation by principal components analysis.

Results: Differential expression of 90 exons separated the IS, ICH and VRFC groups. These included genes such as: HGF (hepatic growth factor), involved in thrombosis and angiogenesis, and NOS1 (nitric oxide synthase 1), implicated in stroke risk. 412 genes displayed DAS and 308 exons with differential expression separated ICH, the three main causes of IS and VRFC. Several genes with DAS belonged to NF-kB and PPAR signaling pathways including: SRA1, steroid receptor RNA activator 1, and Akt1, all of which have been implicated in experimental ICH pathogenesis. NF-kB transcription factor perpetuates inflammation and is activated by ICH. Finally, there were 108 exons with differential expression between ICH and VRFC in the RNA-seq samples. Eighty of these exons differentiated the majority of ICH from VRFC in a separate subject set.
Conclusions: We provide evidence for DAS in whole blood in ICH, IS and its major causes, suggesting disease specific immune responses which could result in biomarkers. Inclusion of both sexes and a further validation of results in a larger cohort is needed.

Title: The role of alpha-synuclein in mediating secondary ischemic brain damage

Authors: *T. KIM, S. MEHTA, B. KAIMAL, K. LYONS, R. VEMUGANTI;
Univ. of Wisconsin - Madison, Madison, WI

Abstract: α-synuclein (α-syn) is a small protein (14.5 kDa) that is abundantly expressed in the adult mammalian brain and predominantly localized in the presynaptic terminals. It is the major component of Lewy bodies, an abnormal protein aggregates, found in chronic neurodegenerative disorders including Parkinson's disease (PD), dementia with Lewy bodies and multiple system atrophy, hence referred to as synucleinopathies. α-syn has been extensively studied for its pathophysiological roles in neurodegenerative disease conditions. However, despite the fact that

acute brain injuries like ischemic stroke share similar molecular mechanisms with chronic neurodegenerative diseases, the scope of research so far has been mainly confined to chronic neurodegenerative diseases particularly in PD. Therefore, we examined whether α-syn also contributes to post-stroke neuronal death and neurological dysfunction. Rodents were subjected to transient middle cerebral artery occlusion (tMCAO) and α-syn induction was silenced with a cocktail of α-syn-specific siRNAs. The levels of α-syn were estimated with qPCR and Western Blots. Post-ischemic motor deficit was evaluated with rotarod, beam walk and adhesive removal test 1 to 7 days after ischemia, and infarct volume was measured on cresyl violet stained brain sections. Cellular changes after ischemia were examined using immunofluorescence staining. Following tMCAO, α-syn levels were significantly up-regulated and phosphorylated at serine-129 in ischemic penumbra. Interestingly, in the ischemic brain non-phosphorylated and phosphorylated α-syn species translocated into the neuronal nuclei. We also observed that silencing α-syn by α-syn siRNA cocktail 2 h prior to tMCAO significantly decreased the infarction and improved the motor function. The neuroprotective effects were still observed when α-syn siRNAs were administered 30 min after the tMCAO. We found that the rate of survival at 7 days after a 90 min tMCAO was remarkably higher in α-syn KO mice (>90%) compared to wild-type control mice (50%). These KO mice also showed significantly smaller infarcts and better motor recovery. Furthermore, α-syn suppression significantly mitigated the post-ischemic pathologic markers including oxidative stress (3-NT), apoptosis (cleaved Caspase-3) and mitochondrial dysfunction (phospho-Drp1). Thus, we presently show that α-syn plays a critical role in neuronal death.

Title: The functional assessment of edaravone-induced neuroprotection after hypoxic insults

Authors: *T. MORITA[1], S. SHIBUTA[1], J. KOSAKA[2], Y. FUJINO[1];
[1]Osaka Univ. Grad. Sch. of Med., Suita-Shi, Japan; [2]Ctr. for Med. Science, Intl. Univ. of Hlth. and Welfare, Ohtawara, Japan

Abstract: Backgrounds:
There are no reports referring to the functional evaluation of the neuroprotective effect of

edaravone on cortical neurons against hypoxic insults (HI). In this study, we investigated the response to neurotransmitters in rat primary cultured cortical neurons which were protected with edaravone against prolonged HI.

Material and Methods:

Neurons prepared from E17 Wistar rats were used after 10-11 days in culture. Shortly before 24h HI, 50μM edaravone was administrated to the neurons. The degrees of neurotransmitter-induced intracellular calcium ($[Ca^{2+}]i$) elevation were measured using fluorescence measurement systems after HI.

To evaluate the effects of neurotransmitters, acetylcholine (ACh) and L-glutamate (Glu), on primary cultured neurons, the mean maximum change in fluorescence intensity (Fmax) upon addition of neurotransmitter was measured and normalized to the baseline fluorescence obtained before neurotransmitter application (F0). We measured the mean value of Fmax/F0 (height) calculated from the integration of $[Ca^{2+}]i$ response curves of the surviving neurons. A height ratio was calculated as follows: the height of the $[Ca^{2+}]i$ response in an experimental culture divided by the height of the $[Ca^{2+}]i$ response in the control culture.

Data are expressed as the mean ± SEM of height ratios. These ratios were compared to normoxic control without edaravone administration.

Results:

When ACh was used as a neurotramsmitter, the height ratio of hypoxic neurons without edaravone was significantly lower than control (0.47 ± 0.14 vs 1.02 ± 0.02, $P < 0.01$). The height ratio of hypoxic neurons protected with edaravone was significantly higher than the ones without edaravone (0.87 ± 0.09, $P = 0.02$). When Glu was used as a neurotransmitter, a similar tendency was seen, however, there was no significant difference among the groups ($P = 0.07$).

Conclusions:

Edaravone showed a significant neuroprotective effect on neurons against HI, especially the responsiveness to ACh was maintained in surviving neurons.

Abstract: Cognitive decline can occur after major surgeries. In older adults post-operative cognitive dysfunction (POCD) has been reported as heralding longer-term cognitive impairment and dementia. Understanding the neural underpinning of POCD is a key step toward developing predictive biomarkers and effective interventions. Past research has established the importance of acetylcholine in cognition. Decrease in cortical acetylcholine levels, due partly to the neuronal loss in the basal nucleus of Meynert (BNM), leads to cognitive dysfunction. Considering that propofol, a widely used anesthetic, is thought to suppress acetylcholine, we examined BNM-seeded whole brain functional connectivity pre- and post-total knee replacement surgery. Non-demented older adults electing total knee replacement surgery with the surgeon and the propofol protocol were enrolled. Participants completed pre-surgery and post-surgery (within 72 hours post-surgery) resting-state fMRI (3T Siemens Verio). BNM-seed whole-brain cross correlation was computed to assess changes in functional connectivity before and after surgery. Compared to pre-surgery, post-surgery BNM-seeded functional connectivity strength declined in multiple brain regions, including cingulate cortex, dorsal lateral prefrontal cortex (DLPFC), superior temporal lobe (STL), and inferior temporal lobe (ITL). Follow-up assessment of cognitive status and structural and functional brain changes is currently underway.

Title: Differential regulation of VEGF co-receptors in the hypoxic developing mouse brain in response to exogenous stimulation of the hypoxia-inducible transcription factor (HIF) system

Authors: *R. TROLLMANN, G. BOIE, M. RICHTER, F. BRACKMANN, S. JUNG;
Univ. of Erlangen, Erlangen, Germany

Abstract: Background: Neovasculogenesis due to hypoxic-ischemic injury represents a common maturation-related compensatory mechanism of the hypoxic brain that is mainly regulated by hypoxia-inducible transcription factors (HIF). However, disturbance of early maturational processes of the developing brain including aberrant angiogenesis and disruption of physiological neuronal and glial differentiation and migration have to be considered. We aimed to investigate in vivo effects of prolyl-4-hydroxylase inhibitor (PHI) FG-4497 and recombinant human erythropoietin (rhEPO) on cerebral vasoactive factors and cerebral vasculogenesis in an established mouse model of acute neonatal systemic hypoxia.
Methods: Neonatal C57BL/6NCrl mice (P7) were exposed to systemic hypoxia (8% O2, 6h; hypoxia chamber INVIVO2 400) and treated with FG-4497 (30/60/100 mg/kg, i.p; Fibrogen) or rhEPO (2500/5000 IU/kg, i.p; Roche) 0h, 24h, and 48h post exposure. After 72h of reoxygenation mRNA expression of VEGF-A, VEGFR-1, VEGFR-2, Nrp-1, Nrp-2, ANGPT-1, ANGPT-2, and TIE-2 was quantified by real-time RT-PCR. Cell type and brain region-specific expression pattern were investigated by RNA in situ hybridization. Vascular development was assessed by PECAM-1 immunohistochemistry and 2D reconstruction (Imaris).
Results: PHI and rhEPO treatment significantly induced differential cerebral target gene activation including additive effects on vasoactive targets (ADM, VEGF-A, CXCR4) under global hypoxia. Both treatment regimens significantly increased cortical vessel length and branching but, VEGF-A co-receptor regulation differed significantly. While PHI treatment at once decreased the mRNA level of VEGFR-2 and Nrp-2 ($p<0.01$) and stimulated the mRNA expression of ANGPT-2 ($p<0.01$) compared to controls decreasing the ANGPT-1/ANGPT-2 mRNA ratio ($p<0.05$) that may indicate functionally elevated and disturbed vascular permeability, rhEPO therapy increased the ANGPT-1/ANGPT-2 ratio in a dose-dependent manner suggesting that HIF-independent regulation of ANGPT-1 is associated with functional stabilization of vessel structures.
Conclusions: Differential regulation of VEGF-A co-receptors in response to exogenous activation of the cerebral HIF system implicates modulation of developmental cerebral vasculogenesis and vasomotor control upon global hypoxia by HIF-dependent as well as HIF-independent pathways. Considering possible regenerative effects of rhEPO on cerebral vascular development in the hypoxic developing mouse brain, long-term effects as well as age-specific aspects of endogenous VEGF-A co-receptor regulation are objectives of our ongoing work.

Title: Methylene blue promotes cortical neurogenesis following photothrombotic stroke in rats.

Authors: D. G. L. TUCKER, M. AHMED, Y. DONG, Y. LU, R. WANG, *Q.-G. ZHANG; Augusta Univ., Augusta, GA

Abstract: Ischemic stroke in rodents stimulates neurogenesis in the adult brain and the proliferation of newborn neurons that migrate into the penumbra zone. The present study investigated the effect of methylene blue (MB) on neurogenesis and functional recovery in a photothrombotic (PT) model of ischemic stroke in rats. PT stroke model was induced by photo-activation of Rose Bengal dye in cerebral blood flow by cold fibre light. Rats received intraperitoneal injection of either MB (0.5 mg/kg/day) from day 1 to day 5 after stroke or an equal volume of saline solution as a control. Cell proliferative marker 5-bromodeoxyuridine (BrdU) was injected twice daily (50 mg/kg) from day 2 to day 8 and animals were sacrificed on day 12 after PT induction. We report that MB significantly enhanced cell proliferation and neurogenesis, as evidenced by the increased co-localizations of BrdU/NeuN, BrdU/DCX, BrdU/MAP-2 and BrdU/Ki67 in the peri-infarct zone compared with vehicle controls. MB thus effectively limited infarct volume and improved neurological deficits compared to PT control animals. The effects of MB were accompanied with an attenuated level of reactive gliosis and release of pro-inflammatory cytokines, as well as elevated levels of cytochrome c oxidase activity and ATP production in peri-infarct regions. Our study provides important information that MB has the ability to promote neurogenesis and enhance the newborn-neurons' survival in ischemic brain repair by inhibiting microenvironmental inflammation and increasing mitochondrial function.

Title: Improved group differentiation of adolescent traumatic brain injury using multi-modal registration and automatic multi-atlas tract extraction (automate) toolkit

Authors: *F. RASHID[1], E. L. DENNIS[2], J. VILLALON-REINA[2], G. PRASAD[2], J. FASKOWITZ[2], T. BABIKIAN[3], R. MINK[4], C. BABBITT[5], J. JOHNSON[6], C. GIZA[3], R. ASARNOW[3], P. THOMPSON[2];
[1]Imaging Genet. Ctr., USC, Studio City, CA; [2]Imaging Genet. Ctr., USC, Marina Del Rey, CA; [4]Harbor-UCLA Med. Ctr. and Los Angeles, [3]UCLA, Los Angeles, CA; [5]Miller Children's Hosp., Long Beach, CA; [6]LAC+USC Med. Ctr., Los Angeles, CA

Abstract: Traumatic brain injury (TBI) is the leading cause of death and disability in children and adolescents; each year, there are 50,000-90,000 new patients that suffer moderate to severe pediatric TBI in the United States alone. Depending on the severity and the type of impact, these injuries can result in a diverse range of pathologies, including short- and long-term disruptions to white matter (WM) integrity. Using diffusion-weighted imaging (DWI) we can noninvasively examine WM integrity, including possible traumatic axonal injury (TAI). Even so, the lesions and heterogeneity of TBI can affect the accuracy of imaging registration - the alignment of images from different subjects. Here we demonstrate an improvement to our DWI analytic workflow. Using information from three imaging modalities: DWI, T1, and FLAIR, we perform an intra-subject, multimodal registration prior to executing our autoMATE (automatic multi-atlas tract extraction) workflow to extract 3D models of tracts and analyze WM integrity. T1-weighted imaging provided a high spatial resolution anatomical scan. FLAIR (Fluid-Attenuated Inversion

Recovery) was used for improved detection of lesions, and DWI assessed the integrity of WM pathways in the brain. Combining information from these modalities results in more accurately registered DWI images. To compare our results, we used Support Vector Machine (SVM), a learning model to classify our connectivity features, and differentiate connectivity patterns in TBI and normal development. **Table 1** demonstrates improvement to our classification outputs when compared to a single-channel registration with our standard autoMATE template and study specific template. This step further improved the classification accuracy for models based on FA (fractional anisotropy) and RD (radial diffusivity), while the outputs for MD were slightly poorer, but close to those from the intermediate registration. Classification based on axial diffusivity metrics also improved with the multi-modal registration. We hope to use this stepwise improvement to better detect subtle brain changes following pediatric TBI.

Title: Test-retest reliability of KINARM robot assessments of sensorimotor and cognitive function in elite athletes: towards the assessment of sport-related concussion

Authors: *C. MANG[1], T. D. MAH[1], M. S. COSH[2], S. H. SCOTT[3], B. W. BENSON[2], S. P. DUKELOW[1];
[1]Clin. Neurosciences, Univ. of Calgary, Calgary, AB, Canada; [2]Winsport Med. Clin., Calgary, AB, Canada; [3]Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada

Abstract: Background: There is a need for improved tools to assess sensorimotor and cognitive deficits after sport-related concussion. Robotic technology allows objective assessment of aspects of sensorimotor and cognitive function that are challenging to evaluate with traditional clinical tools. The purpose of the current work was to evaluate test-retest reliability of robotic assessments (KINARM robot) of reaching, position sense, bimanual motor function, visuospatial skills, attention and decision-making in elite athletes competing in high-speed sports with a risk for concussion.
Methods: Baseline robotic assessments were conducted during the pre-season on 50 healthy,

high-performance athletes (22.2 ± 5.5 years) over three consecutive seasons between 2011 and 2013 (343 ± 55 days). Five robotic tasks (Visually guided reaching, Position matching, Object Hit, Object Hit and Avoid, Trail Making B) were employed, from which 63 parameters that characterize sensorimotor and cognitive function were measured. Test-retest reliability was investigated by determination of intra-class correlation coefficients (ICCs) between seasons 1 and 2 (S1 to S2) and seasons 2 and 3 (S2 to S3). Change in performance on tasks between baseline assessments was also evaluated with multivariate analysis of variance (MANOVA) and where appropriate, post-hoc comparisons within specific task parameters.
Results: ICCs ranged from -.08 to .91 and -.26 to .90 for S1 to S2 and S2 to S3, respectively. ICCs were moderate to good (≥ 0.5) for 46 of 63 parameters (73%) when considering S1 to S2 assessments and for 42 of 63 parameters (66.7%) when considering S2 to S3 assessments. MANOVAs and post-hoc comparisons indicated an improvement in a total of 12 of 63 parameters (19%) measured from 4 of 5 tasks (no changes in performance on Object Hit and Avoid task parameters). All changes in performance were found only when comparing S1 to S2 or S1 to S3. There were no significant differences in task performance on any parameters between S2 and S3.
Conclusion: The results suggest moderate to good test-retest reliability for the majority of task parameters measured from the KINARM robot in elite athletes. Improvements in performance across season to season assessments were observed in relatively few parameters between seasons 1 and 2, and task performance stabilized completely between seasons 2 and 3. Overall, the results suggest that robotic technology can provide a reliable assessment of baseline sensorimotor and cognitive function in elite athletes. Future work will consider the potential use of this information for diagnosis and prognosis of concussion-related neurological deficits.

Title: Characterization of iron deposition changes in cerebral regions of young athletes using susceptibility-weighted imaging

Authors: *X. MAO[1], B. JOHNSON[3], T. M. TALAVAGE[1,2], S. SLOBOUNOV[4];
[1]Sch. of Electrical and Computer Engin., [2]Weldon Sch. of Biomed. Engin., Purdue Univ., West Lafayette, IN; [3]Dept. of Kinesiology, The Pennsylvania State Univ., University Park, PA; [4]Dept. of Kinesiology, The Pennsylvania State Univ., West Lafayette, PA

Abstract: Introduction: Susceptibility-weighted imaging (SWI) has been shown to be sensitive to the iron in the form of ferritin, hemosiderin, and deoxyhemoglobin (Haacke, EM. et al. 2009), providing the ability to measure iron deposition *in vivo*. Our previous study (Mao, X. et al. 2015) has shown that the magnitude data of SWI can reveal the neurophysiological changes associated with Traumatic Brain Injury (TBI) in high school athletes. Here we use phase-filtered SWI data to assess potential changes in brain health of college-aged football athletes over a single season.
Methods: Eighteen (18) college football athletes (ages 19-23, mean=20.7) participated in imaging around a single competition season. SWI were performed before (*Pre*) and after (*Post*) the season, separated by approximately 5 months. None of these athletes was diagnosed with a head trauma during the season. SWI data were acquired on a 3T Siemens Prisma scanner, using an axial 3D multi-echo pulse sequence (TR =36.0ms; FOV=250x320 acquisition matrix). Acquired images underwent a pre-processing pipeline (see Mao, X. et al. 2015) and were then parcellated into 55 disjoint anatomical regions of interest (ROIs) at a gyrus level (Lancaster, JL. et al. 2000) in MNI152 space. ROI-specific intensity changes across the sessions (i.e. *Post*-*Pre*) were measured for each individual subject, and were compared with the averaged group changes, using the Wilcoxon rank-sum test.
Results: Statistically-significant decreases in SWI signal (e.g., Fig. 1) were observed in 10+ (out of 55) ROIs for 8 of 18 (44%) male football players at *Post*, relative to *Pre*.
Discussion and Conclusion: Hypointensity suggests these ROIs have experienced iron deposition during the season, which would be an expected consequence of vessels damaged by repeated subconcussive exposure. Given that SWI is very sensitive to deposition of iron due to microhemorrhage or leaky vessels, this work further argues that the technique has potential to quantify iron deposition as a biomarker of exposure to neural injury, even in the absence of diagnosable symptoms.

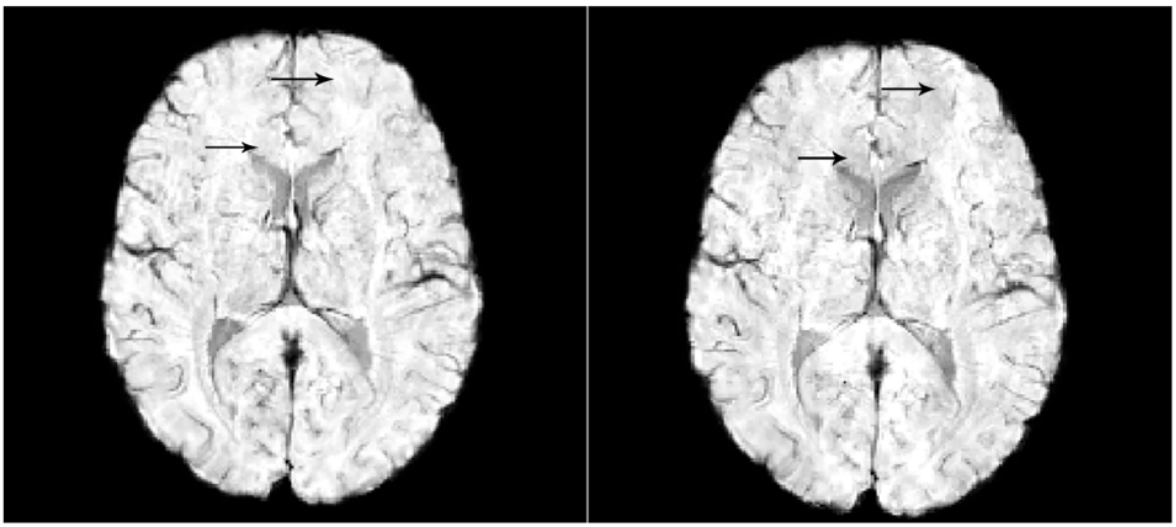

Fig.1 The SWI processed images of *Pre* (left) and *Post* (right) of one specific player in the subject pool. Note the hypointensities (black arrow) are implying the iron deposition changes between the two imaging sessions.

Title: The neural correlates of loss of consciousness during vector memory.

Authors: ***A. D. SPADONI**[1,2], I. A. STRIGO[3], A. N. SIMMONS[1,2];
[1]UCSD, San Diego, CA; [2]Veterans Affairs San Diego Healthcare Syst, San Diego, CA;
[3]SFVAMC, San Francisco, CA

Abstract: Background: Traumatic brain injury is the signature injury of military combat personnel and is linked to mental health problems and disability following deployment. Evidence suggests that loss of consciousness (LOC) compared to alteration of consciousness (nLOC) may

confer greater risk for neurocognitive sequelae. Methods: We used functional Magnetic Resonance Imaging (fMRI) to examine the influence of LOC on working memory for spatiotemporal information (i.e., vector memory) in 30 combat veterans with and without a history of LOC. The task consisted of tracking a moving object as it traveled across the screen (a) within view (vector tracking), or (b) out of view (vector memory) toward a visible target. Subjects were asked to press a button at the moment of anticipated impact. Task accuracy was examined for group by condition interactions using ANOVA. Change in brain activity was examined via linear mixed effects modeling with group (LOC v. nLOC), memory (vector memory v. vector tracking), distance (35 or 75% of the screen) entered as fixed factors; subjects were entered as a random factors. Results: Subjects with a history of LOC compared to nLOC performed significantly worse during vector memory relative to vector tracking during the long distance condition (75% of the screen or a longer period of occlusion). Initial results revealed that the contrast of vector memory versus vector tracking revealed greater activity in a network of regions involving the anterior and posterior cingulate, insula, lingual gyrus, caudate, and temporal gyrus. This initial analysis revealed no significant group X memory X distance interaction on patterns of brain activation (clusters $\geq$ 2106 μL, $p \leq .05$). Despite poorer performance, LOC relative to nLOC individuals were able to mount sufficient neural resources to complete vector memory during periods of visual occlusion. Conclusions: Combat veterans with a history of LOC relative to those without demonstrated poorer spatiotemporal, or "vector," memory. Results suggest that a history of LOC may impact the visuospatial skills, attention, and predictive timing needed to track moving objects during extended periods of visual occlusion. These findings may have important implications for safe driving among other everyday skills that rely on spatiotemporal processing.

Title: Neural basis of cognitive impairments in patient with diffuse axonal injury

Authors: *S. UBUKATA[1], N. OISHI[2,3], G. SUGIHARA[1], W. YASSIN[1,4], T. ASO[2], H. FUKUYAMA[2,3], T. MURAI[1], K. UEDA[1];

Abstract: Diffuse axonal injury (DAI), a major form of traumatic brain injury, is characterized diffused white matter disruption due to shearing forces of the brain. DAI is a main cause of neuropsychological sequelae following trauma. However, the neural bases of such sequelae are poorly understood. The aim of the present study was to assess structural neural network using connectome analysis and to examine the relationship between the altered connectivity and cognitive impairments in patients with chronic DAI. Eighteen patients with DAI (13 male, mean age 38.7± 12.9 years), and 18 age- and gender-matched healthy controls underwent neuropsychological assessments and magnetic resonance imaging. Most patients were diagnosed as having a severe TBI. All patients completed the Wechsler Adult Intelligence Scale-III, Wechsler Memory Scale-Revised, Behavioral Assessment of Dysexecutive Syndrome and Trail making test AB. All participants underwent diffusion tensor imaging (DTI), consisting of 64 non-collinear volumes with b = 1500 s/mm^2 and high-resolution T1-weighted three-dimensional magnetization-prepared rapid gradient-echo (3D-MPRAGE). DTI data processing was performed using the programs in FSL. 3D-MPRAGE data were processed using the VBM8 toolbox of SPM to determine individual-spaced volumes of interest. Deterministic fiber tracking was processed by Diffusion Toolkit using FACT algorithm with FA > 0.15 and angle > 60 degrees. Based on previous studies, we focused on the structural connectivity comprising corpus callosum (CC). 85 × 85 connectivity matrices for the metrics including a number of fiber and FA were calculated by an in-house Matlab script with three parts of CC derived from JHU white-matter atlas and 82 regions of AAL atlas. Statistical analyses were performed by the network-based statistic (NBS) with a t-statistic exceeding a threshold of t = 3.1 and a family-wise error-corrected p-value < 0.05 for the size of each resulting component using 5000 permutation tests. First, group comparisons were conducted to identify the abnormal connectivities in DAI relative to controls. Second, correlation analyses between FA and each of the cognitive variables were performed in DAI. Patients showed impairments in processing speed (PS) and memory function. Connectome analysis showed a reduction in number of fibers and FA in the CC in DAI compared with the controls. Significant correlations were found between the PS score and connectivity between the CC and medial prefrontal, posterior medial regions such as the precuneus. These results suggest that a structural brain network including the CC plays a key role in the cognitive impairments in DAI.

Title: 40-Hz auditory steady-state responses in patients with disorders of consciousness: positive correlation between Coma Recovery Scale-Revised results and phase-locking index

Authors: M. BINDER[1], U. GÓRSKA[1], *I. GRISKOVA-BULANOVA[2];
[1]Psychophysiology Laboratory, Inst. of Psychology, Jagiellonian Univ., Krakow, Poland;
[2]Vilnius Univ., Vilnius, Lithuania

Abstract: *Objective:* Auditory steady-state response (ASSR) is a frequency-domain EEG activity observed in response to periodic auditory stimulation. These responses were shown to be sensitive to changes in the cortical arousal occurring naturally during sleep (Cohen et al., 1991) and artificially, during the general anesthesia (Plourde, 2006). Following this evidence, we aimed to elucidate whether 40-Hz ASSRs could also be sensitive to the state of patients with disorders of consciousness (DOC) as measured with Coma Recovery Scale-Revised (CRS-R).
Methods: 15 patients with DOC were included (11 males and 4 females; mean age±SD 45.5±15.4). The state of the patients was evaluated with the Polish version of the CRS-R (Giacino et al., 2004). In each patient, CRS-R testing took place within one week from the date of the EEG session. The mean total CRS-R score was 8.5±6.1, range 3-20. The 40 Hz click trains of 500 ms duration were presented 100 times with the interstimulus interval of 700-1000 ms through earphones while subjects remained in a sitting position in their beds or wheelchairs. EEG was recorded using 64-channels Biosemi ActiveTwo system. The off-line processing of EEG data was performed in EEGLAB and ERPWAVELAB for MatLab© (Delorme and Makeig 2004; Mørup et al. 2007). After conventional cleaning procedures, epochs of 900 ms were created starting at 200 ms prior to the stimulus onset and lasting for 700 ms post-stimulus. ASSRs were analyzed from FCz location, showing maximal activity. Mean phase-locking index (PLI) within 38-42Hz window was calculated for 100 ms bins. The correlation between PLI values and CRS-R scores was evaluated using Pearson's correlation coefficient (p-values Bonferroni corrected).
Results and Conclusions: The highest PLIs were observed during 200-300 ms period, corresponding to prior observations on 40-Hz ASSRs (Griskova-Bulanova et al., 2016). The PLI values from the periods of 300-400 ms and 400-500 ms after the stimulus onset, corresponding to the entrainment phase of the response, positively correlated to the CRS-R subscales' scores (Auditory, Visual, Communication; $r>0.7$, $p<0.003$) and the total CRS-R score ($r>0.74$,

$p<0.002$), but there were no correlations between PLI values and Motor, Verbal and Arousal subscales. These results emphasize the role of the integrity of auditory system in determining the level of functioning in DOC patients, corresponding to previous observation with fMRI during resting-state paradigms (Demertzi et al., 2015). Our initial results also suggest possibility to use the ASSR protocol as an objective diagnostic method in DOC patient group.

Col. of Med., Philadelphia, PA

Abstract: Radiotherapy in cancer treatment often develop radiation-induced brain injury, also known as radiation encephalopathy (REP). Currently many methods are used to cure REP, but outcomes are limited. To find an effective method of managing REP, we evaluated the protective effect of Calcium leucovorin, a reduced folic acid, on REP in nasopharynx cancer (NPC) patients. The definition of locoregionally advanced NPC followed the staging system of AJCC.

This study included 1080 patients that were diagnosed with NPC with a median follow-up of 8 years (from 2002 to 2014) and survival of 3 years after initial diagnosis. The Leucovorin-Group (Group1) of 163 NPC patients received PFL chemotherapy (cisplatin 80 mg/m², 5-fluorouracil 1000 mg/m²/d, and leucovorin 120 mg/m²) every 3 weeks. The Non-leucovorin-Group (Group2) of 917 patients did not receive leucovorin during the same period. These patients included 262 patients of PF chemotherapy (Group-PF) and 655 patients of other chemotherapy regimens. Data for the two main groups was collected from medical records, including temporal lobe injury, sensorineural hearing loss (SNHL) and other cranial nerves disorders, were evaluated according to MRI, etc. We identified that 11 (6.7%) patients of the Group1 had REP as compared to the 112 (12.2%) in the Group2 (λ^2=4.06, P<0.05). The incidence of REP of the Group1 as compared to the Group2 at 3, 5 and 8 years were 1.2% vs. 3.7%, 2.5% vs.6.9%, 5.5% vs. 9.9%, respectively. The REP occurrence time post-radiotherapy of Group1 was longer than that of Group2 (61.1±7.8 months vs. 50.9 ±4.2 months, p<0.05). Considering the ototoxicity of cisplatin, we then compared the incidence of SNHL in Group1 and Group-PF particularly. The incidence of sensorineural hearing loss (SNHL) in Group1 was much lower than the Group-PF (16.6% vs. 21.4%).The decrease in the incidence and delay of the occurrence time of REP were significantly ameliorated by administration of leucovorin. Subgroup analysis revealed that leucovorin prevented hearing impairment, especially hearing loss in patients underwent cisplatin-based chemotherapy. These findings provide the first evidence that leucovorin has beneficial effects of decreasing radiation-induced brain injury in NPC patients.

Title: Dynamic virtual environments in the computer assisted rehabilitation environment (CAREN): developing novel assessments for service members with comorbid mild traumatic brain injury and post traumatic stress disorder

Authors: ***M. M. ONAKOMAIYA**[1,2], M. M. PAPE[1], K. B. HIGHLAND[3,4,5], D. S. CLAYBORNE[1], S. E. KRUGER[1];

[1]Natl. Intrepid Ctr. of Excellence (NICoE), Walter Reed Natl. Military Med. Ctr., Bethesda, MD; [2]Cherokee Nation Technol. Solutions, Catoosa, OK; [3]Def. and Veterans Ctr. for Integrative Pain Mgmt., Rockville, MD; [4]Uniformed Services Univ. of the Hlth. Sci., Bethesda, MD; [5]Henry M. Jackson Fndn., Bethesda, MD

Abstract: For service members (SMs), mission-essential tasks often require dual-tasking skills, which may be impaired by mild traumatic brain injury (mTBI) and posttraumatic stress disorder (PTSD). Conventional dual-task assessments cannot incorporate visual cognitive tasks during gait, are often time-consuming, and are not military-relevant. The Computer Assisted Rehabilitation Environment (CAREN) enables the incorporation of visual cognitive tasks by integrating multi-planar motion and locomotion with interactive virtual environments (VEs). Thus, our objective was to determine the efficacy of military-relevant dual-task assessment for SMs with comorbid mTBI-PTSD. Male SMs (N=37: mTBI-PTSD = 25; uninjured = 12) completed the PTSD Checklist - Military Version (PCL-M) and three CAREN VEs: 1) Balance Balls (BB), requiring weight-shifting; 2) Balance Cubes (BC), requiring step-shifting; and 3) Dual-Tasking Rank Insignia (DTRI), requiring three single-tasks (walking, rank insignia recognition, and rank insignia discrimination) and two dual-tasks combining walking and the rank insignia tasks (i.e. DTRI-Disc and DTRI-Rec). The main outcomes were time for the BB and BC tasks, and dual-task cost (% change in gait speed) and cognitive error (CE; % change in accuracy) for the DTRI tasks. BB time was significantly correlated with BC time ($r = 0.777$; $p < 0.001$), DTRI-Rec cost ($r = 0.374$; $p = 0.025$) and both DTRI-Disc cost ($r = 0.494$; $p = 0.002$) and CE ($r = 0.574$; $p < 0.001$). DTRI-Disc and DTRI-Rec cost, but not CE, were significantly correlated ($r = 0.903$; $p < 0.001$), and DTRI-Disc cost and CE were significantly correlated ($r = 0.480$; $p = 0.003$) such that gait speed increased as accuracy decreased. When controlling for mTBI history, BC time was significantly related to PCL-M score ($\beta = 1.053$, $p = 0.028$), such that SMs endorsing higher PCL-M scores spent more time on the BC task. BB and DTRI outcomes did not vary by PCL-M score. Developing immersive, military-relevant assessments is essential for improving treatment planning and clinical outcomes. Similar to published reports, we found that accuracy was inversely correlated with gait speed when SMs completed a visual discrimination task during ambulation, supporting dual-task assessment in the CAREN. Moreover, consistent with our previous study in SMs with TBI, those endorsing greater PTSD symptoms spent more time step-shifting, regardless of mTBI history, providing further evidence for utilizing the BC task in identifying comorbid mTBI-PTSD. Future research will determine whether multi-tasking assessments that integrate step-shifting with the visual cognitive tasks are more sensitive to group differences.

Title: Day-time sleepiness after mild traumatic brain injury correlates to initial IGF-1 level

Authors: *Y.-H. CHIANG[1], S.-H. TSAI[2], W.-T. CHIU[1], K.-H. LIAO[4], J.-C. WU[1], K.-Y. CHEN[3];
[2]Inst. of Injury Prevention and Control, Col. of Publ. Hlth. and Nutr., [3]Grad. Inst. of Neural Regenerative Medicine, Col. of Med. Sci. and Technol., [1]Taipei Med. Univ., Taipei, Taiwan; [4]Wan Fang Hosp., Taipei, Taiwan

Abstract: Mild traumatic brain injury (mTBI) is a major public problem that results in several psychiatric problems. The insulin-like growth factor 1 (IGF-1) system is involved in growth and survival signaling in the central nervous system. In addition, IGF-1 has been implicated as a neuroprotective agent in brain injury. The aim of this study is to examine the association between IGF-1 and the disorders of anxiety, depression and sleep among mTBI patients and controls without brain injury. In our observational study, 53 mTBI patients and 116 healthy participants (control group) was evaluated for four psychiatric symptoms and problems, which are anxiety (Beck's anxiety inventory), depression (Beck's depression inventory), daytime sleepiness (Epworth sleepiness scale), and sleep quality (Pittsburgh sleep quality index). The results show significant relationship between IGF-1 and participants' age but not correlated with the weight. Our previous findings showed the IGF-1 level did correlate significantly with these continuous scores, but it was significant when we revealed that IGF-1 was related with the anxiety problem after mTBI. The results of this report show significant relationship between IGF-1 and participants' age, but not correlated with the weight. Finally, our finding suggests that initial IGF-1 level was related with the daytime sleepiness problem one year after mTBI.

Abstract: In this study we used MEG to investigate differences in brain activity in post 9/11 Veterans with and without PTSD and mTBI during the Iowa Gambling Task (IGT). The IGT is a decision making task that requires individuals to balance immediate rewards against delayed consequences over time. Performance is not strongly predicted by IQ or cognitive abilities. Impairments on the task have been observed in people with higher levels of trait anxiety or who have undergone a stress induction, suggesting that individuals with PTSD may perform poorly on the IGT. There is also overlap between the networks implicated in the IGT by lesion and fMRI studies and areas of volumetric difference observed in PTSD (amygdala and cingulate), providing further evidence for a possible negative impact of PTSD on IGT performance. While the effect of TBI on IGT performance has not been described, the IGT is a relatively complex task that may be sensitive to network dysfunction due to small diffuse injuries. Twenty-four right-handed males (average age 38 yrs) who had completed a comprehensive diagnostic interview were included. Subjects were either diagnosed with PTSD alone (6), mTBI alone (4), PTSD+mTBI (5), or had no Axis I diagnosis (9).
Subjects were scanned with a 275 channel CTF Systems Inc. MEG and data were routinely preprocessed. Win and loss trials were analyzed separately. Based on the power spectra of the event related averages for wins and losses for control subjects, synthetic aperture magnetometry (SAM) was used to beamform activity at 1-8, 8-15, and 15-70 Hz using randomly selected resting state epochs as the contrast. SAM maps exhibited increased desynchronization of frontal and parietal networks in subjects with PTSD for losses at 1-8 Hz in comparison to controls.

Interestingly, subjects with TBI-only had patches of synchronization within overall regions of desynchronization in frontal and parietal networks, and thus showed more total synchronization than subjects with PTSD-only or controls for all loss frequencies. Subjects with PTSD+TBI exhibited stronger levels of dorsal desynchronization at 1-8 and 15-70 Hz for losses in comparison to all groups. Maps for wins were more complex but showed similar dorsal desynchronization patterns for all four groups. These results suggest that distributions of synchronous and desynchronous brain rhythms may differentially vary as a function of PTSD and TBI status.

Title: The effects of aerobic exercise on corticospinal excitability in high versus low physically active individuals

Authors: *J. EL-SAYES, T. LULIC, H. J. FASSETT, A. J. NELSON;
McMaster Univ., Hamilton, ON, Canada

Abstract: Regular physical activity can impact cortical function and the propensity for plasticity. Few studies have examined the influence of physical activity level on the propensity for plasticity. Transcranial magnetic stimulation (TMS) can be used to asses short-term plasticity effects and the present study aimed to determine changes in corticospinal excitability that follows aerobic exercise. Additionally, it compared changes in corticospinal excitability after a single session of aerobic exercise in high versus low physically active individuals. Participants included twenty-four young, healthy adults (ages 18 - 30 years) who were divided into two equal groups based on the physical activity scores determined by the Minnesota Leisure-Time Physical Activity Questionnaire: low physical activity (LPA): 708.12 ± 632.89 and high physical activity (HPA): 2149.88. TMS was used to obtain motor evoked potential (MEP) recruitment curves from the first dorsal interosseous (FDI) before and after moderate intensity aerobic exercise that required cycling on a recumbent cycle ergometer for 20 minutes at 50-70% of the age-predicted maximal heart rate. MEP recruitment curves were measured as a function of resting motor

threshold (RMT), and also active motor threshold (AMT) (90-150% RMT/AMT) the required 5-10% of their maximum voluntary contraction of the FDI during MEP acquisition. MEPs were quantified as the peak-to-peak amplitude and recruitment curves were assessed by their slope. Results indicate that in the HPA group, resting MEP peak-to-peak amplitude and the slope of the recruitment curve increases following exercise. MEP recruitment curves and amplitudes were unchanged for the LPA group. These results may suggest that there is a difference in the propensity for neuroplasticity in high versus low physically active individuals. Therefore, it is necessary to consider lifestyle activity when developing and implementing rehabilitation protocols used in clinical populations.

Title: Fetal neuronal exosome miR-9 and its downstream targets BDNF, REST and Synapsin: robust non-invasive maternal biomarkers of ETOH mediated fetal brain injury

Authors: *N. DARBINIAN[1,2], E. J. GOETZL[3], N. MERABOVA[2], E. LAURETTI[2], G. TATEVOSIAN[2], D. MARTIROSYAN[2], L. GOETZL[2,4];
[1]Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA; [2]Ctr. for Neural Repair and Rehabilitation, Shriners Hosp. Pediatric Res. Center, Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA; [3]Univ. of California, San Francisco, CA; [4]Obstetrics & Gynecology, Lewis Katz Sch. of Med. at Temple Univ., Philadelphia, PA

Abstract: **Introduction**: Ethanol (EtOH) can disrupt fetal brain development and formation of synaptic connections but mechanisms elucidated in animal models can be hard to confirm in human models. We hypothesized that altered fetal brain levels of the neuronal regulator microRNA-9 could be detected using our novel non-invasive method: maternal-plasma derived fetal neuronal exosomes (FNEs). **Methods:** We performed a matched case-control study in women at 9 -19 weeks gestation (GA). Heavy EtOH users were compared to unexposed controls matched for fetal sex and GA (10 CNTRL/10 EtOH). Plasma exosomes were precipitated (ExoQuick) and the fetal subset enriched (anti-Contactin-2/TAG1-steptavidin bead absorption). Synaptosomes (SYNPs) were prepared from fetal brain. MiR-9 levels were quantified by qRT-

PCR. Protein levels were assessed by ELISA or q Western blots. **Results**: EtOH was associated with significant down regulation of Mir-9 (FNE, 4.16 fold ↓, $p<0.001$, Brain, 1.2 fold↓, $p=0.004$), which supports a fetal origin for exosomes as Mir-9 is typically upregulated in adults. Similarly, downregulation was observed in Mir-9 downstream double negative feedback targets, REST and BDNF: BDNF FNEs (↓1.2; $p=0.009$), SYNPs (↓1.4; $p=0.04$); REST FNEs (↓1.33; $p=0.04$) SYNPs (↓4.6; $p<0.001$). Brain MiR-9 was strongly correlated with brain BDNF mRNA ($\rho= 0.82$, $p=0.004$). Synaptic injury was robustly associated with EtOH exposure and could be detected non-invasively using FNEs (Figure 1. $p<0.001$ for both) with high correlation between SYNPs and FNEs ($\rho = 0.86$, $p<0.001$). **Conclusions**: Our data suggest that in-utero exposure to EtOH is associated with potentially clinically significant alterations in human fetal brain expression of Mir-9 and downstream genes. Our results also support use of FNEs as a non-invasive approach to confirming mechanisms observed in animal models. FNE results should be correlated with pediatric outcomes to confirm their clinical utility in identifying pregnancies at risk for fetal alcohol syndrome. **Figure 1. Synapsin Expression in FNEs (A) and SYNPs (B) in an In-Vivo Human FAS Model.**

Title: Minocycline reduces chronic microglial activation following traumatic brain injury

Authors: *D. J. SHARP, A. JOLLY, J. COLE, P. JENKINS, M. PATEL, A. P. GOLDSTONE, R. GUNN, P. MATTHEWS, G. SCOTT;
Imperial Col. London, London, United Kingdom

Abstract: Objective:
Traumatic brain injury (TBI) can trigger chronic microglial activation, which may be harmful. The antibiotic minocycline is neuroprotective in animal models of TBI and other neurological disorders. An important mechanism is the inhibition of microglial activation. [^{11}C]PBR28 positron emission tomography (PET). binds to the translocator protein up-regulated by activated microglia. Here, we used [^{11}C]PBR28 PET to test the hypotheses: (1) chronic microglial activation is present in patients at least six months after moderate-severe TBI; (2) chronic microglial activation is higher in areas of WM damage that show progressive atrophy; and (3) minocycline reduces chronic microglial activation after TBI.
Methods:
Fifteen patients at least 6 months after a moderate-severe TBI and controls had structural and diffusion MRI, neuropsychological testing and [^{11}C]PBR28 PET. Patients received either minocycline 100mg orally twice daily or no drug (2:1 ratio) for 12 weeks. Patients had follow up at 12 weeks (with PET) and 6 months (without). [^{11}C]PBR28 volume of distribution (V_T) was estimated with the Logan plot, normalized to whole brain mean (distribution volume ratio, DVR) for cross-sectional analysis.
Results:
[^{11}C]PBR28 DVR was increased in cerebral white matter (WM) and thalamus. MRI measures of WM damage were highest in areas of increased [^{11}C]PBR28 binding. These areas with increased microglial activation showed greater longitudinal atrophy. Minocycline treatment was well tolerated and [^{11}C]PBR28 V_T after minocycline was significantly reduced (mean WM ΔV_T=-23.3%, 95% confidence interval -40.9 to -5.6%) compared to no drug. Patients showed impairments of information processing speed and this showed improvement of borderline significance in the minocycline treated group.
Interpretation:
Brain trauma can trigger long-term neurodegenerative processes, including persistent neuroinflammation. Using PET, we demonstrate that microglial activation is associated with progressive white matter (WM) damage, months and years after moderate-severe TBI. For the first time we show that areas associated with high [^{11}C]PBR28 binding showed greater atrophy over time, suggesting a mechanistic link between TBI-induced chronic neuroinflammation and neurodegeneration. In addition, we show that minocycline treatment in TBI patients produced a widespread reduction in [^{11}C]PBR28 binding, providing *in vivo* evidence of a direct effect of minocycline on chronic microglial activation.

Title: The auditory steady-state response can be a predictable index of conscious outcome in patients with severe head injury in the early stage

Authors: *S.-I. HIRANO;
Osaka Dent. Univ., Osaka, Japan

Abstract: Early diagnosis is important for all patients to provide appropriate treatment. Some electrophysiological examinations have been utilized to estimate the outcome of consciousness disturbance. One of the most influential causes of consciousness disturbance is hypofunction of brainstem reticular formation. Previous studies have suggested that the 40Hz auditory steady-state response (40Hz-ASR) originates in midbrain reticular formation. Hence I used the 40Hz-ASR with the auditory brainstem response (ABR), which reflects the specific ascending activity, to know the brainstem function in patients with severe head injury.
In this prospective study, the usefulness of the 40Hz-ASR as a predictor of consciousness outcome was evaluated. The 40Hz-ASR was examined in 27 patients with severe head injury. All of them were deeply comatose (Glasgow coma scale 3-8). No patient experienced a major complication during the treatment period. The author recorded the 40Hz-ASR and ABR simultaneously, and compared the results to clarify the characteristics and pathophysiological differences of these responses. The author classified the 40Hz-ASR into four groups and the ABR into five groups according to their appearances. The change in patients' consciousness level was noted successively. The author evaluated their condition at discharge following the Glasgow outcome scale, and determined as the final outcome.
The patients who lost waves III and V of the ABR had a poor outcome, and, in general, showed no 40Hz-ASR. In contrast, the ABRs of these patients who showed progressive worsening of 40 Hz-ASRs, were not necessarily disturbed at the same time. The patients who exhibited wave V had low mortality. However, if they showed no 40Hz-ASR during their convalescent stage, the consciousness disturbance persisted and some of the patients became vegetative. The patients who showed good or fair 40Hz-ASR in the acute or sub-acute stage recovered from the coma. Our results suggest that the ABR and the 40 Hz-ASR make original contributors in separate regions, and indicate that the ABR correlated with the vital outcome and the 40Hz-ASR correlated with the consciousness recovery. They might be utilized as indices of the vital risk and consciousness recovery, respectively. Moreover, as the 40Hz-ASR changed before the alteration of the level of consciousness in patients who were improving or worsening, it may serve as a useful tool for early prognostic evaluation of comatose patients. This tendency was not obvious

in the ABR results. The author has obtained Institutional Review Board approval prior to launching this study, and has no COI to declare.

Title: Neural and epigenetic contributions to posttraumatic stress symptoms: The influence of hippocampal volume and glucocorticoid receptor gene methylation

Authors: *M. W. MCNERNEY[1,2], T. SHENG[1,2], A. LEE[2], D. LYONS[2], S. SOMAN[3], J. NECHVATAL[1,2], J. HALLMAYER[1,2], R. O'HARA[1,2], W. ASHFORD[1,2], J. YESAVAGE[1,2], M. ADAMSON[4,2];
[1]VA, Palo Alto, CA; [2]Stanford Med. Sch., Palo Alto, CA; [3]Beth Isreal, Boston, MA; [4]DVBIC, Dept. of Defence, Palo Alto, CA

Abstract: Background: Deployed Veterans often experience physical and psychological trauma during combat and exhibit symptoms of posttraumatic stress (PTSD) after service. As the etiology of PTSD symptoms is complex, a better understanding of the underlying biological mechanisms can potentially inform preventative care and treatment. Recent findings from the fields of neuroimaging and epigenetics have offered important insights about potential brain structures and biochemical pathways of modified gene expression associated with PTSD, but a comprehensive model of predictive biomarkers is still lacking. **Methods**: In the current study, we evaluated the potential of an integrated biomarker model that combined neuroimaging and epigenetic measures. Sixty-seven post-deployed Veterans received high resolution structural brain scans and provided saliva samples for DNA extraction. Based on previous literature, we characterized the overall hippocampal volume (using FreeSurfer; adjusted for total intracranial volume) and quantified methylation of the promoter region of the glucocorticoid receptor (GR) gene (DNA pyrosequencing). The patient sample was split into evenly matched discovery (n = 34) and validation (n = 33) subsamples (balanced across all predictor and outcome variables) to enable validation/generalizability analyses. **Results**: In the discovery subsample, we found that total hippocampal volume, GR methylation, and their interaction were indicative of self-reported PTSD symptom severity (adjusted r^2 = .24, p = .02, all |T|s > 2.35; education and history of

traumatic brain injury (TBI) as covariates). History of TBI was also a significant factor (T = 2.26). A confirmatory analysis with the validation subsample indicated that predicted self-report PTSD symptoms were substantially correlated with patients' actual self-reported PTSD symptoms (r = .37, p = .03). **Conclusion**: Our findings suggest that GR methylation and total hippocampal volume contribute to PTSD symptoms. This finding was confirmed using validation analysis with an independent patient sample. Thus, a more comprehensive biomarker model that incorporates measures from different sources and considers their potential interactions will be valuable towards predicting mental health symptoms.

Title: Preliminary expression profiling of tau-positive cholinergic basal forebrain neurons in the nucleus basalis of Meynert in postmortem chronic traumatic encephalopathy brain: A Chronic Effects of Neurotrauma Consortium Study

Authors: ***E. J. MUFSON**[1], S. E. PEREZ[1], B. HE[1], S. LEE[2], E. PETRKOVA[3], A. C. MCKEE[4], S. D. GINSBERG[2];
[1]Neurobio., Barrow Neurolog. Inst., Phoenix, AZ; [2]Dept. of Psychiatry, Nathan Kline Inst., Orangeburg, NY; [3]Child and Adolescent Psychiatry, New York Univ. Langone Med. Ctr., New York, NY; [4]Neurol. and Pathology, Boston Univ. Sch. Med., Boston, MA

Abstract: Military personnel in the battlefield and athletes in contact sports (e.g., boxing, American football, and hockey) are exposed to mild repetitive traumatic brain injury, which can result in chronic traumatic encephalopathy (CTE). Although in its early stages, the

neuropathology of CTE is characterized by the intracellular accumulation of abnormally phosphorylated tau protein (p-tau), the main constituent of neurofibrillary tangles (NFTs) in the forebrain similar to Alzheimer's disease (AD). Recently, we found that as in AD, the cholinergic neurons within the nucleus basalis of Meynert (nbM) display intracellular tau accumulation and deposition across the pathological stages of CTE. However, molecular mechanisms underlying CTE neurodegeneration are not well understood. Here, we assessed the genetic signature of cholinergic neurons containing the tau pretangle maker pS422 within the nbM obtained from subjects who died with a clinical diagnosis of CTE and received a neuropathological staging assessment of stage II, III, and IV based on NINDS consensus criteria, using laser capture microdissection and custom-designed microarray analysis. Preliminary analysis revealed that between CTE Stages II and III there was a significant upregulation of genes associated with neuropathology and protein aggregation including alpha-synuclein (SNCA), sirtruin 1 (SIRT1) and neprilysin}, NFT formation (MAPK and GSK3B), apoptosis (CASP8, FAS/FASLR), endosomal/lysosomal/autophagy (M6PR, LAMP2, USP1, LIPA, ACP2, and PPT1), RNA and DNA repair and synthesis (RHEB, ERCC1, and DDX1), and neurodevelopment (TSC2, NOTCH-1). By contrast, comparing Stage II to IV, the only significant preliminary gene alteration was the downregulation of the pro-apoptotic gene CASP-7. Comparing Stage III to IV revealed an upregulation of SNCA, JUNB, Protein kinase C epsilon and amyloid-beta precursor protein (APP) genes, each related to AD, as well as downregulation of the inhibitory GABA neurotransmitter transporter, GAT2. These preliminary findings suggest that genes related to protein aggregation, cell survival/death are upregulated during the early pathological stages of CTE along with a late upregulation of the APP gene. Based on these initial findings, drug discovery related to CTE should be directed towards mechanisms of neuron survival rather than focusing solely on amyloid or tau therapies.

Title: Preventing mild traumatic brain injury in women's soccer: an assessment of the relationship between cerebrovascular reactivity changes and daily loading

Authors: *D. O. SVALDI[1], E. C. MCCUEN[1], J. P. E. MUSIC[2], C. JOSHI[3], E. A. NAUMAN[4], T. M. TALAVAGE[5];
[1]Biomed. Engin., [2]Mechanical Engin., [3]Electrical Engin., [4]Mechanical Engin. Biomed. Engin., [5]Electrical Engin. Biomed. Engin., Purdue Univ., West Lafayette, IN

Abstract: As participation in women's soccer continues to grow, prevention of mild TBI (mTBI) has become a major concern for female athletes. Studies suggest (Len & Neary, 2011) that cerebrovascular deficits play an important role in the neurocognitive sequela associated with mTBI. However, the relationship between head impact exposure and cerebrovascular brain changes associated with mTBI is not well understood. Previous FMRI work (Svaldi et al., 2016) comparing asymptomatic female high school soccer athletes experiencing high cumulative loading to female high school non-collision sport control athletes revealed cerebrovascular reactivity (CVR) decreases in soccer athletes comparable to those observed following mTBI (Gardner et al., 2015; Mutch et al., 2014). Here, a larger dataset is used to assess the effect of relative daily loading on observed neuroimaging changes. Cerebrovascular reactivity (CVR) was measured with FMRI (3T GE Signa HDx) using a breath hold challenge as described in (Svaldi et al., 2016). Soccer athletes were imaged before contact (*Pre)*, within the first (*In1*) and second halves (*In2)* of competition, and 1-2 months after the end of competition (*Post)*. Controls were scanned twice (*Test/Re-test)*, 4-6 weeks apart, during comparable periods of activity. Head acceleration events experienced by soccer athletes were monitored as in (McCuen et al., 2015). The (to-date) cumulative peak translational acceleration (CPTA) was calculated for each soccer athlete at each imaging session only using events exceeding 50g. Soccer athletes were divided into three groups (*HighLoad*, *MidLoad*, *LowLoad*) at each imaging session for two analyses: (1) net loading using CPTA, (2) normalized loading (nCPTA), obtained by dividing CPTA by the number of participation days. At each session, changes in CVR were evaluated as a function of exposure (CPTA, nCPTA) for all soccer athletes *(Total*) and after division into groups. CVR changes between sessions were also evaluated for the control athlete cohort. Control athletes exhibited no change in CVR. Soccer athletes (*Total*) exhibited significant decreases in CVR for at all time-points. Decreases were biased by the intensity of daily loading experienced by the individual athletes, rather than by the absolute total loading experienced to-date. From this we conclude that cumulative load and the amount of time over which this load is accrued are both important in assessing the relationship between head impact exposure and observed cerebrovascular changes. Limiting daily loading maybe useful in preventing sports related mTBI.

Title: Concussion alters basal cerebral blood flow and reactive capacity: a dual-echo pcasl fMRI study

Authors: *C. I. MARK[1], A. CHAMPAGNE[1], A. BHOGAL[2], I. JOHNSRUDE[3], D. COOK[1]; [1]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [2]Radiology, Univ. Med. Ctr. Utrecht, Utrecht, Netherlands; [3]Brain and Mind Institute, Dept. of Psychology, Univ. of Western Ontario, London, ON, Canada

Abstract: Objectives
Existing symptom-based and structural brain imaging methods have been of limited help in outcome prognostication or making return-to-play decisions. A possible explanation for persisting deficits is sustained impairment of cerebrovascular autoregulation. Quantitative functional MRI (qfMRI) and robust gas control provides an opportunity to directly image cerebrovascular physiology and may be a more sensitive modality to investigate the pathophysiology of concussion.
Methods
We complement traditional blood oxygenation-level dependent (BOLD) acquisition with simultaneous cerebral blood flow (CBF) measurements during targeted hypercapnic breathing challenges in varsity athletes during the acute (< 7 days), early (14 days) and late (3 months, 1 year) post-concussion stages. Subjects are scanned on a 32-channel receiver coil [Tim-Trio, Siemens]. Following standard anatomical imaging, and acquisition of a CBF quantification image, the breathing task is performed through a sealed rebreathing circuit (RespirAct^{TM}, Thornhill Research Inc) under Dual-Echo pseudo-Continuous Arterial Spin Labelling (DE-pCASL): A block of 2 min hypercapnia at 10 mmHg increase in end-tidal partial pressure in CO_2 above the subject's resting level, preceded and followed by 2 min at rest, under iso-oxia. In-house data analysis includes motion correction, de-trending, spatial smoothing, slice time correction, re-alignment of MR data with the respiratory traces and registration to MNI space. Block designs are used to model BOLD-CVR and quantitative CBF maps.
Results
Preliminary data on 8 concussed (CI, 3 females) and 10 non-concussed (NC, 5 females) athletes over acute and early recovery time points reveal significant abnormal patterns in BOLD-CVR

(p=0.009), baseline perfusion (p=0.008) and CBF-CVR (p=0.006) subsequent to concussion. A reduction in BOLD-CVR is generally observed 7 days post-concussion; grossly recovering after 14 days, with the greatest differences in the frontal cortex. A closer look at the underlying baseline perfusion maps indicates a hyperemic response 7 days post-injury, which does not resolve to normal level after 3 months. Reduced CBF-CVR is observed throughout all time points.

Conclusion

In this study, indications of impaired cerebrovascular regulation, through changes in BOLD, baseline perfusion and reactive capacity, were observed across athletes in the acute and early recovery stages post-concussion. Sustained impaired CVR, while BOLD is restored to normal levels might be indicative of a rising hypometabolic response; a potential homeostatic safety mechanism of the brain to spare healthy tissue.

Title: The influence of aerobic exercise on intracortical circuits in high versus low physically active individuals

Authors: *T. LULIC[1], J. EL-SAYES[2], F. J. HUNTER[2], A. J. NELSON[2];
[1]Dept. of Kinesiology, [2]McMaster Univ., Hamilton, ON, Canada

Abstract: There is emerging evidence that regular physical activity can influence brain function and plasticity. In general, lower limb cycling has been shown to increase corticospinal excitability and reduce short-intracortical inhibition (SICI) in resting upper limb muscles. In addition, the response to a neuroplasticity protocol has been found to be dictated by previous physical activity levels. However, the exact mechanisms by which physical activity promotes plasticity are unknown. Additionally, it is unknown whether levels of physical activity may influence response to an exercise intervention. Hence, the aim of this study was two-fold: 1) to determine if differences exist in intracortical circuitry in highly physically active and low physically active individuals; and 2) to determine whether the amount of change in intracortical

circuitry following a single session of moderate intensity aerobic exercise is modulated differently in high and low physically active individuals. A total of 24 participants (18-30 years) were divided into low-physically active (LPA) and high-physically active (HPA) group based on Minnesota Leisure-Time Physical Activity Questionnaire (LPA: 708.12 ± 632.89, HPA: 2149.88). Electromyographic recordings were obtained from the right first dorsal interosseous (FDI) muscle. Paired-pulse Transcranial magnetic stimulation (TMS) of the left-hemisphere motor cortex was used to assess short-interval intracortical inhibition (2 ms SICI) and facilitation (10 ms ICF), as well as short intracortical facilitation (1.2 and 2.5 SICF) before and following exercise. Exercise involved 20 minutes of moderate intensity (50-70% age-predicted maximal heart rate) lower limb cycling on a recumbent cycle ergometer. There were no differences in SICI, ICF and SICF before or following exercise between LPA and HPA. However, reductions in SICI and were observed in both groups following exercise. These findings show that a short period of aerobic exercise can transiently reduce inhibition and facilitation in the motor cortex. However, the amount of previous physical activity may not influence baseline measures of intracortical circuitry or the amount of change within the circuits following aerobic exercise. Exercise induced reductions in inhibition have been suggested to provide a favorable environment for plasticity induction, and hence it is important to further explore the effects of chronic exercise on plasticity within motor cortex.

Title: Brain structure in premature infants: liberal vs. restricted red blood cell transfusions

Authors: *A. V. TERESHCHENKO[1], A. METZGER[2], V. MAGNOTTA[2], J. WIDNESS[3], P. NOPOULOS[1];
[1]Psychiatry, [2]Radiology, [3]Pediatrics, Univ. of Iowa, Iowa City, IA

Abstract: **Objective:** To assess the neonatal brain structure changes in preterm infants who received red blood cell transfusion for anemia of prematurity.

Methods: As part of the larger clinical Transfusion of Prematures trial, the neonates are randomly assigned to receive red blood cell transfusions according to one of two paradigms: either liberal or restrictive threshold. It is unknown which transfusion strategy is superior for optimal brain development. To accurately measure neonatal brain volumes, a novel neonate brain atlas was developed. To account for brain growth, all volumetric analyses were corrected for total intracranial volume. Analysis of covariance assessed differences in brain region volumes between neonates (n=15) assigned to liberal or restrictive transfusions, controlling for sex, gestational age and chronological age. As multiple studies established pro-inflammatory profile in neonates who receive transfusions, we included a panel of pro-inflammatory biomarkers. Spearman's rank correlation was used to determine the relationships between maximum serum levels of pro-inflammatory biomarkers and brain growth.

Results: Significant sex-by-group interaction was found. Females assigned to the liberal group had lower volumes of cerebral white matter and cerebellum, whereas, males assigned to the restricted protocol had lower volumes of cerebral white matter. Higher serum concentrations of pro-inflammatory cytokines IL-8 and MCP-1 were associated with lower volumes of cerebral white matter. A lower level of the combination of pro-apoptotic cytokines TNF-α, TNF-β, and a marker of endothelial activation sVCAM-1 was associated with higher volumes of cerebral white matter.

Conclusions: Red blood cell transfusions affected brain development in premature infants assigned to liberal or restrictive transfusion protocols via potential inflammatory pathways. Understanding how different red blood cell transfusion practices impact brain growth may lead to significant clinical impact on the treatment guidelines for anemia of prematurity.

Title: Executive dysfunction associated with greater number of lifetime concussions in amateur soccer players

Authors: *L. E. HUNTER[1], M. LIPTON[2];
[2]Radiology, [1]Albert Einstein Col. of Med., Bronx, NY

Abstract: Objectives: Concussion is a common occurrence in soccer that can be caused by collisions as well as heading the ball. While symptoms related to concussion resolve in most people, up to 30% of individuals who suffer a concussion will have chronic impairments that negatively impact their quality of life. Herein, we aim to identify the risk for long -term cognitive deficits due to all causes of recognized concussion in amateur soccer players who have been playing at a similar frequency for an average of twelve years.
Methods: We measured 275 soccer players (mean age 25.8; 202 men, 73 women) enrolled in the Einstein Soccer Study, an ongoing longitudinal study of adult amateur soccer players. History of concussion was captured using a structured questionnaire that asks participants to report the number of lifetime concussions for which they received or were advised to seek medical attention. Executive function, attention, vigilance, working memory, visual learning memory, verbal learning and memory and psychomotor speed were measured using Cogstate, a validated computer based measurement of cognition. We used multivariate linear regressions to examine the association between number of lifetime concussions and cognition in the aforementioned domains. Regressions were adjusted for age, gender, years of education, handedness, race, IQ and total lifetime headings.
Results: 65% of players reported no lifetime concussions, 16% reported 1 lifetime concussion, 10 % reported 2 lifetime concussions, and 9% reported 3-6 lifetime concussions. Number of lifetime concussion was significantly (=1.87, p= 0.021) associated with worse executive function, evidenced by more errors on the Cogstate set-shifting task.
Conclusion: Recognized concussions are associated with executive dysfunction in adult amateur soccer players. Future studies would benefit from investigation of the underlying pathologic mechanisms that subserve cognitive dysfunction.

Title: Unsupervised diffusion component analysis in post-traumatic epilepsy

Authors: *D. DUNCAN[1], P. VESPA[3], A. W. TOGA[2];
[1]Neuroimaging and Informatics, [2]USC, Los Angeles, CA; [3]UCLA, Los Angeles, CA

Abstract: Introduction: Epileptogenesis is common after traumatic brain injury (TBI), and because much is known about the physical history of post-traumatic epilepsy (PTE), it represents a near-ideal human model in which to study the process of developing seizures. The latency period between the injury and the development of seizures is usually short, with a median latency of one year, making it practical to study epileptogenesis with reasonable follow up periods.
Methods: Using scalp EEG recordings for 29 patients as well as depth EEG recordings for 6 of those patients, the goal of our analysis is to find a way to quantitatively detect seizure onset post trauma. A novel approach based on the diffusion map framework, which is considered to be one of the leading manifold learning methods, is proposed. Diffusion mapping provides dimensionality reduction of the data as well as pattern recognition that can be used to distinguish different states of the patient, such as seizures and non-seizure spikes in the EEG. A new algorithm, Unsupervised Diffusion Component Analysis is developed to construct coordinates that generate efficient geometric representations of the complex structures in the data. The algorithm is an adaptation of diffusion maps and is combined with principal components analysis and other techniques. The extensions lead to efficiency in use, in terms of reduced computational complexity, which have the potential to become useful techniques for practitioners in the field. Furthermore, the algorithm is completely automatic and unsupervised, which could potentially be a useful tool for doctors to identify early features of epileptogenesis after trauma. This method is also adapted to the data to enable the extraction of the underlying brain activity.
Results: Some new, interesting and promising results indicating how the proposed algorithm is used to detect spikes in the EEG data as well as other changes over time is shown.
Discussion: This nonlinear and local network approach has been used to determine if the early occurrences of specific electrical features of epileptogenesis, such as interictal epileptiform activity and morphologic changes in spikes and seizures, during the initial week after TBI predicts the development of PTE.

Title: How do the dynamics of functional brain connectivity change during recovery from traumatic brain injury?

Authors: *J. S. CRONE[1], P. M. VESPA[2], E. E. LUTKENHOFF[2], M. M. MONTI[2];
[1]UCLA, Los Angeles, ; [2]UCLA, Los Angeles, CA

Abstract: After severe injury, the brain reorganizes itself recovering gradually from coma. However, some patients remain in a state of wakefulness without or with only minimal awareness. Studying these patients is essential not only for research of consciousness but also for clinical purposes. Despite extensive work, the mechanisms underlying recovery are not well understood.

To address these problems, previous research in patients has focused on the identification of biological markers for impaired consciousness. However, findings remain divergent in respect to effects on global information integration and specific regions involved. This may partly be due to the fact that these studies were only performed in chronic patients. However, the complex dynamic process of traumatic brain injury and recovery of consciousness is most likely taking place in the first days to weeks. Thus, it is essential to investigate dynamics at an acute stage of injury.

Resting-state functional connectivity of 12 acute patients with severe brain injury were investigated at 2 time points during the acute stage (days after the incidence) and during the chronic stage (6 months after). Spatial group ICA was performed with 100 components to define the nodes of the graphs. For the dynamic connectivity analysis, we used a sliding time-window approach. For each time-window, we obtained a 48 × 48 nodes correlation matrix and calculated connectivity strength. To identify the underlying connectivity states, we implemented the approach by Yu et al. (2015, Neuroimage 107, 345-355) based on the modularity of the correlated nodal connectivity strength. Patients were divided in 2 groups; 7 patients being in a state of unconsciousness at the first assessment and 5 patients being in a state of (minimal) consciousness. Variance in connectivity strength and number of states were compared between groups and within patients.

The results show that there is a significant difference of variance in connectivity strength across time between the acute and the chronic stage (see Fig. 1). Interestingly, the variance at the

chronic stage was much higher for those patients who transitioned from unconsciousness at the initial assessment to a state of consciousness compared to those who were already conscious (see Fig. 2). When comparing the number of brain states, only chronic patients who have been conscious from the initial assessment on and show a higher level of cognitive recovery have a higher number of states (see Fig. 3). This indicates that in severe brain injury a flexible repertoire of functional configurations (brain states) is rather a marker of higher level cognitive functioning than of consciousness per se.

Title: Evaluation of a wearable head-up display assisted spine instrumentation system.

Authors: *R. CHEN[1], P. K. HAN[1], P. SI[1], W. D. FREEMAN[2], S. M. PIRRIS[2,3], J. W. YOON[2]; [1]Georgia Inst. of Technol., Atlanta, GA; [2]Mayo Clin., Jacksonville, FL; [3]St Vincent's Spine and Brain Inst., Jacksonville, FL

Abstract: Objective: The primary aim of this study was to determine the safety and feasibility of capturing and streaming neuronavigation images onto a head-up display during spine instrumentation. **Methods:** Using a novel device, neuronavigation images were captured and transferred wirelessly via a password-encrypted network to the head-up display. Medical images from the StealthStation device are captured by a medical imaging capture and stream system, which processes and streams the image onto the head-up display via an encrypted wireless channel (Figure 1). This setup allows physicians to place pedicle screws without having to shift attention away from the patient (Figure 2). Two surgeons used the device intra-operatively in ten patients undergoing spine instrumentation. The surgeons conducted the operations both with and without the head-up display, and screw placement times were recorded. At the end of the procedure, the surgeons completed a survey to gather their opinion of the system. **Results:** 40 pedicle screws were placed using a head-up display. The average screw placement time was shorter when a head-up display was used (4.13 minutes with vs. 4.86 minutes without). The postprocedure survey demonstrated that the surgeons had an overall positive experience using a head-up display. **Conclusion:** A wearable head-up display can benefit current neuronavigation

systems, but larger, outcomes-based trials are needed. An enlarged display and higher processing speed may significantly improve this technology.

Title: A quantitative motor assessment with normative data for traumatic brain injury

Authors: *P. K. JOHNSON[1], C. J. KINCAID[2], S. D. GRIMSHAW[3], E. D. BIGLER[4], S. K. CHARLES[2];
[1]Physiol. and Developmental Biol., [2]Mechanical Engin., [3]Statistics, [4]Psychology, Brigham Young Univ., Provo, UT

Abstract: Conventional exams to assess motor deficits following a traumatic brain injury (TBI) often rely on subjective observations of the clinician conducting the assessment and tend to fail to detect subtle underlying damage in the brain. Motion capture devices developed primarily for gaming make it possible to record finger and hand movements with great speed and accuracy. We leveraged this technology to create a Quantitative Motor Assessment (QMA) to evaluate movement following a TBI and establish a database of normative measures. Our QMA consists of customized software integrated with a portable, inexpensive motion capture sensor, and five movement tests adapted from conventional tests. The tests include measures of balance, efficiency and regularity of finger oscillation (FO), visually guided movement (VGM), kinetic and postural tremor, and reaction time. We administered the QMA to 104 (53 male and 51 female) healthy individuals, 18-50 years old. In addition, we included grip strength, visuomotor integration, and Halstead-Reitan Finger Tapping Test (FTT) for reference. We converted the

captured raw data to meaningful measures on which we conducted a statistical analysis and established a normative database of unimpaired motor behavior. The normative data were generally stereotyped with the following expected differences. We found differences in the number of taps between men and women on the FO test ($p=.007$) and differences in dysmetria between the dominant and non-dominant hands on the VGM test ($p<.001$). On the balance tests, there were differences between Eyes Open vs. Eyes Closed conditions on both Hard Surface ($p<.001$) and Soft Surface ($p<.001$). There was a high correlation between the amplitude and frequency of FO (right $r = .69$ and left $r = .63$), as well as a negative correlation between the mean number of FO and the frequency of FO ($r = -.72$). In addition to these expected differences, we were surprised to find no correlation (right $r=.23$ and left $r=.36$) between the QMA FO and the traditional FTT, which we interpreted to indicate that the QMA test measures a different attribute than the FTT. Current research focuses on administering this QMA to a TBI population and also acquiring MRI brain scans in order to compare their results to the normative data, and to correlate their QMA abnormalities to abnormalities seen on their scans. We expect that the sensitivity, objectivity, low cost, portability, and ease of use will make the QMA a beneficial and accessible tool to clinicians as well as researchers.

Title: Estimation of single subject fMRI reproducibility

Authors: *J. M. JANSMA[1], G.-J. RUTTEN[2];
[1]Elisabeth Hosp., Tilburg, Netherlands; [2]Dept. of Neurosurg., Elisabeth Tweesteden Hosp., Tilburg, Netherlands

Abstract: Introduction. There is an increasing demand for clinical use of fMRI, for instance to aid surgical planning. For these applications, it is important to know the single subject fMRI reproducibility. Although many statistical packages can produce single subject statistical maps, that maps do *not* contain information about reproducibility, but about the chance that there was

activation at the time of the scanning session. Additionally, pattern reproducibility may be more relevant for clinical applications than single voxel value reproducibility. In this study, we estimated the effect of scantime, voxel resolution as well as the size of the examined region on pattern reproducibility in two subjects, scanned three and four times with a commonly used clinical fMRI paradigm. Method. Both subjects performed a verb generation task in a block design with seven 30s task blocks alternated with eight 30s rest periods (3T Philips scanner). A GLM was performed to calculate beta values per voxel (for 2, 3, 4, 5, 6 and 7 blocks), at unsmoothed 4 mm as well as a transformed 16 mm resolution. Activation maps were correlated voxel by voxel for each subject, resulting in six values for subject 1 and three for subject 2, per condition. Values were averaged per subject. Results. Whole brain pattern reproducibility appeared to be relatively high for all conditions in both subjects (subject1: 10.45- 0.59; subject 2: 0.47 - 0.84). Effect of scantime was substantial in both subjects (see figure 1a, b). Effect of resolution was also substantial in one subject, but almost non-existent in the other subject (see figure 1a, b). Limiting the region to left Broca did not reduce reproducibility (4mm resolution; subject 1: 0.60 - 0.81; subject 2: 0.78 - 0.84, see figure 1c). Discussion. Our results shows that within subject pattern reproducibility is at a level that appears to be sufficient to produce information that can be used for clinical applications, even in small regions, at a relative high unsmoothed resolution, and for short scantimes. These results are promising for clinical applications of fMRI such as surgical planning.

Title: Disrupted gamma synchrony after mild traumatic brain injury and its link with cerebellar white matter damage

Authors: *C. WANG[1], M. E. COSTANZO[2], D. KEYSER[3], K. BASHIRELAHI[1], D. DARMON[1], D. L. PHAM[5], M. J. ROY[4], P. RAPP[3];

Abstract: Mild traumatic brain injury (mTBI) has been associated with disrupted structural connectivity due to induced white matter damage and degeneration. However, little is known about how the breakdown of white matter integrity alters functional neuronal connectivity in the brain after mTBI. To investigate this question, we recorded resting state EEG and diffusion tensor imaging (DTI) from a cohort of military service members recently returned from deployment to Iraq or Afghanistan. A newly developed neural synchronization measure, namely, weighted phase lag index (wPLI), was computed from EEG data and the fractional anisotropy (FA), a measure of white matter integrity, was computed from DTI data. Fifteen service members with a history of mTBI (< 3 years) were compared to twenty-two demographically similar controls who reported no history of head injury. In the EEG analysis we observed that phase synchrony at low-gamma frequency band (25-40 Hz) across scalp regions was significantly decreased in mTBI cases compared with controls. In the DTI analysis we observed that the FA of the inferior cerebellar peduncle was significantly lower in mTBI cases compared with controls. More importantly, we found that these two impaired measurements were significantly correlated across subjects in the mTBI group: lower FA of the inferior cerebellar peduncle was associated with lower phase synchrony at low-gamma frequency. These findings suggest that disrupted synchronization of low-gamma activity across cortical areas is likely to be a characteristic functional pathology after mTBI, and its underlying cause may be the breakdown of cortical-cerebellar circuits due to diffuse axonal injury.

Title: Neurocognitive and symptom recovery from sport-related mild traumatic brain injury (mtbi)

Authors: E. ABBASSI[1], H. BRASSEL[1], *A. P. SALVATORE[2];
[1]Rehabil. Sci., Univ. of Texas at El Paso, El Paso, TX; [2]U. of Texas At El Paso, Santa Teresa, NM

Abstract: Introduction: Medical reports suggest sport-related MTBI may result in permanent cognitive and neurological impairments. Frequency of MTBI and a concern about its long-term effects have caused legislative organizations to call for MTBI management programs. The clinical focus is to prevent premature return to play reducing an athlete's risk of receiving another injury. Studies in this field are not consistent regarding recovery duration of MTBI. Some studies show a short recovery time (a few days) whereas others suggest recovery time extends beyond one week of the injury. The main purpose of the present study was to further investigate the recovery duration in MTBI young athletes. **Method:** A computerized neurocognitive test, Immediate Post-concussion Assessment and Cognitive Testing (ImPACT™), was administered to 38 athletes. A pre-injury baseline assessment was conducted and when the athlete sustained an MTBI, post-injury assessments were repeated so that results could be compared. The neurocognitive testing included four composite scores of verbal memory, visual memory, speed of processing, and reaction time. A self-reported list of 22 MTBI symptoms (e.g., headache, nausea, fatigue, sensitivity to noise) captured a total symptom score. The four composite scores and the total symptom score were dependent variables. **Results:** Participants were 17.08 years old (SD = 3.0). The mean time from injury to first, second, and third assessment post-injury was 5, 11, and 18 days, respectively. Repeated-measures ANOVAs were used to determine if mean scores for each of the abovementioned cognitive functions and symptoms differed across the four assessments. Results showed significantly lower scores for all the cognitive functions at the first assessment compared to baseline (all ps < .01); however, scores of the second and third assessments were not significantly different from those of the baseline (all ps > .05). For symptom scores, there was a significantly greater (worse) symptom score at the first assessment compared to baseline (p < .000); difference between symptom scores of the second assessment and baseline was still significant (p = .024), but not symptom scores of the third assessment and baseline (p = .89). **Conclusion:** The present study suggests recovery is

not complete during the first 5 days post-injury. Recovery duration for MTBI symptoms seems to be even longer and extends to the second-week post-injury. MTBI athletes may not recognize the potential risk of MTBI and tend to return to play immediately. However, professionals involved in MTBI management programs should warn athletes against negative consequences of returning to play soon after an injury.

Title: pyMIND: Open-source, python-based multimodal integrated neural data acquisition for conducting basic science research in neurointensive care units

Authors: *U. AGRAWAL[1,2], A. C. OYALOWO[1,2,4], A. PILLING[3], S. LEE[1,2], W. F. ASAAD[1,5,6,7,2];
[1]Dept. of Neurosci., [2]Brown Inst. for Brain Sci., [3]Alpert Med. Sch., Brown Univ., Providence, RI; [4]Grad. Partnership Program, NIH, Bethesda, MD; [5]Dept. of Neurosurg., Alpert Med. Sch., Providence, RI; [6]Norman Prince Neurosciences Inst., [7]Dept. of Neurosurg., Rhode Island Hosp., Providence, RI

Abstract: Neurointensive care units (NICUs) are responsible for alleviating suffering due to primary brain injury as well as predicting and preventing the onset of secondary brain injury. Patients are continuously monitored, and volumes of physiological data are collected—sometimes in a manner that could rarely be recorded in any other context outside of the NICU (e.g. direct measurements of intracranial pressure via intraventricular catheter). Such access presents a unique opportunity for investigating basic science questions about cerebral physiology following injury that may help to improve the quality of care. However, relatively few patients in NICUs undergo any form of continuous brain monitoring. Furthermore, although vitals data is collected continuously, it is discarded, observed intermittently, or presented independently on paper charts that do not represent how the data streams could be related. To address these

problems, we created pyMIND to integrate the vitals routinely collected in the NICU with electroencephalography (EEG) and near-infrared spectroscopy (NIRS). Specifically, pyMIND is an open-source, Python-based interface that establishes a connection to the existing proprietary medical telemetry devices in NICUs, saves the data in a standardized HDF5 format, and visualizes the data in realtime using Vispy, the open-source, interactive 2D/3D data-visualization Python library. By conducting both hypothesis-driven and machine learning-based analyses, we aim to identify biomarkers that predict adverse events such as seizure or vasospasm. pyMIND is being applied to patients with severe traumatic brain injury and spontaneous subarachnoid hemorrhage. Specifically, we plan to explore how the correlation of primary vitals, decreases in regional oxygen saturation (as recorded by NIRS), and prolonged decreases in spectral power of neural activity (as recorded by EEG) correspond to the event of a delayed cerebral ischemia. Ultimately, pyMIND is a potential tool for conducting basic science research in the NICU and improving patient care in the future.

Title: Pain susceptibility after trauma: physical, psychological or premorbid

Authors: *I. STRIGO[1,2], A. SPADONI[3,4], S. INSLICHT[2], A. SIMMONS[4];
[1]Psychiatry, UC San Francisco, San Francisco, CA; [2]SFVAMC, San Francisco, CA; [3]Psychiatry, US San Diego, La Jolla, CA; [4]SDVAHS, San Diego, CA

Abstract: Background: Combat trauma often results in mild traumatic brain injury(MTBI) and posttraumatic stress disorder(PTSD), both of which dramatically increase vulnerability for chronic pain. We have shown that women with PTSD show dysregulated functional brain activity during experimental pain processing that was related to their level of avoidant symptoms. The aim of this study was to better understand the mechanisms of pain processing in men who sustained MTBI during combat.

Methods: 70 males performed validated experimental pain paradigm administered in two sequential runs during fMRI. 46/70 reported history of MTBI and 26/46 also met criteria for PTSD. Change in brain activity and connectivity to repeated application of painful temperature was examined with the linear mixed effects model with group (Controls(n=24), MTBI(n=20), PTSD(n=26)) and administration (run1, run2), entered as fixed factors, subjects entered as a random factor and depression severity (BDI2) entered as covariates.
Results: Significant group by administration interaction to repeated application of thermal pain was observed within right anterior insula(RAI) where both PTSD and MTBI groups showed decreased activation, while controls participants showed increased activation between administrations. Importantly, change in RAI activation across administrations was significantly and inversely correlated to avoidance symptoms only in those with combat-related PTSD. Furthermore, whereas in the PTSD group overall decoupling between RAI and rostral anterior cingulate predicted insula attenuation overtime, increased fronto-insula coupling overtime predicted insula attenuation in the non-PTSD participants, i.e. MTBI and control groups.
Conclusions: The current study provides evidence for the hypothesis that combat trauma interferes with normal processing of acute pain whereby repeated exposure to even brief painful stimuli results in attenuation of insula activation over time. Furthermore, in those with PTSD, anterior insula shows greatest attenuation in those with the highest level of avoidance. These findings enhance our prior work in which we showed that brain injury without significant psychological symptoms disrupts endogenous pain modulation, suggesting dual dysfunction in pain processing and pain modulatory systems in those suffering from co-morbid MTBI and PTSD. Most strikingly, we found that the degree of childhood trauma, the degree of combat exposure and the severity of brain injury were comparable between the two trauma groups potentially pointing to preexisting pain and PTSD vulnerability mediated by weakened core-control circuits.

Title: Magnetoencephalography shows hemisphere compensation in a case of penetrating head injury caused by a metal rod

Authors: *G. RABELLO[1], K. WALTON[1], R. ROZENTAL[2,3], R. M. C. DA SILVA FILHO[4], R. LLINÁS[1];
[1]Ctr. for Neuromagnetism, New York Univ. Sch. of Med., New York, NY; [2]CDTS/FIOCRUZ, Rio de Janeiro, Brazil; [3]Inst. de Ciencias Biomedicas, Univ. Federal do Rio de Janeiro, Rio de Janeiro, Brazil; [4]Service of Neurosurg., Hosp. Municipal Miguel Couto, Rio de Janeiro, Brazil

Abstract: In August 2012, a 24-year-old construction worker suffered an accident wherein a two meter long, over one inch diameter metal rod penetrated his head through the right frontal hemisphere. A rescue team was called, the patient was transported to the hospital, and a craniotomy was implemented to remove the rod. The patient remained conscious, alert and oriented throughout. The rod was successfully removed leaving a cavity predominantly in the middle frontal gyrus. MRI imaging following the incident showed that 11% of the right hemisphere brain mass was lost in the accident. A later MRI, 6 months after the incident, also noted that the anterior thickness corpus callosum was clearly reduced. The patient was put on anticonvulsant drugs, and the only consequences of the accident were two isolated seizures. No personality, social or behavioral change were noted.
Methods: The patient came to the NYU Center for Neuromagnetism and a set of MEG recordings were performed over three days using a 275-channel (CTF) instrument. Several recordings were made. Here we report the results of one that compared left vs. right movement planning, coordination, and execution. This was included since the injury was close to the dorsolateral prefrontal associative cortex and to the premotor cortex. Finger-Thumb tests, in which he sequentially touched each finger of one hand to the thumb, in random order were implemented. Both hands were tested. (100 sets were carried out; 50 with each hand.)
Preliminary results: No mistakes were made. The patient performed the test with the correct hand every time. Low frequency abnormal brain activity was clearly present near the site of the injury. When the right hand was used, an increase in the abnormal activity in the right side was found. When the task was performed with the left hand, abnormal activity on the site of the injury (right) decreased.
Discussion: These findings indicate the presence of functional compensation for the right hemisphere injury. It was noted that when the left hemisphere was engaged in right hand movement, compensation was lost or reduced and abnormal activity was increased. Contrarily, when sites near the injured area (right side) were engaged in left finger movement, less abnormal activity was recorded. This suggests that inter-hemisphere compensation played a fundamental role in the absence of overt movement deficits after injury.

Abstract: Management of PTSD is complicated by the overlapping symptoms of its comorbidities and a diagnosis that relies on self-reporting and a time-consuming psychological evaluation. A strategy of developing unbiased biomarkers for next-generation diagnostics is therefore essential. Herein, we present molecular candidates with potential to be translated into diagnostic applications. The neurodevelopment of PTSD risk has long been explored. Emerging knowledge suggests a significant role of epigenetic plasticity in the development of PTSD pathomechanisms. In this context, we first investigated the expression of targeted proteins, and then we determined the differential methylation of the corresponding genes. A candidate biomarker panel was evaluated by investigating training and test cohorts of PTSD screened from US Operation Iraqi Freedom (OIF) and Operation Enduring Freedom (OEF) veterans. In the training set (to discover potentially predictive relationships), 52 PTSD-positive male veterans of OIF/OEF were matched to 52 controls by age and ethnicity. The independent test set (to assess the strength and utility of the predictive relationship) consisted of age/ethnicity-matched 32 PTSD-positive and 32 PTSD-negative veterans. Veterans with a CAPS score above 40 were identified as PTSD-positive, while those with a score less than 10 were determined to be controls. A 50+ protein panel associated with neurodegeneration was probed with the plasma samples collected from the veterans. Using corrected t-score (cut off 0.05), proteins with significantly altered expression were identified and subsequently validated using the 32/32 test cohort. There were seven proteins which showed similar trends in both test and training sets, and they were duly selected for inclusion in the final panel. In parallel, DNA extracted from the whole blood of the training cohort was bisulfite-converted and probed using a whole genome

methylation array. The differentially methylated probes were annotated to the genes corresponding to the proteins of interest. Targeted bisulfite sequencing validated these preselected regions in both of the test and training sets. Linked with three proteins of interest were three probes (CpG islands) showing differential methylation. PTSD is a multifactorial illness manifested by a number of behavioral and organismal deficiencies. It is essential to develop a multi-omics panel to capture the wide complexity of this illness. Hence, we present a panel of candidate markers consisting of seven proteins. A subset of this panel has additional epigenetic footprints. A more comprehensive investigation with multiple independent cohorts is necessary.

Abstract: Psychological and physical trauma can result in clinical conditions with overlapping symptomology - this makes a differential diagnosis of posttraumatic stress disorder (PTSD) or mild traumatic brain injury (mTBI) difficult. Functional MRI has revealed that PTSD and mTBI might be related to aberrant local patterns of activity, as well as perturbed functional connectivity - i.e. the communication *between* regions - and that this subserves emergent psychological sequelae. Despite this, how trauma impacts *neurophysiological* (as opposed to haemodynamic) mechanisms is unknown, although data suggest trauma alters brain spectral profiles and network topology. Using resting-state magnetoencephalography (MEG), we have shown that electrophysiological coupling between areas in trauma differs in important ways. We compared two clinical groups against two groups of matched controls - soldiers from the Canadian Armed

Forces with combat-related PTSD were contrasted with a combat-exposed, non-PTSD control group of soldiers; and a group of civilians with mTBI were compared to a group of healthy controls. All groups underwent 5 minutes of resting-state acquisition in a 151-channel MEG (CTF Systems). Implementing an atlas-guided 'beamforming' approach, reconstructed time-series from 90 ROIs in cortical and subcortical regions were used to compute resting functional connectivity based on two methods; phase synchrony, defined by the weighted Phase Lag Index (wPLI), and amplitude envelope correlations. Connectivity maps from clinical groups were then contrasted with their respective control groups using the Network-Based Statistic. Elevated connectivity was observed in both trauma groups within and between a number of key regions, particularly those implicated in attention and memory. Most importantly perhaps, these groups were distinguished from each other by the *mechanism* of communication. The PTSD group exhibited fast-wave (high-gamma) phase synchronisation, and the mTBI group were found to differ from controls in low-frequency (delta-through-alpha) amplitude envelope coupling. Hypotheses regarding the mechanistic role of spectrally-mediated, inter-areal communication have posited very distinct functional roles for these oscillatory interactions. They appear to be critical in the dynamic reconfiguration of networks, supporting the integration and segregation of modular brain regions; with efficient interregional communication disturbed in trauma, these perturbations have the potential to describe the clinical symptoms observed in patients and offer accurate discrimination of such conditions.

Title: Combining diffusion tensor imaging and robotics to assess structural changes and sensorimotor recovery following sport-related concussion

Authors: *A. CHAMPAGNE[1], N. COVERDALE[2], H. BRETZKE[2], C. MARK[2], J. NASHED[2], S. SCOTT[2], D. COOK[2];
[1]Ctr. For Neurosci. Studies - Cook Lab., [2]Queen's Univ., Kingston, ON, Canada

Abstract: Following a concussion, or mild traumatic brain injury (mTBI), individuals experience a broad range of cognitive and motor deficits in the acute post-injury period.

Evidence-based return-to-play guidelines are subjective in nature due to our current inability to properly monitor structural and functional recovery of the injured athlete. A quantitative understanding of the relationship between brain injury and motor deficits could provide objective guidelines for the clinical management of mTBIs. The purpose of this pilot project was to determine whether diffusion tensor imaging (DTI) and robotics could be used to quantify recovery patterns following sport-related concussion.To investigate the structural and behavioral changes following mTBI, we collected imaging and sensorimotor data (using the KINARM^{TM} robot) at two time points (<14 days and 3 months), post-injury. Four injured varsity athletes (20.5±0.6 years, 3M) were recruited following mTBI, while ten non-injured athletes (19.9±2.0 years, 5M) served as controls. To determine structural changes in white matter (WM), we performed a region-of-interest analysis in ten bilateral tracts defined using the John Hopkins University DTI-based WM tractography atlas. The mean fractional anisotropy (FA) for each tract was compared between the acute (<14 days) and follow-up (3 months) time points using a paired t-test. The behavioral changes were examined by selecting parameters from the sensorimotor tasks where the injured groups fell outside of the normative range (5 to 95%). These parameters included the task score and median error score from the Object Hit and Avoid task, which recruits higher executive functions such as attention, rapid motor selection and inhibition. Parameter scores were averaged among the groups and compared to the controls to look for signs of recovery. The imaging results showed a significant increase in FA ($p=0.0035$) within the superior longitudinal fasciculus (SLF) of the acute group when compared to the 3 months follow up. Additionally, the task and median error scores showed improvements at 3 months post-injury as they both closely approached the averaged scores from the controls. After 3 months, injured subjects hence performed better and made fewer errors in the first half of the task compared to when they were initially tested after sustaining a concussion. Although preliminary, these results suggest possible associations between WM changes and deficits in visuospatial processing after mTBI, followed by recovery. This provides exciting potential for the combined use of neuroimaging and cutting-edge robotics to assess recovery after concussion.

Title: Striatal dopamine transporter regulation in obesity

Authors: ***C. WU**[1], S. P. GARAMSZEGI[2], X. XIE[2], D. MASH[2];
[1]Pharmacology, Miller Sch. of Med., [2]Neurol., Univ. of Miami, Miami, FL

Abstract: Obesity is associated with excessive overeating and preference for palatable, high-fat foods. Increased sensitivity to palatable-food reward drives overeating when accompanied by insufficient inhibitory control. High caloric food and addictive drugs increase dopamine release in brain reward circuits, which mediate their reinforcing effects. The dopamine transporter (DAT) plays a central role in regulating dopamine reward in mesolimbic and nigrostriatal pathways. Studies in rodents demonstrate decreased cell-surface DAT expression in the nucleus accumbens (NAc) and dorsal striatum induced by high-fat diet. We report here quantitative measures of DAT mRNA expression in the substantia nigra (SN) (n=40) and protein in the ventral striatum (n=40) from postmortem human brain sampled from normal weight and obese subjects over a range of body mass indices. Radioligand binding assays using (^{3}H)WIN35,428 demonstrated that DAT binding sites are negatively correlated with BMI in the ventral striatum ($r= -0.47$; $p<0.01$). Dopamine transporter gene expression was significantly decreased in the substantia nigra of obese subjects ($p<0.001$). Dopamine reward deficiency has been suggested to contribute to compensatory overeating of carbohydrates leading to human obesity. Primary food-reward is mediated by dopamine release in the striatum and deficient nucleus accumbens dopamine function contributes to primary food reward and obesity. A shift in the underlying dopaminergic control from ventral to dorsal striatum coincides with the development of habitual behaviors. Our results confirm that human striatal dopamine function is decreased in obesity, which may underlie the compulsive food intake associated with development of habitual overeating. Title: Physiological consequences of mild traumatic brain injury in individuals with acute and chronic symptoms

Authors: A. L. YASEN[1], E. K. EDWARDS[1], M. M. LIM[2,3], K. B. WEYMANN[2,3], *A. D. CHRISTIE[1];
[1]Univ. of Oregon, Eugene, OR; [2]VA Portland Hlth. Care Syst., Portland, OR; [3]Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Chronic symptoms of mild traumatic brain injury (mTBI) are experienced by more than 5 million Americans, yet little is known about the underlying physiology. Although alterations in motor cortex function have been shown acutely following mTBI, such findings have not been extended to individuals with chronic symptoms. The purpose of this study was to examine motor cortex excitability, inhibition, and the associated neurotransmitter concentrations in individuals with acute and chronic symptoms following mTBI. Participants included 7 individuals within 72 hours of an mTBI (21.1±2.4 years; acute), 5 individuals with symptoms lasting more than 3 months (31.0±12.1; chronic) and 12 uninjured individuals (20.9±0.9; control). First, transcranial magnetic stimulation was used to assess intracortical inhibition, via cortical silent period (CSP) duration, and corticospinal excitability, via resting motor threshold (RMT) and motor evoked potential amplitude (MEP). There were no differences across groups in RMT (p=0.13) or CSP duration (p=0.20). However, MEP amplitude was significantly higher in individuals with chronic symptoms compared with controls (p=0.02), and tended to be higher in acutely-injured individuals than controls (p=0.07). Next, concentrations of the excitatory and inhibitory neurotransmitters glutamate and GABA, respectively, were assessed in the primary motor cortex using ^{1}H magnetic resonance spectroscopy (MRS). Both glutamate and GABA concentrations were lower in acutely-injured individuals compared with controls ($p\leq0.001$), and lower in individuals with chronic symptoms than either controls ($p\leq0.001$) or acutely-injured ($p\leq0.05$) individuals. The excitatory-to-inhibitory ratio (EIR) was calculated for MRS measures using the ratio of glutamate:GABA. The EIR was higher in both injured groups compared with controls ($p\leq0.001$), but was not different between the acute and chronic groups (p=0.30). These results suggest a possible imbalance between excitatory and inhibitory neurotransmitters following mTBI, which manifests functionally as a higher net excitability of the motor cortex. Importantly, these physiological consequences appear to be similar in acutely-injured individuals and those suffering from chronic symptoms.

Title: Pain-related white matter tract deficit in patients with mtbi related persistent headache

Authors: *M. LIM[1], A. KHALAF[1], Z. YANG[1], V. METZGER-SMITH[1], J. CORDERO[1], Y. HE[1], S. SHUKLA[2], L. LIN[1], D. SONG[1], R. LEE[1], G. POLSTON[1], A. TSAI[2], A. LEUNG[2]; [1]UCSD, LA Jolla, CA; [2]VA San Diego Healthcare Syst., La Jolla, CA

Abstract: Introduction: Persistent headache is one of the most prevalent debilitating conditions in patients with mild traumatic brain injury (MTBI). Previous functional imaging studies suggest patients with MTBI suffer from a state of diffuse axonal injury and diminished prefrontal cortical modulation in pain perception [1]. However, the correlation between the structural deficit and impaired pain modulatory function in this patient population is largely unknown. The current study compares the difference in white matter tract fractional anisotropy (FA) between patients with MTBI related headache and healthy controls. **Method:** Diffusion Tensor imaging (DTI) data were acquired in a GE 1.5 T MRI scanner for ~10 minutes for each scan with the following imaging parameters: repetition time = 16.1 sec, TE = minimum, FOV=25.6 cm, 60 oblique slices AC/PC-aligned encompassing the whole brain, and voxel size =2x2x2 mm^3. 54 directions were collected with a b-value of 1000 s/mm^2, and 5 volumes with no-diffusion weighting. All individuals' FA maps were loaded into a non-paired 2-tail T-test to assess the statistical difference between the FA values of the two groups. The resulting significant ($P<0.01$) clusters (>50 voxel cluster threshold) were extracted and their anatomical locations were identified using Johns Hopkins University white matter tractography atlas and confirmed with DTI based white matter atlas provided by the FMRIB Oxford, UK. All analyses were performed in BrainVoyager (Maastricht, Netherland). **Result:** 12 MTBI patients (10 male) with an average age±SD of 35.0±8.0 years old and daily persistent headache intensity greater than 3 on 0-10 numerical rating scale, and an equal number of age and gender matched healthy controls completed the study. The MTBI showed a significant ($P<0.01$. cluster size=139) lower FA in the right anterior thalamic tract near right prefrontal cortex, and left superior longitudinal fasciculus near the left prefrontal cortex. **Conclusion:** The observed white matter tract deficits in regions linking prefrontal cortex and sensory discriminatory regions of pain perception among patients with MTBI are in line with the prefrontal pain modulatory functional deficits found in this patient population.

Title: Electrophysiological markers of variations in perceptual and cognitive processing in coma

Authors: *R. L. MAH, J. F. CONNOLLY, A. E. FOX-ROBICHAUD, C. HAMIELEC; McMaster Univ., Hamilton, ON, Canada

Abstract: Previous work over the last two decades has shown strong positive predictive power of the N1 and mismatch negativity (MMN) ERP components in comatose patients. Beginning with work from Kane et al. (1993, 1996) to studies from Fischer et al. (1999, 2004, 2006), Naccache et al. (2005), and Tzovara et al. (2013), the consensus appears to be that the presence of the N1 and MMN are good predictors of awakening from coma. A common thread with this prior work is the focus on single points in time. Kane et al. used the best response from multiple sessions collected across several days while the patient was still comatose. Fischer et al. and Naccache et al. used only one recording per patient, while Tzovara et al. used two sequential recordings. This approach has served the field well, however it does not offer the opportunity to examine whether variations occur in ERP components with repeated recordings occurring over a 48-hour period. The present study studied whether a waxing and waning of the N1 and MMN occurred in comatose patients who had suffered traumatic brain injuries. We recorded multiple sessions of an auditory oddball mismatch paradigm using tone-length deviants over a period of 48 hours to capture the modulation of the MMN as the patient's level of consciousness changes. Continuous EEG was recorded from 32 sites positioned according to the 10-20 standard. We present a case study of a 29-year old male involved in a motor vehicle collision. He presented with a right parietal subdural hematoma, acute traumatic subarachnoid hemorrhage and diffuse axonal injury, and scored 4/15 on the Glasgow Coma Scale at the initiation of data collection. In total, 17 blocks of data were acquired, each with approximately 30 minutes of active testing with an average inter-block interval of two hours. From these blocks, five showed typical N1 and MMN components, and an additional four blocks showed typical N1 components to the standard tone without the presence of the MMN. Blocks showing typical N1 and MMN activity in the patient were compared to data gathered from healthy controls—N1 and MMN amplitudes were reduced in the patient, however latency was unaffected. The patient had emerged from his coma at the one-month follow up. These data reveal two key points: Electrophysiological markers of early perceptual and pre-attentive processing are not merely observable in coma but appear to wax and wane across a relatively short period of time; and, use of these early responses as

prognostic indicators of the potential for emergence from coma may be less reliable than previously thought. It is possible that poor prognostics for some patients may be more to do with the transient state of the patient at the time of testing.

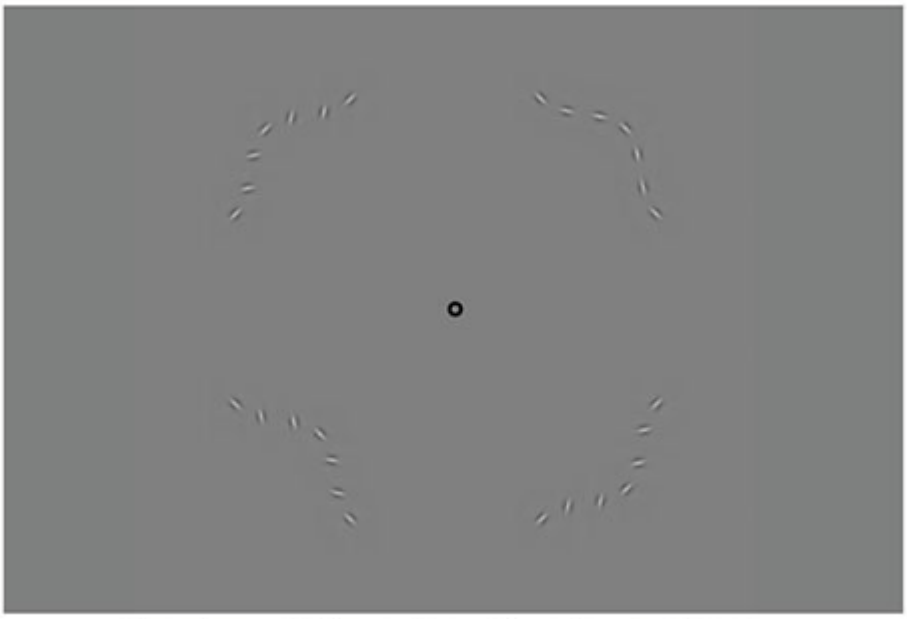
Title: Mild traumatic brain injury patients recruit compensatory mechanisms to integrate visual information

Authors: *T. RUIZ[1], D. SPIEGEL[2], A. BALDWIN[2], R. HESS[2], R. FARIVAR-MOHSENI[2]; [2]Ophthalmology, [1]McGill MUHC, Montreal, QC, Canada

Abstract: Visual disturbances following mild traumatic brain injury (mTBI) are putatively caused by diffuse axonal injury and/or neural loss. Loss of local axonal connectivity in a visual circuit such as V1 would have the anticipated effect of reducing lateral inhibition between columns of neurons representing different orientations at distinct visual field locations. This reduction could make it more difficult for the visual system to deal with a noisy visual image, for example, because local interactions could not disambiguate competing representations. Thus local disruptions of axons would be expected to increase processing errors—increase noise—for tasks requiring integration of orientation across space.Recovering from or compensating for higher internal noise could take one of two forms—either a direct mechanism restores the system to a lower noise level, or the system integrates over a larger range of cortical columns to minimize the influence of the noise. Our newly designed contour integration task specifically enables us to assess visual field defects in terms of internal noise and spatial integration (efficiency). Integration of the stimuli requires processing of the orientation of each Gabor patch in its visual field location, and integrating this information over the visual space occupied by the Gabors forming the contour. In a 4AFC paradigm, participants (mTBI n=50; control n=20) were asked to identify the contour with good continuity from three contours with added orientation noise, each presented in a different visual field quadrant. Curvature thresholds were determined by modulating the amplitude of the curve via a performance dependant staircase. A linear

amplifier model was fitted to estimate the amount of internal noise and spatial integration (efficiency).Results show that while mTBI patients do exhibit higher internal noise, they paradoxically also exhibit higher efficiency in integration. This suggests a simple compensatory mechanism—the integration over a larger amount of retinotopic cortex, in order to overcome the increase in internal noise.



The contours consist in seven Gabor patches resting on a cosine curve.

Here, the good continuation choice is located in the upper right quadrant.

Title: Alcohol dependence after blast versus non-blast TBI in an OEF/OIF veteran population

Authors: *B. ARYANFAR[1], K. PANIZZON[2,3], A. PAPAZYAN[2], C. SPINELLI[2], A. SHINDE[2,5], R. WALLIS[2,4];
[2]Neurol., [1]VA Greater Los Angeles Healthcare Syst., Los Angeles, CA; [4]Neurol., [3]David Geffen UCLA Sch. of Med., Los Angeles, CA; [5]Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: OBJECTIVE: To evaluate the prevalence of alcohol dependence in veterans of Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF). Who have had blast versus non-blast traumatic brain injury (TBI) BACKGROUND: One of the signature injuries for veterans deployed in the OEF and OIF conflicts is that of TBI, particularly blast TBI. In addition, alcohol dependence is a relatively frequent sequelae of TBI. METHODS: We conducted a pilot, retrospective chart review of patients with TBI seen at the Poly-Trauma Clinic of the VA Greater Los Angeles Healthcare System. We collected data regarding blast versus non-blast TBI in OEF/OIF veterans. In addition, we collected data regarding alcohol use, which was categorized as positive or negative using the AUDIT-C screen. RESULTS: A total of 737 charts were reviewed. Of these, 375 were identified as OEF/OIF subjects with a confirmed diagnosis of TBI. The racial/ethnicity background of these subjects was 42.9 % Caucasian, 10.9% African-American, 28.5% Hispanic, 4.3% Asian, and 13.4% Other. We found that a mean 64.8% ± 5.1 (n = 243) of subjects had suffered blast-TBI and 35.2% ± 3.6 (n = 132) had non-blast TBI. The mean age of subjects with blast TBI was 32.8 ± 1.2 years, while those with non-blast TBI was 34.4 ± 1.6 years. The prevalence of alcohol dependence following TBI was 27.7% ± 5.4 (n=104). Alcohol dependence was diagnosed in a mean of 25.9% ± 3.0 (n = 63) subjects with blast TBI, and 31.1% ± 3.6 (n = 41) in those with non-blast TBI. The mean AUDIT-C score for male subjects who were positive for alcohol dependence was 6.9 ± 0.5 with blast-TBI, while those for non-blast TBI was 7.5 ± 0.7. CONCLUSION: In this population of OEF/OIF veterans with TBI, alcohol dependence was reported relatively frequently following both blast and non-blast exposure.

Ctr., Los Angeles, CA; [7]Dept of Neurosurg. and Div. of Pediatric Neurol., UCLA Brain Injury Res. Ctr., Los Angeles, CA

Abstract: Following a moderate/severe traumatic brain injury (msTBI), many patients experience prolonged recoveries. Here we present longitudinal data from a pediatric msTBI cohort, showing that a functional neuroimaging biomarker at 2-5 months post-injury can predict longitudinal changes in white matter (WM) structural integrity. We studied 21 children (16M/5F) with msTBI, assessed 2-5 months post-injury and again 13-19 months post-injury, as well as 20 well-matched healthy control children. We assessed CC function through interhemispheric transfer time (IHTT), measured using event-related potentials (ERPs), and related this to diffusion weighted magnetic resonance imaging (dMRI) measures of WM microstructure. To assess white matter integrity, we used a method developed in our lab, autoMATE (automated multi-atlas tract extraction), to generate along-tract measures of fiber integrity from dMRI data. Half of the TBI patients had significantly slower IHTT at the first time-point (TBI-slow-IHTT, N=11), and half were in the normal range (TBI-normal-IHTT, N=10). These groups did not differ from each other in clinical or demographic variables. The TBI-normal-IHTT group did not differ significantly from healthy controls, either in WM integrity at either assessment or in the longitudinal trajectory of WM integrity between evaluations. In fact, they appear to show signs of recovery of WM integrity longitudinally. In contrast, the WM integrity of the TBI-slow-IHTT group was significantly lower than healthy controls across a large portion of the WM. Longitudinal analyses showed the TBI-slow-IHTT group experienced a progressive decline in WM integrity throughout the brain. We have discovered a biomarker that identifies a subset of

patients with impaired callosal integrity in the first months post-injury who experience widespread continuing and progressive degeneration in the first year post-injury.

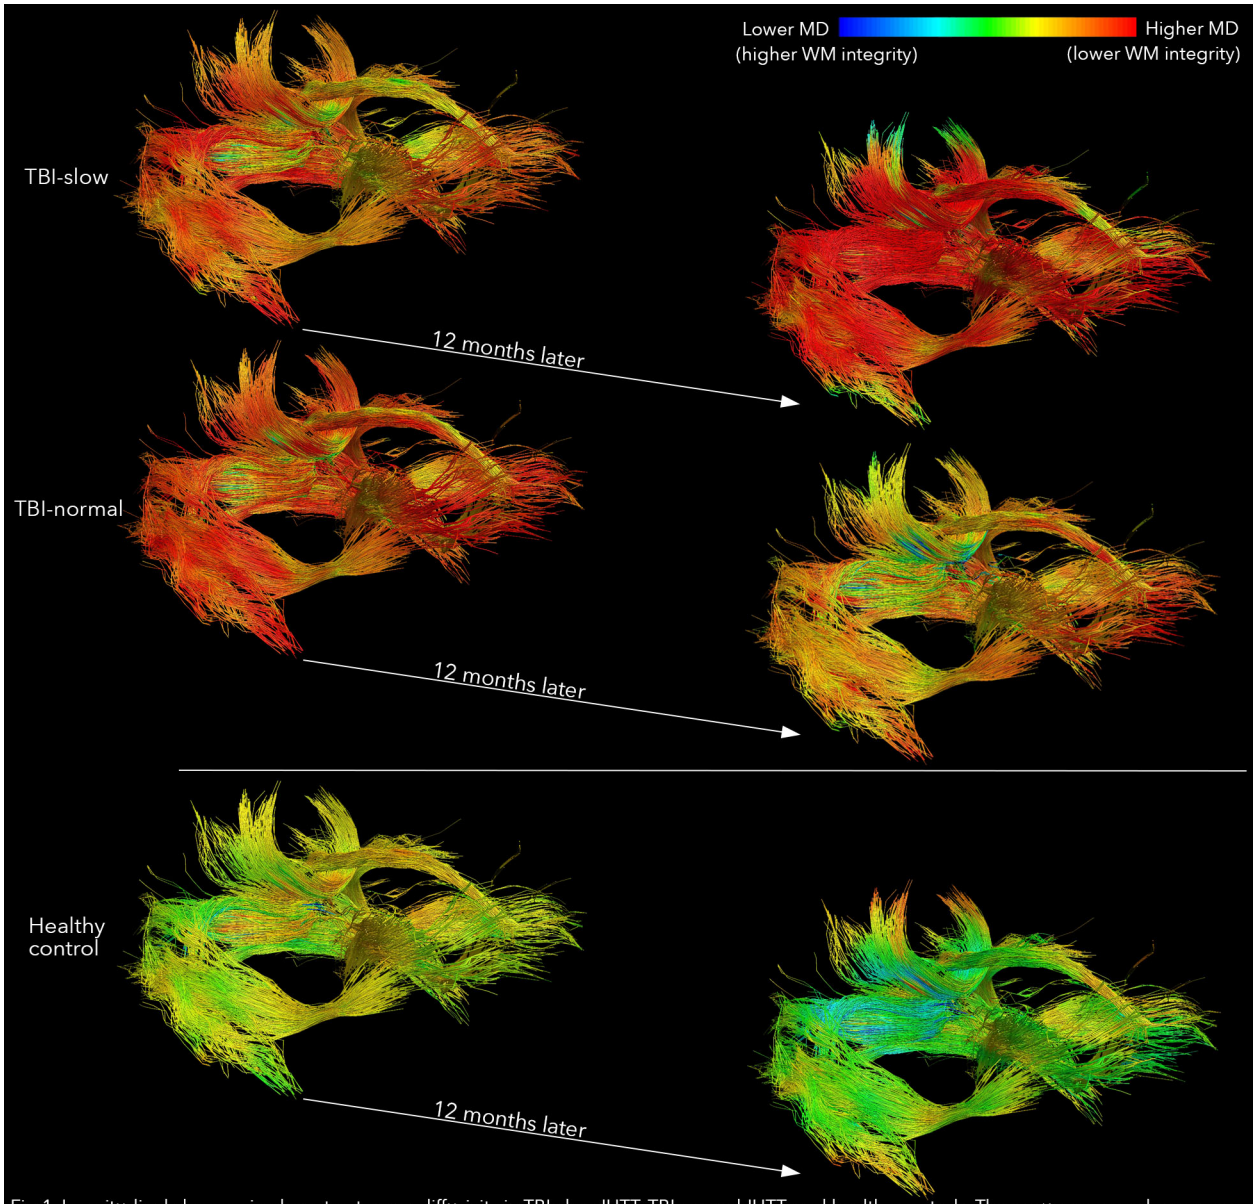

Fig 1. Longitudinal changes in along-tract mean diffusivity in TBI-slow-IHTT, TBI-normal-IHTT, and healthy controls. The group-averaged maps are shown for both time points, across TBI-slow-IHTT (N=11), TBI-normal-IHTT (N=10), and healthy controls (N=20). Approximately 12 months passed between the beginning and ending time point. As indicated in the legend, blue areas have the lowest mean diffusivity (MD) and therefore highest WM integrity, while red areas have the highest MD. The healthy controls show minimal decreases in MD. The TBI-slow-IHTT group shows widespread increases in MD. The TBI-normal-IHTT group shows a mixture.

Title: The relationship between overt responsiveness and white matter abnormalities in patients with disorders of consciousness

Authors: *C. A. STAFFORD[1], A. OWEN[1], D. FERNÁNDEZ-ESPEJO[1,2];
[1]Psychology, Univ. of Western Ontario, London, ON, Canada; [2]Psychology, Univ. of Birmingham, Birmingham, United Kingdom

Abstract: The differential diagnosis of disorders of consciousness (DOC) is made on the basis of bedside behavioural scales, such as the Coma Recovery Scale-Revised (CRS-R). The patient's ability to produce discernable behavioural indicators in response to various sensory stimuli determines whether the patient is diagnosed as in a vegetative state (VS) or a minimally conscious state (MCS). The VS is characterized by reflexive responses, while the MCS is characterized by intentional responses. Recent neuroimaging studies have emphasized the problems related to this reliance on external behaviour: if an aware patient was unable to produce overt responses due to a motor dysfunction, they would be misdiagnosed as VS. It has been proposed that damage to motor thalamo-cortical pathways could explain the lack of intentional motor responses after brain injury in an otherwise aware patient. We used diffusion tensor imaging to reconstruct and assess the structural integrity of thalamo-motor tracts in DOC patients and in healthy controls. Patients were grouped into one of two categories: responsive (MCS+ emerging from the MCS) or non-responsive (VS). These groups showed a significant difference in the structural integrity of the thalamo-motor tracts ($F(1,10)=7.086$, $p=.024$), as measured by mean fractional anisotropy (FA). Moreover, FA of these tracts correlated with the patients' CRS-R score ($rho=.847$, $p=.001$ and $rho=.712$, $p=.009$, for left and right respectively). Our results suggest that damage to motor fibres plays a role in the degree of external responsiveness exhibited by DOC patients. The associated reduction in the patients' overt motor performance could be masking their level of awareness, and thus interfering with diagnostic accuracy.

Title: Accumulated head trauma predicts longitudinal white matter diffusion alterations in college athletes

Authors: *A. R. ASTURIAS[1], M. CIESLAK[2], L. VOLZ[2], C. GREENE[2], J. D. RALSTON[3], S. T. GRAFTON[2];
[2]Dept. of Psychological and Brain Sciences, Inst. for Collaborative Biotechnologies, [1]Univ. of California Santa Barbara, Santa Barbara, CA; [3]X2 Biosystems, Redwood City, CA

Abstract: Measures of white matter diffusion that characterize myelin integrity have been shown to change in the event of repetitive subconcussive head impact exposures. However, it remains unclear how many head impact exposures, and at what severities, are required to induce either reversible or persistent changes in white matter that are reliably detectable by diffusion imaging. We hypothesized that changes in diffusion would be associated with a cumulative dose of head impacts. Wearable head impact monitors were used to quantify the number and intensity of head impacts accumulated by a group of college athletes throughout a soccer season. In parallel, serial diffusion spectrum (DSI) of white matter were acquired and used to calculate multidimensional anisotropy (MDA). 10 female soccer players were monitored for head impacts throughout a season of collegiate soccer. Head impacts were recorded by X2 Biosystems' xPatch wearable sensors. Linear and rotational accelerations were processed using proprietary algorithms to estimate cumulative impact power. Cumulative impact power was used as a measure of the head trauma accumulated prior to each scan. DSI were acquired at 4 time points; 3 throughout the season and 1 three months post season(pseudo-baseline). 11 matched control DSI datasets were acquired from subjects with low risk for head trauma or history of concussion. DSI was reconstructed with generalized q-sampling imaging, which was then used to calculate MDA. Control distributions of MDA were characterized by the covariance of MDA values across all subjects. Mahalanobis distance was then calculated to determine voxelwise abnormality for each scan. Abnormal was defined by an extreme Mahalanobis distance in groupings of 100 or more adjacent voxels. Recorded impact counts per player ranged from 11 to 82 for the season. Clusters of abnormal voxels were detected in several subjects. The count of abnormal voxels correlated with cumulative head impact power prior to each scanning session. Some abnormal voxel groupings identified within during-season scans were not present in the psuedo-baseline scans.

We observe a relationship between cumulative head trauma load and longitudinal changes in white matter diffusion using high angular resolution DSI imaging. Critically, MDA estimates were also used as an alternative to less sensitive metrics such as fractional anisotropy. This approach, when combined with high performance wearable head impact monitors, demonstrates promise for detecting and characterizing potential sub-concussive head trauma.

Title: Sensory connectivity and lesion type predict hand function in children with unilateral spastic cerebral palsy

Authors: *D. GUPTA[1,2], A. BARACHANT[1,2], A. M. GORDON[3], H.-C. KUO[3], J. B. CARMEL[1,2,4], K. M. FRIEL[1,2,4];
[1]Early Brain Injury and Recovery Lab., Burke-Cornell Med. Res. Inst., White Plains, NY; [2]Weill Cornell Med. Col. of Cornell Univ., New York, NY; [3]Teachers Col., Columbia Univ., New York, NY; [4]Blythedale Children's Hosp., Valhalla, NY

Abstract: The goal of this study was to examine the predictive value of sensory and motor system connectivity and lesion type on hand function in children with unilateral spastic cerebral palsy (USCP). In typically developing children, sensory and motor function are primarily mediated via crossed (contralateral) connections, as opposed to same-sided (ipsilateral)

connections. In children with USCP, an early brain injury often leads to sensory-motor reorganization, where ipsilateral motor connections on the lesioned side are seen to persist. Ipsilateral sensory connections are less common. Given the large scale adaptation in the motor system to unilateral brain injury and smaller scale adaptation in the sensory system, we hypothesized that loss of crossed *sensory* connections would be more predictive of hand function than loss of crossed *motor* connections. In addition, sensory circuits being established early in development have been shown to be more affected by cortical lesions than periventricular (PV) lesions. Thus, we hypothesized that cortical lesions would cause greater hand impairment than PV lesions. 23 children with USCP participated in anatomical, physiological and behavior testing of the sensory and motor systems. Anatomically, lesions were defined using MRI, and principal sensory and motor pathways were reconstructed using DTI. Physiologically, somatosensory evoked potentials (SSEPs) were recorded in response to vibrotactile stimulation of the index fingers; and EMG responses to motor cortex stimulation with TMS were recorded. For behavior, sensory hand function was tested with the Cooper stereognosis test and two-point discrimination; while motor hand function was assessed with the Jebsen-Taylor Test and box and blocks. We found that for the impaired hand, presence of significantly discriminable SSEP in the contralateral hemisphere, and a preserved contralateral sensory tract in DTI were both highly predictive of good hand motor and sensory function (Cohen's kappa agreement between group of subjects with good hand function and testing modality = 0.83 and 0.48 respectively, with kappa > 0.75 being strong agreement, and kappa < 0.40 poor). Lesion type was also predictive of hand function (kappa = 0.47). By contrast, the presence of contralateral motor connections—both physiological from TMS and anatomical from DTI—was less predictive of hand function (kappa = 0.24 and 0.32 respectively). Thus, sensory connectivity is more predictive of hand function in children with USCP than motor connectivity. This indicates that therapies to restore anatomical and physiological sensory connectivity may be important for recovery of sensory-motor function.

Title: Heart rate, minute ventilation, and maximum oxygen uptake in healthy and post-concussed collegiate female athletes

Authors: *D. C. MALLOY[1], S. ADAMS[2];
[2]Hlth. and Exercise Sci., [1]Pfeiffer Univ., Misenheimer, NC

Abstract: Background: A sport-related concussion is a form of mild traumatic brain injury (mTBI) with common symptoms such as fatigue, headache, and dizziness that tend to alleviate recovery within seven to ten days. However, neural symptoms can persist anywhere from three to twelve months following onset and can lead to the development of post-concussion syndrome (PCS). There is limited knowledge regarding the effects of an exercise stress test and the respiratory functions in post-concussed (within one year) athletes.**Purpose:** The purpose of this study was to determine if there were differences in heart rate, minute ventilation, and aerobic capacity during exercise on a treadmill in healthy and post-concussed (within one year) collegiate athletes.**Methods:** 14 female athletes, 7 healthy controls and 7 previously concussed, performed a maximal exercise test following a modified Balke protocol with a constant speed of 7.5 mph and an increasing grade each minute on a treadmill ergometer. Self-reported scale measurements were taken prior to and immediately after exercise and metabolic measures were recorded using a portable metabolic cart. Primary outcome measures included heart rate (HR), minute ventilation (VE), and maximum oxygen uptake (VO_2 Max). Linear regression analysis of VO_2 and HR as well as VO_2 and VE with Shapiro-Wilk test was performed. Statistical significance was determined at $p \leq 0.05$.**Results:** The healthy control and post-concussed groups reported the following outcome measures: VO_2 Max (42.8±5.6), HR (191.7±13.3), VE (79.7±7.5) and VO_2 Max (40.1±6.1), HR (180.6±13.7), VE (87.0±8.3) respectively. In the healthy control group, there was a significant linear relationship ($p=0.005$, $R^2=0.821$) between VO_2 and VE, but no significance between VO_2 and HR ($p=0.168$, $R^2=0.342$). In the post-concussed group, there was no significance between VO_2 and VE ($p=0.540$, $R^2=0.079$) or VO_2 and HR ($p=0.698$, $R^2=0.033$). **Conclusion:** This preliminary data indicates that there are noticeable differences between the respiratory functions of healthy and post-concussed (within one year) female collegiate athletes. The post-concussed athletes had variability in VE in relationship to VO_2 Max, whereas healthy athletes had a linear relationship. This suggests that the respiratory control center in post-concussed athletes may not be as efficient during a maximal exercise protocol. A larger participant population is needed to determine the significance of these differences in respiratory function.

Title: Role of subconcussive head impacts in pre- and postseason changes in SCAT3 scores

Authors: *A. SHAH[1], B. STEMPER[1], R. CHIARIELLO[1], A. LAROCHE[1], Y. WANG[2], L. NELSON[1], M. MCCREA[1];
[1]Dept. of Neurosurg., [2]Dept. of Radiology, Med. Col. of Wisconsin, Milwaukee, WI

Abstract: Head impact exposure during routine participation in American football has been associated with cognitive changes in the absence of concussion. Correlating characteristics (number/severity) of head impact exposure with clinical consequences remains important to protect athletes and determine informed exposure limits. To date, characteristics of head impact exposure were outlined for Division I college athletes, but correlation to clinically-meaningful changes was not reported. 205 Division III football athletes participated in this study during the 2013 season. xPatch sensors (X2 Biosystems) adhesively attached to the skin behind the ear collected head impact data during games and practices. Data were downloaded from the sensor at the end of each session. Peak linear acceleration was analyzed for each head impact that exceeded a pre-defined threshold of 10 g. All participating athletes underwent Sport Concussion Assessment Tool 3 (SCAT3) testing for baseline assessments at the beginning of the season. A cohort of 53 athletes repeated the assessments at end of the season. Two enrolled athletes were concussed during the season and removed from the cohort. A total of 22,023 impacts were recorded in the remaining 51 athletes with average resultant peak linear acceleration (PLA) of 26.4 g and a maximum of 165.5 g. To determine a threshold for significant impacts, total number of head impacts above an acceleration threshold during the season was correlated with the difference between pre- and post-season SCAT3 scores using Pearsons correlation. The threshold for significant impacts was varied between 10 and 170 g in 5 g increments and separate correlation analyses were conducted for each threshold level. Significant ($p<0.05$) correlations were identified between SCAT3 scores and PLA ranging from 40 to 130 g with strongest correlation ($R=0.45$) for number of impacts above 75 g. A greater number of significant head impacts was associated with greater SCAT3 changes. This study identified for the first time a positive correlation between the number of significant head impacts and pre- to post-season changes in common postconcussive symptoms in non-injured athletes. Continued analysis of this type may contribute to informed exposure limits (number/severity) to better protect athletes and reduce the risk of concussion symptom burden.

Title: Comparison of age-related brain atrophy in elderly East Asians and Caucasians

Authors: *H. JANG[1], H. KIM[1], H. LEE[2], K. KIM[1];
[1]Brain and Cognitive Sciences, Seoul Natl. Univ., Seoul-City, Korea, Republic of; [2]Col. of Med., Univ. of Ulsan, Seoul-City, Korea, Republic of

Abstract: Objective: This study investigated whether the age-related brain atrophy rate differs among ethnic groups. Brain volume decreases with increasing age and the severity of brain atrophy rate is a predictor of subsequent neurodegenerative disease like Alzheimer's. Brain is known to be morphologically different across races, especially between Asian and Caucasian populations. Therefore, this study investigated whether the age-related brain volume loss differs between Koreans and Caucasians.
Methods: The data of 96 cognitively normal Koreans (female=48, male=48; mean age=74.97±6.01) from the Korean Longitudinal Study on Cognitive Aging and Dementia (KLOSCAD) and 96 cognitively normal Caucasians (female=48, male=48; mean age=74.90±6.63) from the Alzheimer's Disease Neuroimaging Initiative (ADNI) (http://adni.loni.usc.edu) were selected. Three-dimensional T1-weighted MR images were acquired on 3.0 Tesla scanner. Volumes of total brain, gray matter (GM), white matter (WM), white matter lesions, ventricles, and cerebrospinal fluid were investigated as well as the selected subcortical regions with Freesurfer 3.0.5 (Martinos Imaging Centre) After adjusting the head size in each volume of interest (VOI), the atrophy rates (regression coefficients of age predicting VOI) between two ethnic groups were compared.
Results: Compared to Caucasians, Koreans showed faster atrophy rate in GM volume ($p=0.002$) but slower atrophy rate in total brain ($p=0.044$) and WM volume ($p<0.001$) with age. The ethnic difference in GM atrophy rate was more significant in females ($p=0.016$) than males ($p=0.043$). Interestingly, Korean elderly WM volume showed no significant age-related decline. By sub-analysis in each lobe, the ethnic difference in atrophy rate in female GM was significant only in the frontal lobe ($p=0.033$) whereas that of male GM was significant in broader regions across the frontal ($p=0.025$), parietal ($p=0.022$), and temporal ($p=0.042$) lobes.
Conclusion: According to this study, age-related GM atrophy was faster in Korean, whereas WM atrophy was faster in Caucasians. Environmental and genetic differences, such as higher education attainment in the Caucasian population and higher percent body fat in the East Asian

population, could be possible candidates contributing to the observed differences in GM and WM, respectively. However, factors affecting these ethnic differences need to be directly investigated in future research. The findings from this study implicate that the aging process can be better understood by studying brains of different ethnic groups and that the effective interventions against neurodegeneration might vary across ethnicity.

Title: A brain-computer interface for communication with DOC patients

Authors: ***C. GUGER**[1], B. ALLISON[2];
[1]g.tec Guger Technologies OG, Schiedlberg, Austria; [2]Guger Technologies OG, Schiedlberg, Austria

Abstract: Brain-computer interfaces are often used for control, rehabilitation, spelling, but an emerging application is assessment of patients with disorders of consciousness (DOC). DOC patients have varying levels of cognitive activity, with categories such as vegetative state (VS) and minimally consciousness state (MCS). For the physician or family members, it is difficult to know which cognitive functions are left. But it is crucial to learn whether patients can understand conversations or can even communicate.
The current study screened patients in the VS, MCS+, MCS- state as well as ALS patients that are completely locked-in. The system works with (i) auditory P300, (ii) vibro-tactile P300 with 2 tactors (VT2) and (iii) vibro-tactile with 3 tactors (VT3). In (i) and (ii), odd-ball paradigms are presented to the patient for 4-8 minutes, and the patient has to actively count either deviant auditory stimuli or deviant vibro-tactile stimuli. In (iii), the patient has one tactor on the left hand, one tactor on the right hand and one on a neutral midline location. The person has to count either the stimuli on the left or right hand to produce a corresponding P300 response. Then, the evoked potentials are calculated and statistically analyzed. Additionally, brain-computer interface (BCI) algorithms are trained on the data to provide an objective measure of classification accuracy. In the next step, questions can be asked to the patient, who can answer by counting the stimuli on the right hand to say YES and on the left hand to say NO. An

interesting case participated in an assessment recently. The patient was diagnosed as MCS and performed the auditory evoked potential, the vibro-tactile 2 tactor and the vibro-tactile 3 tactor experiment with 100 % classification accuracy, each. The evoked potentials of all three experiments showed clear P300 responses with a significant difference between target and non-target stimuli. The auditory experiment needed 20 deviant stimuli to reach 100 % accuracy. The VT2 protocol was especially effective, leading to 100% classification accuracy after only three trials. The VT3 protocol also led to 100 % accuracy after only 15 stimuli showing that the patient very likely could communicate. Next, the communication mode was used to answer questions. In the example above, the assessment results appeared comparable to a healthy control person, which was very important information about the patient for his family. The system can assess DOC patients and help us understand if they can do standardized cognitive tasks. More data will be collected to identify how many patients can use the system for communication.

Title: Differentiation of emotional trauma and loss of consciousness through examination of cortical thickness

Authors: *A. SIMMONS[1,2], A. D. SPADONI[2,1], R. KLAMING[1], I. STRIGO[3,4];
[1]UCSD, La Jolla, CA; [2]SDVAHS, San Diego, CA; [3]UCSF, San Francisco, CA; [4]SFVAHS, San Francisco, CA

Abstract: Background: Trauma experienced by combat veterans often includes both emotional and physical components. This has led to difficulty in the dissociation of Post traumatic Stress Disorder (PTSD) from post concussive symptoms. We have found that a key determinant of the impact of Traumatic Brain Injury (TBI) is whether an Loss of Consciousness (LOC) was experienced. Here we look to see if cortical thickness data was related to the LOC status or PTSD status in a sample of concussed combat veterans. Methods: Cortical thickness was calculated in a sample of 60 TBI veterans comprised of similarly sized samples of PTSD+/LOC+, PTSD-/LOC+,PTSD+/LOC-, and PTSD-/LOC- using Advanced Normalization Tools (ANTs). Results: There was a significant effect of LOC on cortical thickness, specifically

the bilateral inferior frontal and superior temporal lobes showed a significant reduction in cortical thickness in both LOC groups. PTSD did not show any marked difference in these regions. Conclusions: The initial data appears to suggest that LOC has significant effects on cortical thickness in combat exposed mild TBI regardless of the presence or absence of PTSD. This suggests that while damage may not be observable on a single subject clinical observation of T1 images that there is marked changes in brain regions associated with concussive injury.

Title: Interactions between COMTval158met polymorphism and trauma history in Active-Duty Marines: a role in the development of PTSD

Authors: *J. DESLAURIERS[1,2], D. T. ACHESON[1,2], M. A. GEYER[1,3], D. G. BAKER[1,2], C. NIEVERGELT[1,2], V. B. RISBROUGH[1,2];
[1]Psychiatry, Univ. of California San Diego, LA Jolla, CA; [2]Veterans Affairs Ctr. of Excellence for Stress and Mental Hlth., La Jolla, CA; [3]Res. Service, San Diego Veterans Affairs Heathcare Syst., La Jolla, CA

Abstract: Background and objectives: Posttraumatic stress disorder (PTSD) affects 7-8% of the American population and is even higher in military veterans. The catechol-*O*-methyltransferase (COMT) enzyme is implicated in the catabolism of dopamine and plays a key role in cortical signaling. The COMTval158met polymorphism has been associated with a greater risk of neuropsychiatric disorders, including PTSD. Our objectives were to investigate (1) whether COMTval158met polymorphism interacts with PTSD diagnosis to impair fear response and extinction, and (2) whether COMTval158Met genotype modifies combat exposure effects on fear responding in Marines and Navy Corpsmen.
Methods: Participants completed the Clinician-Administered PTSD Scale (CAPS), the Life-Event Checklist (LEC), Childhood Trauma Questionnaire (CTQ) and Deployment Risk and

Resilience Inventory-2 (DRRI-2) before (n = 714) and after (n = 452) deployment to Afghanistan. Fear acquisition and extinction were assessed at each visit using fear-potentiated startle.
Results: Before deployment, Met/Met carriers diagnosed with PTSD displayed significantly greater fear-potentiated startle to the CS- (safety signal) during acquisition and extinction compared to Met/Val and Val/Val carriers. Childhood trauma significantly modified this association, as only Met/Met carriers with PTSD that endorsed childhood trauma had a higher fear-potentiated response to the CS- during extinction compared to the same carriers that did not endorse childhood trauma. After deployment, we found that an elevated fear-potentiated response to the CS+ (danger signal) was found only in Met/Met carriers reporting a high combat exposure score, independently of their PTSD diagnosis, compared to the same carriers with low combat exposure score, confirming a genotype × trauma interaction.
Conclusions: These findings replicate previous studies showing that the Met/Met carriers with PTSD are more likely to show increased fear responding compared to Val/Val carriers with PTSD, and extend this finding to show that this association is modulated by early life exposure. Importantly, Met/Met carriers also exhibit increased fear responding after combat trauma, regardless of PTSD diagnosis, suggesting some acute loss of fear regulation after trauma in Met/Met carriers as a whole. These results support also the key role of gene-environment interactions in the development of psychiatric disorders, including PTSD. Further work will be necessary to understand the mechanisms underlying the modulation of cortical signaling by the COMTval158met polymorphism and fear extinction memory impairments in PTSD pathophysiology.

Title: Modular connectivity between amygdala and the ventral visual stream.

Authors: *A. M. MEIER[1], Q. WANG[2], A. BURKHALTER[1];
[1]Washington Univ. Sch. of Med., Saint Louis, MO; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Visual information informs an organism about emotionally salient objects, such as predators, food, and mates. Salient cues are processed in the amygdala, which integrates input from many sensory modalities to drive behavioral responses. In primates, the amygdala reciprocally connects with the ventral 'what' visual cortical stream specialized for object discrimination and not the dorsal 'where' stream specialized for visuomotor guidance (Baizer et al, 1993; Freese and Amaral, 2005). Here we examined the reciprocal connectivity between amygdala and different areas of mouse visual cortex. To study projections to the amygdala, we injected BDA, an anterograde tracer, into each of ten visual areas. Injection sites were identified using callosal projections labeled with bisbenzimide, enabling parcellation of visual cortex into distinct areas (Wang and Burkhalter, 2007). We found that all ventral stream extrastriate areas project to the lateral amygdala. Dorsal stream and V1 provide few projections to the amygdala. Postrhinal cortex (POR) provides the strongest input and is the only area that also projects to basolateral amygdala (BLA). We next studied projections of the amygdala to ventral stream areas by anterograde viral tracing from the BLA and lateral amygdala. We found that the amygdala provides input to layer 1 of posterior ventral stream areas including POR and the Posterior area (P). Few amygdala inputs to layer 4 were found, resembling cortico-cortical feedback projections. Previous work found modularity in primary visual cortex delineated by expression of type 2 muscarinic acetylcholine receptor (M2), and that these separate modules possess distinct visual tuning properties and connectivity (Ji et al, 2015). We thus stained tissue with an antibody against M2 in order to examine possible modularity of projections from amygdala. Amygdala projections to POR and P avoided M2+ patches, targeting M2- 'interpatches' instead. Third, we determined the origins of projections from the amygdala to POR by injecting the retrograde tracer DY into POR. We found that the lateral amygdala, but not BLA project to POR. In summary, the amygdala is selectively and reciprocally connected to the ventral visual stream, suggesting a role of the ventral stream in processing affectively salient objects. Additionally, amygdala feedback to posterior ventral stream areas avoids M2+ clusters, indicating a possible modular organization of affective stimulus processing related to visuomotor guidance.

Title: Maintenance of spatial information modulates beta rhythms within MT cortex

Authors: *Z. BAHMANI DEHKORDI[1], M. DALIRI[2,1], Y. MERRIKHI[1], M. PARSA[3], B. NOUDOOST[4];
[1]Sch. of Cognitive Sci., Inst. For Res. In Fundamental Sci., Tehran, Iran, Islamic Republic of; [2]Biomed. Engin. Dept., Iran Univ. of Sci. and Technol., Tehran, Iran, Islamic Republic of; [3]Computer Sci., Montana State Univ., Bozeman,, MT; [4]Cell Biol. and Neurosci., Montana State Univ., Bozeman, MT

Abstract: Psychophysical experiments have shown that remembering a location enhances visual discrimination performance at that location. Findings in our lab indicate that neurons in extrastriate visual areas receive a strong top-down signal from prefrontal cortex during the maintenance of spatial information. Although delay-period activity is very weak or non-existent in these visual areas, their sensitivity to incoming visual signals is enhanced during spatial memory maintenance. One possible explanation for this increase in sensitivity to visual input without an increase in baseline firing rate is that the top-down signal provides a sub-threshold modulation. Since the local field potentials (LFPs) are believed to reflect the level of input to an area, we sought to determine whether, and in what frequencies, extrastriate LFPs are modulated during spatial memory maintenance. For this purpose, we recorded neuronal spiking and LFP signals in the middle temporal (MT) area of rhesus monkeys performing a memory-guided saccade task. In this task, the target was presented for one second; the monkey had to remember the target location during a 1.5-2 second blank delay, and then saccade to the remembered location when the fixation point disappeared. Linear array electrodes were used to simultaneously record the activity of multiple MT neurons and LFPs. We measured the power density function (PSD) of the LFPs at each recording site prior to target presentation, during target presentation, and during the memory period. The PSDs were normalized based on the PSD prior to target presentation. The beta (15-30 Hz) power significantly increased during the memory period. Evaluating the temporal relationship between spikes and LFP signals revealed a significant increase in the locking between spikes and the phase of ongoing beta oscillations

during the memory period. We also found that the beta power during the memory period predicted the upcoming saccade accuracy and the reaction time: trials with higher beta power had more precise and faster saccadic responses. These findings provide a mechanistic insight into how the maintenance of spatial information contributes to enhanced sensory processing, potentially underlying the behavioral effects of spatial working memory.

Title: Differential expression of the m1 acetylcholine receptor by inhibitory neurons in macaque MT and LIP indicates distinct neuromodulatory compartments in cortex

Authors: *J. J. COPPOLA, A. A. DISNEY;
Psychological Sci., Vanderbilt Univ., Nashville, TN

Abstract: Chemical signaling between neurons has generally been viewed as a simple relationship in which an action potential in the presynaptic neuron leads to signal transduction in the postsynaptic neuron. However, diffuse regulation by neuromodulatory systems that signal, at least in part, via volume transmission may violate many aspects of the tightly coupled relationship assumed to be true for classical synaptic transmission. Various features of the local cortical circuit, including axonal density, tissue tortuosity, receptor localization, and signal termination mechanisms introduce variability to non-synaptic transmission. These anatomical and functional characteristics form local cortical sub-compartments between which modulatory signals can vary considerably. In the present study, we explore one aspect of these compartments by comparing cholinergic receptor expression by inhibitory neurons across cortical areas. Dual immunofluorescence labeling was used to identify neurons expressing the muscarinic acetylcholine receptor m1 (m1AChR) and gamma-Aminobutryric acid (GABA) in the middle temporal area (MT) and the lateral intraparietal area (LIP) of the macaque. We found a larger proportion of m1AChR-expressing neurons to be immunoreactive for GABA (GABA-ir) in MT than in LIP. Our results indicate, at least in terms of m1AChR expression by inhibitory neurons, that MT and LIP represent distinct neuromodulatory compartments. Previously, in macaque

visual areas V1 and V2, the proportion of m1AChR-expressing neurons that is GABA-ir was found to be larger in V1 than in V2. Together, these results indicate differential targeting of inhibitory and excitatory neurons by the cholinergic system across visual areas, and support the hypothesis that macaque cortex is divided into distinct neuromodulatory compartments based on features of the local circuit.

Title: Understanding the relationship between specific spatial abilities and map reading skills using fMRI

Authors: A. J. BIES, *M. E. SERENO;
Univ. of Oregon, Eugene, OR

Abstract: Map reading is a common human activity, yet there is little research on the underlying cognitive abilities and neural processes used during map reading. This study uses functional magnetic resonance imaging (fMRI) to evaluate the relationship between different spatial abilities (as specified by psychometric tests) and map readings tasks. We investigated the neural basis of two previously identified spatial abilities (spatial scanning and spatial relations) and two map reading tasks (shortest path and left/right turn decisions) which are hypothesized to rely on the two different spatial abilities. Spatial scanning involves the ability to quickly and accurately survey a spatial pattern to identify a path through it while spatial relations is the ability to rapidly perceive and manipulate simple patterns (e.g., mentally rotating an object). The results show striking similarities in activation patterns from the spatial scanning and shortest-path tasks, suggesting that the spatial scanning ability contributes to this particular map reading exercise. Activity patterns in the spatial relations and left/right turn decision tasks had significant differences (e.g., there was activation in the parahippocampal place area (PPA) and retrosplenial cortex for the left/right turn map task but not the spatial relations task), suggesting that participants are not mentally rotating maps to complete this task. In fact, there was significant activity in several areas known to be important for scene processing and navigation (such as the PPA and retrosplenial cortex) during both map tasks and the spatial scanning task but not the

spatial relations (mental rotation) task. We conclude that using a map not only requires spatial scanning skills but also a more recently defined spatial ability of spatial orientation or perspective taking.

Title: Spontaneous cortical waves in area MT of the awake marmoset

Authors: ***Z. W. DAVIS**[1], L. MULLER[1], T. J. SEJNOWSKI[1], J. MARTINEZ-TRUJILLO[2], J. REYNOLDS[1];
[1]Salk Inst. for Biol. Studies, La Jolla, CA; [2]Western Univ., London, ON, Canada

Abstract: Traveling waves are a ubiquitous property of cortical dynamics. They have been observed across species, in multiple cortical areas, under anesthesia and in the awake state, in spontaneous activity and following sensory stimulation. Cortical waves can be revealed using spike- or stimulus-triggered averaging of neural signals. To examine the properties of cortical waves, such as their patterns of propagation, velocities, and frequency of occurrence, individual waves need to be detected. We implanted a Utah array over area MT of a common marmoset (Callithrix jacchus), which lies on the cortical surface, and recorded spiking and local field potentials as the animal sat in front of a computer monitor. We then used a recently developed phase-based approach to detect and measure the spatiotemporal profiles of individual traveling waves. With this method, waves were detected in ongoing activity of several local field potential (LFP) frequency bands. We reasoned that if traveling waves propagate via fixed anatomical pathways, spatiotemporal patterns of activity should be repeatable. However, if the functional

properties of these pathways vary with network state, waves could vary across sensory conditions. To test this, we measured the spatiotemporal properties of waves in two luminance conditions. We found that waves follow stereotyped spatial profiles and that the profile of observed wave directions was preserved across luminance conditions. However, the speed of waves increased systematically with luminance. These results demonstrate that discrete cortical waves are present in the spontaneous activity of Area MT in the awake marmoset, that individual waves can be readily detected, and that wave velocity, but not direction, varies with luminance.

Title: Response sparseness for natural movies in macaque V1 and V4 estimated by 2-photon calcium imaging

Authors: *K. IKEZOE[1,2], T. FUKAZAWA[2], S. NISHIMOTO[2], S. MITA[2], I. FUJITA[2]; [1]Dept. of Physiology, Div. of Med., Univ. of Yamanashi, Chuo, Yamanashi, Japan; [2]Grad. Sch. of Frontier Biosciences, Ctr. for Information and Neural Networks (CiNet), Osaka Univ. and Natl. Inst. of Information and Communications Technol., Suita, Osaka, Japan

Abstract: Every sensory event evokes responses in a population of neurons across brain areas. Barlow (1972) previously proposed that as we ascend in the hierarchy of the mammalian visual cortical pathway, “a relatively small population of neurons are active, and each says a lot when it is active.” We tested this hypothesis via estimating the response sparseness in the primary visual cortex (V1) and a mid-tier cortex (V4) along the ventral visual pathway of monkeys using 2-photon calcium imaging techniques.
We loaded neurons with calcium indicator (Cal-520 AM) in layer 2 or 3 of V1 and V4 and then recorded fluorescence signals from individual neurons during the presentation of a natural movie to two monkeys (*Macaca fascicularis*) under analgesic and immobilized condition. The movie was 3 minutes long, composed of short clips, and presented 10 times. The refresh rate of the movie was 24 Hz. We estimated firing rates of neurons using deconvolution techniques from fluorescence signals sampled at 30 Hz. We analyzed 1857 V1 neurons and 1833 V4 neurons that

responded reliably across the 10 repeated trials. From the response matrix of video frames vs. neuron identities, we computed lifetime sparseness (LS) for each neuron and population sparseness (PS) for each video frame of the movie. LS indicates what fraction of video frames elicits responses in a given neuron, and PS indicates what fraction of neurons responds to a given video frame. Both LS and PS vary from 0 (equal responses to many stimuli or among neurons) to 1 (strong responses to limited stimuli or in particular neurons).
LS was smaller in V4 than in V1 (V1: 0.41, V4: 0.35; Wilcoxon rank-sum test, $p < 0.01$). Similarly, PS was smaller in V4 than in V1 (V1: 0.41, V4: 0.38; $p < 0.01$). Generally, PS becomes smaller for a neural population among which signal correlation, the similarity of response patterns to video frames, is high. However, the signal correlation between neurons was higher in V1 than in V4 (V1: 0.07, V4: 0.03; $p < 0.01$). Therefore, the difference in signal correlation cannot account for the difference in PSs. Instead, PS in each imaged site was correlated with LS in V1 and V4 (V1: $r = 0.84$, $p < 0.01$; V4: $r = 0.84$, $p < 0.01$, Spearman's rank correlation).
Thus, V4 neurons responded more broadly to natural scenes than V1 neurons, and the fraction of active neurons for natural scenes become larger in V4 than in V1. These results do not support Barlow's hypothesis.

Title: Model of MT spike count variability accounts for state-dependent tuning disparities

Authors: *J. LOMBARDO, M. MACELLAIO, B. LIU, S. E. PALMER, L. C. OSBORNE;
Univ. of Chicago, Chicago, IL

Abstract: Sensory neurons have variable responses to repeated presentations of the same stimulus. The structure of this trial-to-trial variability within a population directly affects the ability to decode stimulus identity. We compared the spike-count variability of *macaque* MT neurons in both the awake and anesthetized state, finding a state-dependence of variability and variability tuning. In the anesthetized state, the data is well modeled by a Poisson process with variable multiplicative gain. This model predicts a variance to mean ratio, or Fano factor (FF), that is strictly increasing with spike count. However, in the awake state, inverted Fano factor tuning is observed, with decreasing FF at higher spike counts at preferred directions of motion. We developed a unified model of spike count variability that captures the U-shaped Fano factor tuning observed in the awake state, as well as the super-Poisson variability observed in the anesthetized state. In our model, the state-dependent FF tuning changes are mediated by a switch from a low-gain state in the awake state to a higher gain state when anesthetized.

Title: Functional topography of the cortical inputs to layer 1 neurons of medial secondary visual cortex in mice

Authors: *Y.-W. LAM, S. SHERMAN;
Univ. of Chicago, Chicago, IL

Abstract: Layer 1 of the neocortex consists mainly of the apical tufts of pyramidal neurons and horizontally oriented axons from"matrix" thalamic neurons and other cortical areas. It also contains sparsely scattered GABAergic neurons that innervate cells of lower layers. We studied the topography of the cortical input to layer 1 neurons using laser-scanning photostimulation in coronal slices from brains of Balb/c mice. Layer 1 neurons of the medial secondary visual cortex

were identified in slices as the cells sparsely distributed above the well-packed somata of the layer 2/3 and recorded in voltage-clamp mode held at -45 mV. The slices were then perfused with ACSF containing nitroindoliny-caged-glutamate and stimulated with a UV laser (355 nm wavelength). Photostimulation of cortical layers 2 to 6 evoked responses in about 50% of the recorded neurons. Half of these responses consisted solely of EPSCs and the remainder had a mixture of EPSCs and IPSCSs. We did not see much evidence of local GABAergic input to these cells, suggesting that local connections among these layer 1 cells are sparse at best. Our results suggest that layer 1 neurons receive monosynaptic and polysynaptic inputs from neurons in lower layers within the same region of neocortex, further suggesting that these cells integrate converging inputs from thalamus, other cortical areas, and local inputs.

Title: Stereoscopic depth may increase cognitive responses within visual comfortable zone

Authors: *H. CHO[1], M.-K. KANG[2], S. AHN[1], M. KWON[1], J. CHOI[1], S. C. JUN[1];
[1]Sch. of Information and Communications, Gwangju Inst. of Sci. and Technol. (GIST), Gwangju, Korea, Republic of; [2]Imaging Media Res. Ctr., Korea Inst. of Sci. and Technol., Seoul, Korea, Republic of

Abstract: Stereoscopic three-dimensional contents including 3D movies, 3D TV, head mounted display (HMD), and augmented reality have become popular in recent days. Although excessive stereoscopic depth images can cause visual fatigue and discomfort, proper 3D images can increase sense of realism and viewing experience. In this paper, we hypothesized ‘cognitive zone’ exists within visual comfortable zone. Stereoscopic depth may increase cognitive responses in the brain and is saturated within the visual comfortable zone. In this reasoning, we investigated cognitive responses for four different stereoscopic depth levels within the comfort zone. Simultaneous EEG/MEG acquisition technique was introduced to collect the cognitive

responses of eight participants. We defined subject-specific retinal disparities and designed a single trial-based stereoscopic viewing experimental paradigm. In the single trial analysis, we observed that as depth level increased from 1 to 3, there was a time-locked increase in the N200 component in MEG and the P300 component in EEG on the occipital and the parietal areas, respectively. Averaged retinal disparity of depth level 3 was -0.34 ± 0.036. After 3D depth exceeded the depth level 3, the amplitude of cognitive responses decreased. From these findings, it is expected that cognitive response is likely to be saturated in the visual comfort zone, while depth perceptual load may increase as depth level increases.

Title: Transsaccadic integration of spatial frequency information in an fMRIa paradigm

Authors: *B.-R. BALTARETU[1], B. T. DUNKLEY[2], J. D. CRAWFORD[1];
[1]York Univ., North York, ON, Canada; [2]Hosp. for Sick Children, Toronto, ON, Canada

Abstract: To date, the neural correlates of feature information integration across saccades (i.e., transsaccadic integration, TSI) are relatively unknown. Using fMRI adaptation, we found that right inferior parietal lobule (IPL; specifically, SMG) and extrastriate cortex (putative V4) are sensitive to objet orientation in a space-fixed reference frame (Dunkley et al., submitted). Here, we used fMRIa to uncover the cortical correlates of spatial frequency in a space-fixed reference frame. Functional data were collected across 11 participants while they observed a vertical grating of a given spatial frequency in the center of the screen, followed by a grating at the same ('Repeat' condition) or different ('Novel' condition) spatial frequency. Participants were required to either fixate in the same position (Fixation task) or to make a saccade to the opposite fixation point (Saccade task). Participants were instructed to decide via a 2AFC task if the subsequent grating was repeated or novel. The Saccade task produced specific, significant ($p<0.05$) summation (repeated > novel; repetition enhancement, RE) in frontal cortex and

adaptation (novel > repeated; repetition suppression, RS) in occipito-parietal areas. The Fixation task produced specific, significant ($p<0.05$) summation (RE) in an extensive occipito-parieto-frontal cluster of areas. We also conducted a region-of-interest analysis to explain parietal and occipital areas found to be involved in transsaccadic memory of object features (Prime et al., 2008; Malik et al., 2015). This indicated regions of significant Novel vs. Repeat effects in several additional parietal and occipital areas, possibly explaining our previous TMS results. Overall, TSI of spatial frequency produced a similar pattern of cortical activation as the pattern for TSI of object orientation in our previous study (although details differed), suggesting a general role for occipital-parietal cortex in spatiotopic TSI of low-level object features.

Title: Diffusion properties of human visual white matter correlate with stereoacuity

Authors: *H. OISHI[1,2], H. TAKEMURA[2,1,3], S. C. AOKI[2,1], I. FUJITA[2,1], K. AMANO[2,1]; [1]Grad. Sch. of Frontier Biosci., Osaka Univ., Osaka, Japan; [2]Ctr. for Information and Neural Networks (CiNet), Natl. Inst. of Information and Communications Technology, and Osaka Univ., Osaka, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Binocular disparity is an important cue for depth perception. Disparity-sensitive fMRI responses have been reported in a variety of visual cortical regions (Tsao et al., 2003), suggesting that the disparity information is transferred among several areas throughout white matter pathways. Human psychophysical studies identified substantial individual differences in sensitivity for detecting disparity (stereoacuity; Zaroff et al., 2003; Hess et al., 2015). Here we examined how the structural properties of visual white matter pathways are related with the individual difference in streoacuity by combining psychophysics and diffusion-weighted Magnetic Resonance Imaging (dMRI).We measured disparity discrimination threshold for 19 participants with normal or corrected-to-normal vision (age 20-37, mean: 25.1). Completely stereoblind participants were screened out in a prior test. We used circular patches of dynamic random-dot stereograms, each consisting of a center disk and a surrounding annulus. We changed binocular disparity of the disk across trials while keeping the annulus always at 0

disparity. The participant's task was to determine whether the disk appeared in front of or behind the annulus. We observed substantial individual differences in performance of this task, and classified participants into two groups: high- (N=10; median threshold: 0.014 deg) and low-performance (N=9; median threshold: 0.073 deg) groups. We also collected dMRI data using a 3T MRI scanner (2 mm isotropic voxels, 64 angular directions) from the same 19 participants. For dMRI data analysis, we used probabilistic tractography to identify the major visual white matter pathways, optic radiation (OR), the forceps major, and the vertical occipital fasciculus (VOF). For each group of participants, we then calculated Fractional Anisotropy (FA) along these pathways in order to evaluate the structural properties of each pathway. We found a significant difference of the FA in the central portion along the right VOF between the high-performance and low-performance participant groups. Moreover, FA along the right VOF was negatively correlated with disparity discrimination threshold across participants ($R=-0.795$; $p<0.001$). In contrast, FA did not exhibit any inter-group difference or correlation with stereoacuity along the OR and forceps major. The VOF is known as a pathway to link dorsal and ventral visual cortex (Yeatman et al., 2014; Takemura et al., 2015). Our results indicate that the stereoacuity reflects the structural properties on the pathway involving with dorsal-ventral communication, rather than the early visual pathways such as the OR.

Title: Laminar patterns of interareal axonal projections reveal a hierarchical organization of mouse visual cortical areas.

Authors: *R. D'SOUZA[1], Q. WANG[1,2], A. MEIER[1], A. BURKHALTER[1];
[1]Dept of Neurosci., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Upon receiving thalamic input, primary visual cortex (V1) sends signals to extrastriate cortical areas, which themselves connect with each other and with V1 with varying strengths. Visual processing is thought to be hierarchical, wherein signals are sent from V1 to increasingly higher areas depending upon the relevant features of visual stimuli, even while each area is targeted by multiple areas. Cortico-cortical connections can be broadly classified as being feedforward (FF) if they send information deeper into the cortex, feedback (FB) if they provide descending inputs from higher to lower areas, or lateral if they connect areas at equal levels of a processing hierarchy. A critical step in understanding how computations within such a distributed processing system leads to visual perception and function requires the identification of the cortical hierarchy, if any, through which signals flow. Using anatomical criteria of interareal axonal projections, the structural hierarchical organization of the cortical visual system has been proposed in primates (Felleman and Van Essen, 1991) and rats (Coogan and Burkhalter, 1993). Because the mouse has emerged as a widely used model for studying cortical circuits and function, due to its genetic tractability, we aimed to identify a multilevel hierarchy through which mouse visual cortical areas communicate. To do this, the anterograde tracer, biotinylated dextran amine (BDA), was injected into each of ten identified visual areas, and axonal termination patterns in each of the other nine areas were examined. The areas were identified by their locations relative to landmarks formed by retrogradely-labelled callosally projecting neurons, which were imaged *in situ* before the brain was coronally sectioned. Projections from V1 to higher areas tended to selectively target layers 2 to 4 (L2-4) while only weakly terminating in L1. On the contrary, FB projections to V1 strongly targeted L1, while preferentially avoiding L2-4. We therefore used the ratio of the density of axonal terminations in L2-4 to that in L1 (‘density ratio’, DR) as a measure for quantifying the hierarchy of connections, and generated a 10x10 matrix of DRs of over 85 interareal pathways. The DR for each area to each of the nine targets was averaged, and the average DR was compared between areas for statistical significance. The analyses revealed at least five hierarchical levels through which visual areas interconnect, with V1 at the bottom, and the postrhinal (POR) and anteromedial (AM) areas at the top of the hierarchy. By further dividing the areas into the dorsal and ventral streams (Wang et al., 2012), we propose the hierarchical organization of each stream.

Title: Steady-state signatures of visual short-term plasticity and perceptual filling-in

Authors: *S. M. LONG, M. A. GANNON, M. M. GARDNER, N. A. PARKS;
Psychological Sci., Univ. of Arkansas, Fayetteville, AR

Abstract: An artificial scotoma is a stimulus-induced analog of retinal deafference; created by superimposing a circumscribed area of uniform luminance on a dynamically altering white noise background. When viewed for several seconds, an artificial scotoma fades from awareness, becoming perceptually filled-in by the dynamic background stimulus. Single-cell work in non-human primates has previously described a phenomenon called 'climbing activity' in which activity of cells within scotoma representations of extrastriate cortex increase responsiveness over time and become responsive to dynamic background stimuli beyond the boundaries of their classical receptive fields (De Weerd, Gattass, Desimone, and Ungerleider, 1995). Here, we used steady-state visual evoked potentials (SSVEPs) to provide an index of climbing activity in human extrastriate cortex and examine its relationship to the perceptual filling-in of an artificial scotoma. EEG was recorded from observers, while they viewed an artificial scotoma display consisting of a six degree mid-gray disc superimposed upon a dynamic background of small white dots for a period of 18 seconds. The dynamic background of this display refreshed at rates of 5 Hz, 10 Hz, or 20 Hz and observers indicated by button press when the scotoma disc began to become filled-in by the background. Time-frequency analyses of SSVEPs were used to examine temporal modulations in spectral EEG power at the dynamic background's driving frequency leading up to the observers' report of perceptual filling-in. Consistent with climbing activity in extrastriate cortex, spectral power at the SSVEP's driving frequency increased in the seconds preceding the report of perceptual filling-in. Climbing activity indexed by the SSVEP further correlated with observers' mean fill-in time of the artificial scotoma disc. These findings provide an index of climbing activity and provide further evidence that the perceptual filling-in of an artificial scotoma is mediated by invading activity originating beyond the scotoma's classical retinotopic boundaries.

Title: Selective flow of sensory-motor information in the reciprocal connectivity in mouse frontoparietal cortex

Authors: ***T. SATO**[1], T. K. SATO[2], M. HASEGAWA[1], T. ITOKAZU[1], R. KIMURA[1]; [1]Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]Technische Univ. München, Munich, Germany

Abstract: Cortical areas are intertwined with networks of reciprocal long-range connectivity. However, the circuit logic underlying such connectivity is still unclear. Here we report a simple rule on the reciprocal connectivity between sensory and motor areas in mice. Using a newly developed eye movement task, combined with two-photon calcium imaging, electrical stimulation, and anatomical tracing, we identified a motor area that controls eye movements in the medial prefrontal cortex ($mPFC_{eye}$). $mPFC_{eye}$ encodes not only motor command signal, but also visual information that instructed the eye movements. Unexpectedly, dual encoding was also found in visual areas in the parietal cortex ($V_{parietal}$) where we found reciprocal connectivity with $mPFC_{eye}$. Primary visual cortex, in contrast, shows only visual encoding. Remarkable similarity and strong reciprocal connectivity between $mPFC_{eye}$ and $V_{parietal}$ apparently implied little functional segregation of the two. However, segregated information flow was uncovered by axonal calcium imaging: $mPFC_{eye}$ preferentially sends motor information to $V_{parietal}$, whereas $V_{parietal}$ visual information to $mPFC_{eye}$. We speculate that long-range reciprocal connectivity acts as a selective filter which prevents reverberant loops, leading to efficient sensory-motor interactions.

Title: Space and choice in mouse parietal cortex during virtual navigation

Authors: *M. KRUMIN, K. D. HARRIS, M. CARANDINI;
Univ. Col. London, London, United Kingdom

Abstract: Posterior parietal cortex (PPC) is a nexus of sensory and motor areas. In primates it is believed to perform operations such as coordinate transformations and decision making. In rat PPC, some experiments revealed decision signals, but others revealed signals related to navigation. Can these two views be reconciled? To address these questions we trained mice on a virtual reality task that involves both decision-making and navigation. The mice traversed a virtual corridor with a vertical grating painted on one of the side walls. They were rewarded for reporting the position of the grating by either turning right or left at the end of the corridor. Their success rates increased with increasing grating contrast. The animals typically indicated their choices early: trajectories leading to left and right turns diverged well ahead of the end of the corridor.While the mice performed the task, we used 2-photon calcium imaging to record populations of neurons in PPC. Most cells showed activity that was correlated with the animal's choice: they preferentially fired during trials ending in a specific choice. In addition, these cells fired reliably during a specific period during the trial, forming a sequential activation, as different cells fired during different periods (Harvey et al. Nature, 2012). As a consequence, the animal's choice could be predicted from activity of these cells, including well before the animal turned at the end of the corridor. An alternative analysis revealed that the activity of PPC neurons was strongly modulated by the mouse's virtual position along the corridor (z) and virtual head direction (θ). Many of the cells had localized 'space fields' in these coordinates, and this z-θ model gave a prediction of each neuron's activity with explained variance of up to 89% (21±16% for all active cells). These space fields could occur at any location in z-θ coordinates, and indeed the neurons recorded in a single session typically tiled the T-maze.Neural activity was also modulated by other sensory or behavioural parameters, e.g. the visual stimulus, or the motor actions of the mouse. However, for the majority of the cells the space fields accounted for the largest fraction of the neural responses.These results suggest that mouse PPC can play a key role in visually guided behavior. Neural activity showed strong modulation by multiple behaviorally relevant features of the acquired task. These features include not only position in the environment and, possibly, the traces of perceptual decisions, but also virtual heading angle, motor actions, and visual stimulus - all of which are an inherent part of this complex behavior.

Abstract: The ventral pathway of the primate visual system is involved in form processing and object recognition, but only the early stages of this pathway are well understood. While most neurons in the primary visual cortex are tuned for orientation and spatial frequency, cells in area V4, an intermediate stage along this pathway, appear to be selective for more complex visual patterns and have been more difficult to characterize. V4 neurons have been shown to respond to aspects of shape, texture and color, and it is likely that additional important axes of representation remain to be discovered. In many past studies attempting to understand V4, the stimulus design and analysis were driven by a specific underlying hypothesis and model. To avoid inherent pitfalls in this approach, and discover novel encoding dimensions, we take a more model-free approach to reanalyze responses of V4 neurons to the set of simple shapes (PC2001) introduced by Pasupathy & Connor (2001). We focus on two main questions: Do V4 neurons fall within clusters in terms of how they respond to the shape set? and, What do the V4 responses tell us about the shape set, i.e., do the shapes cluster in terms of the responses they evoke across the population of neurons? The PC2001 stimulus set provides a unique opportunity to understand V4 encoding because nearly the same set of 370 stimuli (51 shapes at up to 8 rotations) have been presented in several studies of well-isolated single units in macaque V4 over many years. We accumulated data from 3 studies (6 animals) for a total of 272 neurons. We defined a rotation-invariant metric between pairs of cells based on their responses to the shape set such that cells with shape preferences that are rotated version of each other will be separated by a very small distance. Using multiple clustering methods, we found 4 major clusters that included ~20% of the cells. We determined how well the cells within each cluster were fit by published models for V4 - the angular-position and curvature (APC) model and the spectral receptive field (SRF) model - and we examined how well the clusters could be distinguished in APC and SRF parameter space. For each cluster, we also found a subset of shapes that played a significant role in distinguishing that cluster from the rest of the neurons. Overall, our clustering identified novel categories of units that were not distinguished based on the parameters of existing models (APC

and SRF), and we were able to identify clear intuitive dimensions, e.g., tuning for stimulus area and isoperimetric quotient, which did distinguish these clusters. These clusters offer important hints for the design of novel stimuli to better understand shape encoding in mid-level vision.

Title: Primate prefrontal cortex and the representation of partially occluded shapes

Authors: A. FYALL[1], H. CHOI[2], E. T. SHEA-BROWN[3], *A. K. PASUPATHY[2];
[1]Univ. of Washington, Seattle, WA; [2]Biol. Structure, [3]Univ. Washington, Seattle, WA

Abstract: How the primate brain successfully recognizes occluded objects is an enduring puzzle in Systems Neuroscience. Despite dramatic advances in deep learning algorithms, recognition under occlusion continues to stump artificial vision systems. Feedback signals from higher cortices, an oft omitted component in artificial systems, have been hypothesized to underlie the success of the primate brain but this claim has not been physiologically tested. Here we show that neurons in the primate prefrontal cortex, a high level cortical region implicated in the executive control of behavior, exhibit stronger and more selective responses to occluded than unoccluded shapes during the performance of a shape discrimination task under occlusion. This is unlike visual area, V4, where responses decline with increasing occlusion levels. While the earliest transients in V4 decline with increasing levels of occlusion, we demonstrate that many neurons exhibit a second transient that emerges after the onset of PFC responses and, like in PFC, show a stronger modulation for occluded stimuli. These results, replicated by a simple two-layer V4-PFC network model, suggest that PFC inputs could be utilized to selectively boost responses of some V4 neurons to occluded shapes thereby increasing their selectivity and facilitating better discrimination under occlusion.

Title: Neural responses in the inferior temporal cortex to partially occluded and occluding stimuli

Authors: ***T. NAMIMA**, A. PASUPATHY;
Dept. of Biol. Structure, Univ. of Washington, Seattle, WA

Abstract: Image segmentation - the process by which scenes are segmented into component objects - is a fundamental aspect of vision and a cornerstone of scene understanding; its neural basis, however, is largely unknown. Partial occlusions pose a special challenge to segmentation because, unlike non-overlapping stimuli, they require the parsing of overlapping contours and regions and/or the grouping of noncontiguous regions. To begin to understand how partially occluded stimuli are segmented in the primate brain, we studied the responses of single neurons in IT cortex to shape stimuli subjected to increasing levels of occlusion. We asked whether IT responses are consistent with a segmented representation whereby responses of each neuron are dictated by either the occluded or the occluding stimulus, but not both.
We recorded from 52 well-isolated, single IT neurons as animals were engaged on a sequential shape discrimination task. On each trial, two stimuli were presented in sequence and the animal had to report whether the stimuli were the same or different with a rightward or leftward saccade, respectively. The second stimulus in the sequence was occluded with randomly positioned dots; occlusion levels were titrated by varying occlude dot. Some neurons (10/52, 19%) showed strong responses to unoccluded stimuli and responses declined with increasing levels of occlusion. These neurons behaved quite like those in IT cortex during passive fixation (Kovacs et al., 1995) and their responses were consistent with a direct encoding of the raw (unsegmented) image. Most IT neurons (37/52, 71%), however, showed weak responses to unoccluded shape stimuli

and stronger responses under occlusion, independent of the shape of the occluded stimulus. These results support the idea that many IT neurons encode just the occluding stimuli supporting a segmented representation.

Title: Generation of a mesoscale connectome of the mouse visual system using individual functional maps for viral targeting

Authors: ***P. A. GROBLEWSKI**, A. BERNARD, A. CETIN, C. FARRELL, D. FENG, M. GARRETT, N. GAUDREAULT, K. E. HIROKAWA, A. HO, T. KEENAN, A. KRIEDBERG, Y. LI, F. LONG, V. MALDONADO, S. MIHALAS, L. NG, J. PHILLIPS, T. SIUDA, C. THOMPSON, W. WAKEMAN, C. KOCH, H. ZENG, J. A. HARRIS;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: The purpose of the Next Generation Connectivity project is to create a comprehensive mesoscale connectome that maps the inputs to, and outputs from, the mouse visual system with cortical layer and cell type specificity. This project extends the findings of the existing Allen Mouse Brain Connectivity Atlas by adding components that improve precision, increase specificity, and enhance characterization of mouse visual circuitry. Specifically, the aims of Next Generation Connectivity are to generate 1) an inter-areal retrograde projectome, 2) an inter-areal and cell type-specific projectome using axonal and synaptic labeling, 3) a target-defined inter-areal and cell type-specific anterograde projectome, and 4) an inter-areal and cell type-specific retrograde trans-synaptic connectome. Here we describe the use of intrinsic-signal-imaging (ISI) to obtain retinotopic and sign maps of the visual cortex in individual mice to precisely guide injections of fluorescent anterograde and retrograde viral tracers into specific locations within primary and higher visual areas. Briefly, mice are first implanted with a headframe that allows for through-skull ISI of the visual cortex while mice view a periodic drifting bar stimulus covering the entire field of view — the resulting maps are then used to guide tracer injections using a custom suite of integrated software and hardware. Using high-throughput 2P serial imaging, coronal sections of the injected brain are generated, viral infection sites are then annotated and all brains are registered to the 3D common coordinate framework (CCF) through our informatics data processing pipeline. Individual ISI maps are then overlaid onto the CCF

using surface vasculature patterns. The steps of this workflow, from the initial surgery to final ISI map overlay, require a common registration system that allows for precise alignment of the mouse brain across all experimental and analysis platforms. Lastly, to showcase the results of this project workflow we will present preliminary Next Generation Connectivity datasets that are currently available through our public data portal (www.brain-map.org).

Title: The structure of population coding and fluctuations in mouse visual cortex.

Authors: ***G. K. OCKER**, S. DE VRIES, R. AYER, J. SIEGLE, D. DENMAN, J. LECOQ, R. C. REID, M. A. BUICE;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The Cortical Activity Map Project contains 2P calcium imaging from simultaneously recorded populations of hundreds of neurons in awake mice. Its recordings together span layers 2-5 in areas V1 and the secondary areas LM, AL and PM and are in response to both synthetic and naturalistic stimuli. This dataset offers a powerful new tool for examining population coding in the mouse visual system. The structure of fluctuations in population activity and the relationships between those fluctuations and neurons' stimulus preferences can have powerful effects on population coding. To assess information processing across visual areas and layers, we examine how well different stimuli can be decoded by correlation-based and correlation-ignorant decoders. We then examine how coding performance in different visual areas relates to the structure of fluctuations in the populations' activity.

Title: Characterization of calcium events and spiking activity *In vivo* and their relationship in multiple cell types using transgenic mouse lines

Authors: *U. KNOBLICH, J. WATERS, C. REID, C. KOCH, H. ZENG, L. LI;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: Two-photon (2-p) calcium imaging using genetically encoded calcium indicators (GECIs) has been widely adopted to monitor the activity of groups of neurons. However, the relationship between calcium events and spiking activity is not yet fully understood, making it difficult to link these studies to the large body of existing knowledge about neuronal firing. This spike-to-calcium transfer function depends on several factors, including the particular GECI, the cell type it is expressed in (due to differences in ion channels and intrinsic calcium dynamics), its expression level, and the behavioral state of the animal (due to changes in calcium dynamics, e.g. by neuromodulators). Previous studies have largely relied on virus injections to deliver GECIs into the cells of interest, creating another source of variability due to differential uptake and expression of the virus.
Transgenic mouse lines provide a way to achieve more uniform expression of GECIs in a specifically targeted population of cells, enabling a more straightforward comparison of activity across cells and animals. Using our newly developed intersectional transgenic mouse lines expressing GCaMP6f or GCaMP6s in a Cre-dependent manner, we examine the statistics of spontaneous and stimulus-evoked calcium events across the target layer 2/3 population in primary visual cortex, and their dependence on the state of the animal. In addition, we perform concurrent 2-p calcium imaging and 2-p targeted cell-attached recordings in the same neurons to simultaneously measure spiking and calcium activity to directly characterize their transfer function. These results will be beneficial for interpreting existing as well as future calcium imaging data such as the output of the Cortical Activity Map Project at the Institute.

Title: Functional characterization of visual responses in the Cortical Activity Map

Authors: *S. E. DEVRIES, M. GARRETT, G. K. OCKER, M. A. BUICE, J. LECOQ, A. BERNARD, D. FENG, L. NG, S. OLSEN, C. REID, H. ZENG, C. KOCH;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: In order to explore how features of the sensory environment are represented by cortical circuits, the Allen Institute for Brain Science has recently released the first survey of neural activity in the living brain, the ALLEN Cortical Activity Map. Using high-throughput 2-photon calcium imaging, we have systematically recorded the visual responses of neurons in the awake mouse cortex, generating a dataset that spans multiple visual areas, cortical layers, and Cre lines. Using transgenically expressed GCaMP6 under the control of specific Cre drivers, we captured the responses from specific neuron populations to a wide range of visual stimuli, both synthetic and natural, designed to efficiently capture the visual response properties of cortical neurons. Neurons are individually characterized by their spatial receptive field structure, their temporal dynamics, and their orientation, spatial and temporal frequency tuning. Further, responses to natural images and movies serve to compare the spatial and temporal response properties to activity in a more naturalistic context. This is an extremely rich dataset for exploring cortical computations involved in visual information processing. Here, we examine how these visual response properties are transformed across different cortical layers and visual areas. Further, we evaluate how naturalistic stimulus statistics alter the spatial and temporal processing of visual stimuli throughout the mouse's visual pathway, highlighting non-linear processes in the cortical circuit.

Title: The common coordinate framework: a 3d mouse brain atlas delineated by multi-modality references

Authors: *Q. WANG, J. A. HARRIS, Y. LI, J. ROYALL, P. LESNAR, S.-L. DING, B. FACER, K. HIROKAWA, A. HO, S. SUNKIN, A. BERNARD, C. KOCH, H. ZENG, L. NG; Allen Inst. for Brain Sci., Seattle, WA

Abstract: Brain atlases are essential tools for neuroscience research. Conventional mouse brain atlases built in 2D format from coronal and sagittal sections such as "*The Mouse Brain in Stereotaxic Coordinates*" (Paxinos and Franklin, 2001) and the *Allen References Atlas* (Dong, 2008). These 2D atlases have been widely used in the field but cannot simply transform to an accurate 3D brain atlas due to imperfect alignment among the images caused by the tissue processing procedure. In order to integrate, visualize and analyze multi-modal big data, it is necessary to build a high resolution 3D mouse brain atlas. In the present study, we first built an average 3D template from the block-face images of 1675 adult laboratory mouse (C57BL/6J and transgenic mice) brains with 10 micron isotropic resolution. This high resolution average template allowed us to see more than 100 cortical and subcortical structures without any further staining. These visible structures were drawn in 3D space with the 3D drawing tool ITK-SNAP. Next, to delineate structures that were not immediately visible on the average template we registered, using local and global alignment, additional data to the average template, including, 1) five reference data sets, 2) connectivity data from the Allen Mouse Connectivity Atlas, and, 3) block-face scanned brain images from 30 transgenic mouse lines. Using these data sets, a total of 43 cortical areas, and their subdivisions, were reconstructed from surface views using a curved cortical coordinate system in the Common Coordinate Framework (CCF). For example, by overlaying the virtual callosal connections made from more than 100 injections throughout the contralateral cortical areas and visuotopic maps made from 26 injections in the primary visual area with the average template, 9 higher visual areas were delineated in this 3D space. Each delineated higher visual area has its own unique shape and size on the surface views. Three and six more visual areas were reconstructed in our 3D atlas compared to what is available in the Dong's Atlas and the Paxinos and Franklin's atlas, respectively. In addition, 187 subcortical gray matter structures, and 82 white matter structures were reconstructed in 3D space. Some of these structures have not been previously annotated in other atlases. For example, the lateral geniculate nucleus was further subdivided into shell, core and ipsilateral retina projection zones based on both the transgenic data and retina projection data from the Allen Mouse Connectivity Atlas.

With accurately reconstructed cortical and subcortical structures in 3D space, the CCF provides a foundation for integrating, analyzing and visualizing multi-modal big data.

Abstract: As a portion of the Cortical Activity Map (CAM) Project, a major initiative at the Allen Institute for Brain Science, head fixed adult mice are shown both artificial and natural visual stimuli while high-throughput 2-photon calcium imaging data are recorded from the mouse visual cortex to assess stimulus processing across cortical layers, cortical areas, and Cre lines. In addition to this effort, to assess the accuracy of statistical inference cell-attached electrophysiological (ephys) data are collected simultaneously with two-photon calcium imaging (ophys). This latter experiment reveals, particularly when imaging at the lower magnification required to cover the mouse cortex, that a large number of spikes are not represented by the fluorescence signal, and conversely, an upward transient in the fluorescence signal does not always correspond with
the occurrence of a neuron action potential. Despite considerable methodological effort, it remains a challenge to associate fluorescence signal with neural spiking. In this work, a three-part approach is taken to estimate neural receptive-fields and filters: (i) generalized linear models of spiking are estimated directly from flu-orescence signal without direct knowledge of spike times, (ii) methods of estimation make explicit use of the calcium moments to facilitate (iii) the incorporation of calcium models derived from the joint ephys/ophys experiment. Finally, the quality of this approach is assessed through the use of large-scale, biophysically detailed simulations. These simulations account for realistic cellular and somatic Ca-transients, and emulate a patch of cortical tissue using single-neuron models of mouse V1 taken from the Allen Institute Cell Types data base, with observation-consistent rules of inter-neural connectivity.

[1]Structured Sci., [2]Allen Inst., Seattle, WA

Abstract: The Allen Institute for Brain Science is conducting in-depth surveys of the mouse visual system to better understand the components and computations of the mammalian brain. In particular the **ALLEN Cortical Activity Map** project is a survey of cellular visual responses across multiple brain areas, cortical layers and neuronal populations. We used two photon calcium imaging to simultaneously record from a large number of cortical neurons while an awake mouse was watching a set of standardized visual stimuli. To restrict to specific neuronal sub-populations, we also surveyed a number of different transgenic mice expressing the calcium indicator Gcamp6f against 4 different cre reporters line in the layer 2/3, layer 4 and layer 5. Standardizing data collection, data curation and data analysis is a key component of a survey. Here we present our efforts to normalize data collection across multiple two photon instruments, operators and live animals. In particular, we describe how we balanced automation of both data collection and data curation with standardized operating procedure (SOPs). In addition, as any systems neuroscience experiment, we needed to synchronize and monitor a large number of data streams: two photon movies, visual stimulation movies, eye tracking movies, animal body movies as well as numerous associated meta-data. To that end, we built an automatic reporting system that monitor more than 100 parameters across all data streams recorded during each experiment. We eventually converged to a subset of parameters that allowed us to track individual experiments efficiently. Experimental bias in data curation is another key issue in systems neuroscience. Traditionally, as these experiment are technically challenging, most studies have relied on a low number of animals and experiments to report their findings. Here we

leverage our large dataset (353 experiments) to explore how our criteria for data curation affected visually evoked responses.
Overall, our current platform allowed to collect as many as 50 experiments per week without any backlog in data curation. For this survey, we recorded more than 40,000 neurons in 35 animals across 17 locations (area, layer, and cre-line). This dataset provides a unique opportunity to relate visually evoked activity across 4 different visual areas: V1, AL, LM, PM and will be extended in future data releases.

KOCH; Allen Inst. for Brain Sci., Seattle, WA

Abstract: The Cortical Activity Map project is a physiological survey of neural activity in the visual cortex during sensory stimulation in awake behaving mice. By systematically measuring visual responses from neurons sampled from selected brain areas, cortical layers, and Cre lines harboring cell-specific activity reporters (GCAMP6), a rich dataset has been created. This serves as a resource for quantitative exploration of the functional properties that underlie coding of sensory stimuli through the visual pathway, at both the single-cell and population level. Experimental results from standardized image acquisition, combined with models of cortical

computation, have been generated using a robust, scalable laboratory methodology and neuroinformatics processing workflow. Unionized data formats facilitate visualization and accessibility of data, that is open to the community via the ALLEN Brain Atlas web portal. The project product includes primary sources of data derived from reflectance-based intrinsic signal imaging (ISI) and single neuron response properties measured by 2-photon calcium imaging, accompanied by metadata capturing animal state during engaged or passive visual stimuli. The cellular responses to a wide array of visual stimuli are presented in a novel organization that permits aggregated analysis of single and group populations as a comprehensive survey of visual activity. Anatomical registration of data into a common coordinate framework utilized by other standardized, high density datasets allows for exploration of relationships across anatomical, connectional and genetic axes. Expansion of this dataset is ongoing, and will ultimately include simultaneous activity measurements in response to visual stimuli, sampled from genetically defined cell types in multiple anatomically relevant areas, compounded with behavioral task engagement. Together, the data and its cross-modal integration will provide a community resource to elucidate how distinct features of the visual world are encoded.

Title: Development of customized instrumentation for standardized, high-throughput *In vivo* imaging and analysis.

Authors: ***T. M. KEENAN**, J. PERKINS, D. SULLIVAN, T. SIUDA, R. DIETZMAN, D. WILLIAMS, P. HARGRAVE, C. SLAUGHTERBECK, P. GROBLEWSKI, J. LECOQ, N. GAUDREAULT, C. FARRELL;
Allen Inst. for Brain Sci., Seattle, WA

Abstract: The Allen Institute for Brain Science is pursuing a multi-methodological approach to understanding brain function and how it is engendered through molecular mechanisms, morphology, local and long-range connectivity, and neural coding. The upcoming Cortical Activity Map (CAM) product elaborates the coding of visual information within primary and higher-order mouse visual cortex using in vivo single cell responses to diverse visual stimuli in different cell types, layers, and functional regions. When paired with a visual system-focused connectivity atlas created through the Next Generation Connectivity (NGC) project, the neuroscience community can more effectively explore how different forms of visual information are interpreted and parsed within the mouse visual system.
The generation of coding and connectivity data that can be effectively compared and subsequently correlated with other data modalities being pursued at the Allen Institute requires the development of an integrated suite of tools, imaging instruments, and cross-platform systems. Here we detail the design and implementation of those tools, instruments, and systems and how they have enabled efficient, large-scale data collection with novel levels of standardization and statistical reproducibility.

Title: Cascade Models of Cortical Activity Map based on structural connectivity

Authors: *R. IYER, N. S. GRADDIS, S. DE VRIES, J. A. HARRIS, M. A. BUICE, S. MIHALAS;
Allen Inst. For Brain Sci., Seattle, WA

Abstract: It is traditional for models in vision to link the activity of the neuron to the visual stimulus presented. However, as many cortical neurons are several synapses away from the visual input, how to express and parameterize all these transformations into a simple model remains unsolved. We have developed a cascade model of V1 neurons in mouse visual cortex which is based on priors of separation of the visual inputs into predetermined ON and OFF channels, which allows us to combine two linear-nonlinear stages. This model resulted in an improvement in the capacity of the model to explain the activity of individual neurons, but it

makes little use of the structural knowledge, and there is an expectation that each additional stage introduces a nonlinearity. At the Allen Institute for Brain Science, we recently performed measurements of the mesoscopic structural connectivity of the mouse brain (ALLEN Mouse Brain Connectivity Atlas). We combine the data from the inter-regional connectivity model constructed from this data with prior data from the literature to generate a set of hypotheses as to the most likely sources of feedforward information from the other populations. Recent unprecedented measurements of *in vivo* activity in the ALLEN Cortical Activity Map allows us to map activity at a large number of intermediate stages in mouse visual pathways. To characterize the responses we compare two strategies: In the first strategy the responses of neurons for each population are linked directly to the stimulus input. This is realized using either a standard generalized linear model, or by employing a two stage cascade model. We characterize the responses and generate a set of filters using this method. In the second strategy, we characterize subsequent populations (e.g. L2/3 in V1) using the generalized linear or cascade model of the previous population. Such a strategy will potentially allow us to climb on the structurally defined hierarchy of the visual cortex, building one stage at a time as the data from the Cortical Activity Map pipeline becomes available. This will allow us to analyze the similarities between the structural hierarchies and changes in neuronal code.

Title: Highly conserved functional boundaries of the visual cortex are observed using standardized methods for intrinsic signal imaging in a broad survey of the mouse visual cortex

Authors: ***N. GAUDREAULT**, S. CALDEJON, F. GRIFFIN, E. KENJI LEE, M. GARRETT, J. ZHUANG, P. GROBLEWSKI, K. HIROKAWA, J. HARRIS, W. WAKEMAN, F. LONG, L. NG, C. SLAUGHTERBECK, T. KEENAN, C. FARREL, J. PHILLIPS, H. ZENG, A. BERNARD;
Allen Inst., Seattle, WA

Abstract: The Allen Institute for Brain Science is conducting in-depth surveys of the mouse visual system, to better understand the components and computations of the mammalian brain. To evaluate the functional topography of the mouse visual cortex we developed a standardized

imaging platform that provides highly reproducible cortical maps. We used intrinsic signal imaging (ISI) to measure the changes in hemodynamic response to visual stimuli to generate maps of functionally defined visual areas. These maps were subsequently used to target specific visual areas in mice that were part of larger surveys to evaluate brain structure and function. Our recent efforts to expend the ALLEN Mouse Brain Connectivity project utilized ISI-derived retinotopic and sign maps to target injections of anterograde or retrograde viral tracers into functionally identified locations within primary and higher visual cortical areas. The Cortical Activity Map project is a survey of visual responses at the cellular level, and utilized the ISI-derived cortical maps to guide 2-photon calcium imaging experiments in functionally receptive retinotopic locations in primary and higher visual areas. To achieve standardized data acquisition across all experimental platforms, mice were fitted with a custom head frame designed to ensure accurate spatial registration within and between imaging systems. Retinotopic maps were generated in response to a visual display of drifting bar stimuli containing flickering checkerboards, swept along the four cardinal directions, under light anesthesia. Cortical area boundaries were delineated using an automated segmentation algorithm, and maps curated based on stringent criteria to ensure data quality. Over 400 ISI image sets were acquired, from over a dozen transgenic mouse lines. Based on this vast amount of standardized data, we compared visual area organization across multiple experimental variables, including surgical preparation, early adult development in male and female animals, and across multiple transgenic lines. Using metrics extracted from the segmented maps we characterized the variability in number of identifiable visual areas, boundary position, area size and visual field coverage for primary and higher visual areas. Overall we found highly reproducible topography of specific visual fields across multiple experimental conditions and Cre lines, with some notable differences. The ISI map data that was generated for these surveys has been evaluated for quality standards, quantitatively standardized, informatically processed for display in a spatially annotated 3D common coordinate framework, and is now made publically available.

Abstract: The Allen Institute for Brain Science has embarked on a major new project to study mouse cortical activity during sensory stimulation and behavior. This study systematically measures visual responses in different cortical areas using two-photon calcium imaging of GCaMP6-labeled neurons targeted using Cre driver lines.
We present here the Allen Cortical Activity Map Data Portal, a data resource for understanding and modeling, coding and processing of visual information by characterizing single cell visual response properties such as orientation, spatial and temporal frequency tuning, temporal dynamics and spatial receptive structure and how they correlate with cortical areas, layers and Cre-lines. The use of common Cre-lines and registration to the Allen Common Coordinate Framework permits the integration of information from the Allen Mouse Connectivity Atlas and the Allen Cell Types Database towards understanding how the components of the cortex (circuits and cell types) give rise to functional visual response properties.
All data, including tools for search and analysis, is freely available via the Allen Brain Atlas data portal (brain-map.org). Raw and time series data can be downloaded through the Allen Brain Atlas API in Neurodata without Borders (NWB) format. Additionally, the accompanying Allen SDK provides example source code and functions to foster community use and analysis of this dataset.

Title: Developmental origin of the function & circuits organization in the mouse visual cortex

Authors: *Y. LI[1], Y. DAN[2];
[1]ZIINT, Interdisciplinary Inst. of Neurosci. and Te, Hangzhou, China; [2]Univ. of California at Berkeley, Howard Hughes Med. Inst., Berkeley, CA

Abstract: Recently, a clonal-functional relationship has been established in the mouse visual cortex (V1), such that clonally related neurons ("sister cells") shared similar orientation preference despite apparent "salt-and-pepper" organization of rodent V1 (Li et al 2012; Ohtsuki et al 2012). Interestingly, the functional similarity between sister cells observed in Ohtsuki et al (2012) was weaker than Li et al (2012), suggesting that cell lineage might not the only determinant of response selectivity. Li et al (2012) found great similarity in animals that were imaged shortly after eye opening (postnatal days 12-17 [P12-17]), whereas Ohtsuki et al (2012) observed more diversity in preference in older animals (P49-62), indicating the possible impact of visual experience. However, several differences in methodology make it difficult in reconciling the results from these two studies. For example, the embryonic stage when the progenitors were labeled is different. In addition, the number of labeled cells per clone cluster is also different: The study by Li et al study, using in utero injection of GFP-expressing retrovirus at late stages of neurogenesis (E14-16), usually labeled a small number of neurons cluster per clone (<10 in most cases). The study by Ohtsuki et al, using a Cre-driver mouse line to label sister cells, can labeled ~600 cells derived from a common progenitor cell at the beginning of the neurogenesis (~E11). In order to explore the role of experience in specifying response properties of clonally related V1 neurons, we made in utero injection of GFP-expressing retrovirus at earlier embryonic stage (E11-12) & compared the functional similarity of orientation preference in sister cells between different age groups. Injection of retrovirus at earlier stage resulted in labeling a larger size of clones. Our goal is to use two-photon calcium imaging & in vivo circuit mapping method in order to understand the functional significance of circuits reorganization among sister cells in V1 & clarity the extent to which visual experience impact the patterns of connections & response properties that are specified by cell lineage.

Title: Dependence on visual features, running speed and virtual speed across the mouse visual cortex

Authors: *E. M. DIAMANTI, A. B. SALEEM, K. D. HARRIS, M. CARANDINI;
Univ. Col. London, London, United Kingdom

Abstract: During navigation based on visual cues, the activity of neurons in mouse primary visual cortex (V1) is influenced by at least three factors: (1) the visual features of the environment; (2) the visual speed generated by self-motion, and (3) the animal's running speed. It remains unknown, however, whether the weighing of these three factors differs across V1, and whether it is different in higher visual areas.

To answer this question we placed mice in a virtual reality environment and measured calcium signals from broad portions of visual cortex using widefield imaging and two-photon microscopy. Transgenic mice expressing GCaMP6f in cortical pyramidal cells were head-fixed and free to run on a linear treadmill. We tested three conditions. In the first condition ("closed-loop") animals traversed a virtual corridor containing four prominent visual landmarks, and the speed of the corridor (virtual speed) matched the animal's running speed. In the second condition ("open-loop") we replayed previous sessions to the animal regardless of its behavior. In the third condition we measured responses in the dark.

Widefield imaging data showed that the dependence of visual responses on virtual speed differed between V1 regions devoted to the upper and lower visual field. In closed-loop, responses in upper-field V1 regions were more strongly modulated by speed than lower-field V1 regions. To assess whether the effect of speed was mediated by running or virtual speed, we turned to the open-loop condition. Activity in upper-field V1 regions was strongly modulated by running speed and minimally affected by virtual speed. The effect of running speed was prominent even in the dark, where it strongly modulated responses all across the visual field.

Preliminary analysis of single-neuron responses in V1 and higher visual areas using two-photon microscopy shows that responses of up to 50% of recorded neurons are well predicted by the position of visual landmarks and speed. We are investigating whether single neurons in different regions of V1 and higher visual areas also differ in the way they combine visual with non-visual features.

Our data suggest that when a mouse moves through an environment with visual cues, responses in V1 are modulated differentially, depending on receptive field location.

Title: Serotonergic modulation of visual response properties in awake mouse primary visual cortex

Authors: *A. MICHAIEL, C. NIELL;
Inst. of Neurosci., Univ. of Oregon, Eugene, OR

Abstract: The neurophysiological mechanisms underlying aberrant sensory processing observed in schizophrenia and psychosis are poorly understood. The serotonin $5HT_{2A}$ receptor has been implicated in these psychopathologies and is thought to underlie symptoms such as sensory hallucination. Additionally, administration of $5HT_{2A}$ agonists causes sensory hallucinations. However, the neuromodulatory effects of serotonin on visual processing at the level of single neurons and populations of neurons is poorly understood. Using single-unit extracellular recordings with multi-site silicon probes in awake mouse primary visual cortex (V1), we characterized changes in cortical dynamics across layers in response to pharmacological manipulation of serotonin $5HT_{2A}$ receptors. Additionally, using optogenetic tagging, we identified neurons expressing the $5HT_{2A}$ receptor, allowing us to characterize response features of this neural subpopulation, as well as to separate the direct effects on $5HT_{2A}$ expressing neurons from indirect effects on downstream neurons. The hallucinogenic $5HT_{2A}$ agonist, DOI (2,5-Dimethoxy-4-iodoamphetamine), yielded bidirectional changes in firing rates, layer-specific changes in response properties, and decreases in correlated activity across populations of neurons. Co-administration of ketanserin, a $5HT_{2A}$ antagonist, with DOI abolished these changes. Ketanserin alone had little effect on neural activity in V1. Our data shows that activation of $5HT_{2A}$ receptors modulates visual processing at the level of single neurons and across populations of neurons.

Title: Dissecting functional organization of mouse visual cortex

Authors: ***M. HU**[1], R. V. RIKHYE[1], M. J. GOARD[2], M. SUR[1];
[1]Picower Inst. for Learning and Memory, MIT, Cambridge, MA; [2]Biol. Sci. II, Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Although it is known that mice have roughly ten distinct visual areas, the specific function of each area and interactions between areas remain poorly understood. In this study, we used both wide-field and single-cell calcium imaging from awake, head-fixed mice, which transgenically expressed GCaMP6f, to functionally segment the entire visual cortex. First, to identify the gross organization of the visual areas, we performed retinotopic mapping using a custom-built wide-field epi-fluorescence microscope. Next, we characterized the responses of neurons within each segmented area to drifting gratings with various directions and spatial temporal frequencies. Within V1, we found a gradient of bias of averaged peak orientation (from vertical to horizontal orientations) along binocular to monocular axis. We also found systematic variations in averaged peak spatial and temporal frequencies along the same axis. The averaged peak temporal frequency in area LM exhibit a similar distribution (a mirror of V1) in visual space, indicating its role as the second visual area along the feedforward visual pathway. These results suggest that the different visual areas are sensitive to different visual features. To further test this hypothesis, we perturbed either the phase or the amplitude content of natural movies. The phase spectrum of natural movies contains information about salient image features, such as edges; whereas the amplitude spectrum contains low-level information, such as luminance. Interestingly, we found that medial regions (such as medial posterior part of V1 and posterior part of PM) were more selective to phase, while lateral regions (such as lateral anterior part of V1 and AL) were more selective to the amplitude spectrum. Together, our results reveal that mouse visual cortex has organized representation of different visual features, which is globally extended through an entire set of areas. This distribution may already present in V1 and further elaborated in different higher visual areas.

Title: Functional diversity of VIP interneurons in mouse primary visual cortex

Authors: *E. RICHLER, E. M. CALLAWAY;
Salk Inst. SNL-C, La Jolla, CA

Abstract: Activity in the cerebral cortex is in continuous balance between inhibition and excitation. Many subtypes of inhibitory interneurons exist, each with unique roles in cortical function. Almost all interneurons can be classified based on their expression of one of the three major non-overlapping neural markers parvalbumin, somatostatin, and the 5HT3a receptor. Further subdivisions are possible based on additional molecular markers, function, and morphology. Vasoactive intestinal peptide (VIP) expressing interneurons, which represent one such subdivision within the 5HT3aR group, have been recently found to mediate cortical disinhibition, and to play a role in state-dependent neural activity in the cortex. However, there is evidence to indicate that VIP neurons do not comprise a uniform group, and it is unclear if all VIP neurons behave similarly. Here we address this by studying whether the recently observed effect of locomotion on VIP neurons differs based on factors such as cortical depth and additional neural markers. We are using VIP-Cre mice and Cre-dependent AAV vectors to target GcaMP6 expression to VIP neurons across cortical layers of mouse V1. Using in vivo calcium imaging we have found that locomotion affects the activity of nearly all VIP neurons, but that these effects vary. Most VIP neurons show increased activity with locomotion, but a few show a decrease, and there appears to be a layer bias in the magnitudes of the increases. We are also conducting immunostaining post hoc to identify VIP neurons that express other neural markers such as calretinin. Taken together, these experiments will reveal and stratify functional diversity among VIP interneurons.

Title: Functional *In vivo* connectivity of Vasoactive Intestinal Peptide expressing inhibitory interneuron subtypes in mouse visual cortex

Authors: *A. GARG[1,2], A. E. CASALE[1], E. M. CALLAWAY[1];
[1]Salk Inst. For Biol. Studies, LA Jolla, CA; [2]Neurosciences Grad. Program, UCSD, La Jolla, CA

Abstract: Knowing the characteristics and connectivity patterns of different cell types, and their functional impacts *in vivo* is necessary for understanding functional cortical circuits. Inhibitory GABAergic neurons play an important role in increasing the functional capabilities and diversity of cortical circuits. A subset of these neurons expressing vasoactive intestinal peptide (VIP) is recruited during specific behavior in mice, such as running. These cells preferentially inhibit somatostatin (SOM)-expressing neurons in mouse neocortical layer 2/3 of the primary visual cortex (V1). Previous *in vitro* work from our lab has demonstrated that VIP neurons can be separated into two distinct subsets based on their expression of calretinin (CR): VIP+/CR+ and VIP+/CR-. Each of these subsets preferentially targets different neurons. VIP+/CR+ neurons, which make up approximately 40% of the VIP-expressing population, target SOM+ cells.
We aim to study the effects of activation of these two subsets of neurons *in vivo* in order to better understand the circuit mechanisms at play. To address this question, we utilized Flp and Cre mouse lines (CR-Cre/VIP-Flp) and an intersectional adeno-associated virus (AAV) that expresses Channelrhodopsin-2 (ChR-2) under the control of Flp and Cre recombinases. After separating the VIP neuron population into VIP+/CR+ and VIP+/CR- subpopulations, we performed extracellular electrophysiological recordings in V1 of awake, behaving mice using silicon high-density electrode arrays. Due to the role of VIP and SOM-expressing neurons in orientation tuning and surround suppression, mice were shown several different visual stimuli, including gratings of differing orientations, size, and spatial frequency. Neuronal responses were sorted into clusters and responses were separated by cortical depth to investigate whether any of the functional circuit effects are layer-dependent.

Title: Response profiles of a neuronal population excited by intracortical microstimulations in the mouse visual cortex

Authors: *N. SUEMATSU[1,2], K. TAKATANI[1], Y. HAYASHIDA[1], Y. OKAZAKI[2], T. YAGI[1,2];
[1]Grad. Sch. of Engin., [2]Global Ctr. for Med. Engin. and Informatics, Osaka Univ., Osaka, Japan

Abstract: An intracortical visual prosthesis, which is one of the possible approaches for restoring vision in blind patients, is based on the observations that electrical stimulation applied into visual cortices evoked light perceptions in the patients in accord with the retinotopy. However, previous studies on human and monkey suggested that the minimum stimulus intensities evoking the light perception were unpredictable; sometimes repetitive stimulus current pulses of only a few microamperes in amplitude were enough, but sometimes the amplitude of several tens of microamperes was needed. In order to study if the electrical stimulation can reliably excite the cortical neurons, we recorded populational neuronal responses induced by microstimulation (200-μs biphasic pulse; 5-80 μA/phase) with an in-line multi-channel electrode (Ir-Ox tips; 10-30 kΩ at 1 kHz; MicroProbes, MD, US) inserted in the primary visual cortex (250 μm deep from the surface) of the C57/BL6 mice (n = 5) by utilizing a voltage-sensitive dye imaging technique. We quantified the stimulus-induced excitatory responses with the Naka-Rushton function: $R_{max}I^n/(I_{50}{}^n+I^n)$; where the response amplitude is described as a function of the stimulus intensity 'I', the maximum response amplitude 'R_{max}', the stimulus intensity that induces half-maximum response amplitude 'I_{50}', and the slope constant 'n'. We found that measurable responses were able to be induced by only 10 or 20 μA/phase of the "single-pulse" stimulus, and its peak amplitude was fitted by the Naka-Rushton function with I_{50} = 22/15-25 μA/phase and n = 3.0/2.5-3.4 (median/1st-3rd quantiles, n = 10), suggesting that the neuronal excitation is reliable and the stimulus threshold can be lower than the perceptual one. When the stimuli were simultaneously applied through 300-μm-separated tips of the electrode, the response at the in-between point was equal to, or smaller than, the linear summation of the responses induced by the single-electrode stimulation, even in the rising phase of the response at which a

synaptic inhibition did not take place. Our findings will provide essential information for characterizing the cortical activation pattern induced by multi-site microstimulation, and thus for understanding the phosphene perception in visual prostheses.

Title: Spatial clustering of tuning in mouse primary visual cortex

Authors: ***D. L. RINGACH**[1], P. J. MINEAULT[2], E. TRING[2], N. D. OLIVAS[3], P. GARCIA-JUNCO-CLEMENTE[3], J. T. TRACHTENBERG[3];
[1]Neurobio. & Psychology, [2]Neurobio., UCLA, Los Angeles, CA; [3]UCLA Neurobio., Los Angeles, CA

Abstract: The primary visual cortex of higher mammals is organized into two-dimensional maps, where the preference of cells for stimulus parameters is arranged regularly on the cortical surface. In contrast, the preference of neurons in the rodent appear to be arranged randomly, in what is termed a salt-and-pepper map. Here we revisited the spatial organization of receptive fields in mouse primary visual cortex by measuring the joint tuning of pyramidal neurons in the orientation and spatial frequency domain. We found that the similarity of tuning decreases as a function of cortical distance, revealing a weak but statistically significant spatial clustering. Clustering was also observed across different cortical depths, consistent with a columnar organization. Thus, mouse visual cortex is not strictly a salt-and-pepper map. At least on a local scale, it resembles a degraded version of the organization seen in higher mammals, hinting at a possible common origin.

Title: Common adaptive dynamics in somatosensory and visual cortex of mice

Authors: *N. J. PRIEBE[1], Y. KATZ[2], B. LI[3], I. LAMPL[2];
[1]Univ. Texas, Austin, Austin, TX; [2]Weizmann Inst. Of Sci., Rehovot, Israel; [3]UT Austin, Austin, TX

Abstract: In our natural environment, the intensity of sensory stimuli vary greatly - over several orders of magnitude - surpassing the dynamic range of neurons. Yet our sensory systems are able to convey sufficient information to guide appropriate behaviors. Sensory neurons accomplish by dynamically adjusting their operating points in the face of changing contexts. We take a comparative approach to uncover the dynamics of sensory adaptation across the neocortex by studying the responses to brief (20 ms), discrete stimuli in somatosensory cortex (S1, whisker deflection) and visual cortex (V1, light flash). To reveal the timecourse of adaptation we performed whole cell recordings in S1 and V1 while presenting these brief stimuli at different frequencies. Low frequency sensory stimulation, less than 2 Hz, evokes complex, biphasic responses lasting up to 500 ms. As stimulation frequency increased the response duration to a single stimulus becomes faster and the amplitude was dramatically attenuated. Both S1 and V1 responses decline dramatically average, such that the response to a single stimulus at 10 Hz is only 12% of the response at 0.5 Hz. We also uncovered a large, frequency-dependent response at the end of the sensory stimulation. The peak of the "off" response occurs between 250 and 800 ms following the end of the stimulation. The latency of the off response appears to be related to the amount of adaptation expressed in individual neurons. To determine whether this off response might occur to detect changes in input statistics we played 10 Hz stimulus trains in which one or two of the stimuli were absent. These "oddball" stimulus conditions evoked large response in sensory neurons to the stimulus absence, similar to the response we observe at the end of high frequency stimulation. As both V1 and S1 neurons were characterized by the off and oddball responses, these responses may be reflect a general adaptive process to signal changes in our environment instead of the actual environment.

Title: All-optical interrogation of functional connectivity in mouse visual cortex

Authors: *L. E. RUSSELL, A. M. PACKER, H. W. P. DALGLEISH, M. HAUSSER; Wolfson Inst. for Biomed. Res., Univ. Col. London, London, United Kingdom

Abstract: Visual cortex neurons sharing similar receptive fields are more likely to form monosynaptic connections, creating highly interconnected sub-networks (Ko et al 2011). This organisation of preferential connections forms a functional network architecture that could enable pattern completion of degraded or weak input. To make causal links between connectivity and activity patterns during pattern completion, the ability to simultaneously manipulate and record the activity of multiple neurons with cellular resolution in vivo is critical. Recently we developed a new strategy for performing simultaneous two-photon optogenetic activation and calcium imaging by co-expressing C1V1, a red-shifted opsin and GCaMP6, a genetically encoded calcium indicator (Packer et al 2015). A spatial light modulator allows multiple user-selected neurons to be targeted for spatiotemporally precise optogenetic activation, while simultaneous fast calcium imaging provides high-resolution network-wide readout of the manipulation. Here we present a number of enhancements we have made to this toolkit that further increase its utility in probing functional connectivity in mouse visual cortex. First, we determine interneuron subtype identity by transgenic expression of an additional fluorescent marker. Next, through the use of custom chronic optical windows, we enable pharmacological intervention during all-optical experiments. After functionally characterising the network, ensembles of similarly, or randomly, orientation-tuned cells are selected for controlled photostimulation and the local network response is recorded while delivering sub-optimal visual stimuli to mice in various behavioural states. This approach enables us to probe the functional connectivity, and in particular the potential for pattern completion, of layer 2/3 mouse visual cortex.

Title: Enhanced spatial resolution during locomotion and heightened attention in mouse primary visual cortex

Authors: ***P. J. MINEAULT**[1], E. TRING[1], J. T. TRACHTENBERG[2], D. L. RINGACH[2]; [1]Neurobio., UCLA, Los Angeles, CA; [2]UCLA Neurobio., Los Angeles, CA

Abstract: We do not fully understand how behavioral state modulates the processing and transmission of sensory signals. Here we studied the representation of the retinal image in mice that spontaneously switched between a state of rest and a constricted pupil, and one of active locomotion and a dilated pupil, indicative of heightened attention. We measured the selectivity of neurons in primary visual cortex for orientation and spatial frequency, as well as their response gain, in these two behavioral states. Consistent with prior studies, we found that preferred orientation and spatial frequency remained invariant across states, while response gain increased during locomotion relative to rest. Surprisingly, relative gain, defined as the ratio between the gain during locomotion and the gain during rest, was not uniform across the population. Cells tuned to high spatial frequencies showed larger relative gain compared to those tuned to lower spatial frequencies. The preferential enhancement of high spatial frequency information was also reflected in our ability to decode the stimulus from population activity. Finally, we show that changes in gain originate from shifts in the operating point of neurons along a spiking nonlinearity as a function of behavioral state. Differences in the relative gain experienced by neurons with high and low spatial frequencies are due to corresponding differences in how these cells shift their operating points between behavioral states.

Title: Neural adaptation and position tolerance increase along a putative ventral visual pathway in rats

Authors: ***D. KALIUKHOVICH**[1], H. OP DE BEECK[2];
[1]Fac. of Psychology and Educational Sci., [2]Lab. voor Biologische Psychologie, KU Leuven, Leuven, Belgium

Abstract: Most neuroscience techniques target rodents as the primary animal model to study neural circuits. By contrast, primates are seemingly exclusively used to study higher-order perception and, in particular, vision. Recent studies demonstrated commonalities between the visual systems of rats and primates. Here we further test these commonalities and, specifically,

examine how neural adaptation and position tolerance change along a putative ventral visual pathways in rats (Vermaercke et al., 2014). Based on the literature in primates, an increase for both was expected. To test this, we recorded multi-unit extracellular spiking activity in primary visual cortex (V1) and a downstream area LI of head-restrained Long Evans rats. During recordings for each examined multi-unit site we identified two non-overlapping positions within its receptive field and then probed the activity of that site with 3 different stimuli evoking a strong, an intermediate and little response, respectively. We tested 15 stimulus conditions that were presentations of a single stimulus at either position ($N = 6$) and presentations of either two identical ($N = 3$) or two different ($N = 6$) stimuli in all combinations at the two identified positions. Stimulus conditions were delivered to the animals in sequences ($N = 10$), with each sequence including all possible pairwise transitions between the tested conditions ($N = 226$ presentations). Each stimulus condition was presented for 300 ms and separated from each other by a 300 ms long blank inter-stimulus interval. We collected 58 ($N = 4$ rats) and 52 ($N = 3$) multi-unit sites in the areas V1 and LI, respectively. We analyzed the data separately for the early (25-175 ms relative to stimulus onset) and late (175-325 ms) phases of the neural response. Neural adaptation was present in each of the 2 areas. We observed no difference in the degree of adaptation across the 15 conditions in either brain area and response phase. Yet, the area LI showed a significantly ($p < 0.05$) higher degree of adaptation than V1 (67% vs. 33%) for both response phases. The latter held true irrespective of the response strength to the adapter stimulus ($p < 0.05$). We found significant position tolerance (preservation of stimulus selectivity across the two positions, $p < 0.05$) only for the early phase of the neural response in the area LI but not for either response phase in V1. Importantly, we failed to reveal position tolerance in V1 despite increasing the sensitivity of our tests. To conclude, our results (*increase in neural adaptation and position tolerance*) parallel those of primates. As thus, this provides further evidence in support of the use of rats as an animal model to study the visual system.

Title: Modulation of V1 neurons activity by the lateral-posterior nucleus in mice.

Authors: *U. KEYSAN, N. CORTES, S. THOMAS, C. CASANOVA;
École d'optométrie, Univ. de Montréal, Montreal, QC, Canada

Abstract: In mammals, information about the visual world reaches the primary visual cortex (V1) via the lateral geniculate nucleus. Subsequently, through cortico-cortical connections, specific aspects of the visual scene are processed by higher visual areas. In conjunction with this hierarchical organization, there is a complex network of bilateral connections between visual cortices and the pulvinar, considered as the largest extrageniculate visual thalamic nucleus. Despite an increasing number of studies on pulvinar and associated pathways, the exact function of this thalamic complex remains unknown. In this study, we investigate the functional impact of the lateral posterior (LP) nucleus (homologue of the primate pulvinar) on the activity of V1 neurons in mice using optogenetic stimulation. LP nucleus of transgenic mice expressing Channelrhodopsin-2 under Thy-1 promoter (strain : B6.Cg-Tg (Thy1-COP4 / EYFP) was stimulated by light pulses (470 nm, 20 pulse trains of 5 ms each at 10 Hz) delivered by an optical fiber. Extracellular recording of the activity of V1 neurons was performed using tungsten electrodes. Visual stimuli consisted in moving bars and drifting sinewave gratings of varying parameters (direction, contrast, spatial or temporal frequency and size). Preliminary data show that a subset of V1 neurons could be directly activated by the photostimulation of the LP nucleus. In contrast, when LP stimulation was performed in association with visual stimuli, neural responses were decreased by 30 % in average. Further, the response profiles of V1 neurons to size-increasing stimuli were affected by the photostimulation of LP. In summary, these preliminary data suggest that the LP nucleus can exert a contextual modulation of the activity of neurons in the mouse primary visual cortex.

Title: Understanding neural representations in early visual areas using convolutional neural networks

Authors: *Y. ZHANG[1], C. MASSOT[1], T. ZHI[2], G. PAPANDREOU[3], A. YUILLE[3], T. LEE[1]; [1]Ctr. for the Neural Basis of Cognition and Computer Sci. Dept., Carnegie Mellon Univ., Pittsburgh, PA; [2]Peking Univ., Beijing, China; [3]UCLA, Los Angeles, CA

Abstract: We compared the neural representations of population of macaque V1 and V2 neurons in response to visual stimuli of different degrees of complexity with model representations of AlexNet (a convolutional neural network) and several models of V1 and V2. We found that AlexNet matched the neural data better than others, particularly for complex stimuli. Our analysis showed that it matched better because of (1) normalization and nonlinear pooling mechanism, and (2) more complex and diverse stimulus preference. Among all layers of AlexNet, the first pooling layer matched V1 neurons the best in terms of individual tuning as well as population representation, and the second pooling layer matched V2 neurons the best. We visualized the preferred features of the units corresponding to real neurons using deconvolutional networks and found that some V1 neurons could not be described by simple Gabor filters, and that some V2 neurons appeared to encode more complex surface structures such as textures. These findings suggest that V1 and V2 neurons might have more complex codes than previously thought.

Title: Tracking neurochemical and BOLD-changes in the human visual cortex using simultaneous short echo semi-LASER spectroscopy and BOLD-imaging at 7 Tesla

Authors: *B. IP, A. BERRINGTON, A. T. HESS, A. J. PARKER, U. E. EMIR, H. BRIDGE; Univ. of Oxford, Oxford, United Kingdom

Abstract: Magnetic resonance imaging using the blood-oxygenation-level-dependent response (BOLD-fMRI) is the technique of choice for non-invasive, high spatial resolution measurement

of human brain activity. Proton magnetic resonance spectroscopy (^{1}H-MRS) can be used to quantify neurochemical concentrations, both at rest and during brain activity. Combining BOLD-fMRI with ^{1}H-MRS provides insight into the neurochemical changes during brain activity. However, successful combination of these measurements must address two issues: 1) the BOLD-response affects ^{1}H-MRS spectra, causing artefactual changes in signal that limit the interpretability and strength of metabolite quantifications; 2) BOLD-fMRI and ^{1}H-MRS measurements must be collected simultaneously to support a direct comparison. Previous ^{1}H-MRS studies have corrected for BOLD-induced artefacts using estimates of spectral line narrowing, and collected BOLD-fMRI and ^{1}H-MRS data in separate scans. Here, we acquired short echo semi-LASER ^{1}H-MRS and BOLD echo planar imaging (EPI) data in the same time volume at 7T. Participants viewed 64-sec stimulus blocks of a flickering checkerboard alternating with a blank screen. Correction for the BOLD-response was achieved by measuring subject specific T2* changes using the unsuppressed water signal, and by correcting metabolite data for BOLD-induced spectral line narrowing. After BOLD-correction, LCModel quantification detected differences between stimulation and rest periods in multiple metabolites, most notably significant increases in glutamate (2.27 % ± 0.69 s.e.m., $p < 0.01$) and glutamate + glutamine (3.38 % ± 0.89 s.e.m., $p < 0.01$), consistent with previous studies using prolonged visual stimulation. We also found a significant correlation between glutamate and BOLD-fMRI time courses ($r = 0.56$, $p = 0.001$). Here we demonstrate the feasibility of simultaneous ^{1}H-MRS and BOLD-fMRI at 7 T to track dynamic neurotransmitter and BOLD-changes using stimulation blocks of 64-sec, a time scale well suited to the study of human brain function.

Title: Sparse and distributed codes of neuronal population in primary visual cortex

Authors: *Z. LI[1], Y. ZHANG[1], M. LI[2,3], F. LIU[2,3], H. JIANG[2,3], T. LEE[1], S. TANG[2,3];
[1]Ctr. for the Neural Basis of Cognition and Computer Sci. Dept., Carnegie Mellon Univ., Pittsburgh, PA; [2]Sch. of Life Sci. and Peking-Tsinghua Ctr. for Life Sci., Peking Univ., Beijing, China; [3]IDG/McGovern Inst. for Brain Res. at Peking Univ., Beijing, China

Abstract: Large-scale Ca imaging in neurons in the superficial layer of V1 in awake behaving monkeys (Tang et al. 2015) showed that the rigorous responses of the neural population are extremely sparse, only 0.5% of the 1225 neurons that can be activated by a large set of natural images will respond to a given image at each trial at a magnitude that is greater than half of its peak response. These neurons did exhibit weak and moderate responses to a larger set of stimuli. To understand the amount of the image information is encoded in the strong sparse responses and the amount encoded in the weak responses, we perform decoding analysis of the neural signals. We applied K-Nearest Neighbor classifier to do decoding experiments. Every time we use some of the repeated trails in the Ca imaging dataset to train and do test on the left out trails, and report the accuracy as the average of all experiments. The basic finding is that the responses of 0.5% of the neurons help to achieve almost 50% of the achievable accuracy. Important to emphasize that different sets of 0.5% are activated for different images. But almost 50% of the accuracy is help achieved by the weak responses of the other 99.5% of the neurons as distributed codes. This suggests each V1 neuron serves as a specialist, encoding specific feature with rigorous response, as well as a generalist, participating in population coding of a large set of stimuli using weak or moderate responses.

Title: Tuning similarity predominates over retinal or cortical proximity in accounting for the correlated spontaneous activity in human visual cortex

Authors: *J. RYU, S.-H. LEE;
Dept. of Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: The brain perceives and acts on the environment by recruiting a large pool of neurons, which are often far apart but act in concert, affecting animal or human sensory, motor, and cognitive behavior. Intriguingly, these large-scale activities are far from random, exhibiting robust patterns of correlation in the absence of stimulation or task. Thus, for understanding the neural processes substantiating a given cognitive function, it is important to identify what relationships in neural populations contribute, and with what degrees, to the structure of correlated activity. To this end, we used functional magnetic resonance imaging in human visual cortex (V1,V2,V3), and explored systematic patterns that govern the slow correlated activities arising spontaneously. Previous imaging studies reported the resting-state correlation in visual cortex varies as a function of distance between receptive fields ('retinotopic distance') or over cortical surface ('cortical distance'). However, single cell studies have indicated that neuronal activities are correlated among neurons tuned to similar stimulus features ('tuning similarity'). However, it is difficult to tease apart these three factors' contributions to the correlated activities in human visual cortices, because systematic representation of stimulus tuning over the cortical surface imposes interdependency between tuning similarity and spatial proximity. Here, we evaluated the individual contributions of tuning similarity and distance factors to correlated variability in resting-state cortical activity by separating out confounded contributions from other factors. We found that it is the tuning similarity that governs the correlated fMRI activity both within and between early visual areas. The tuning similarity in spatial frequency predominated over the other factors in explaining the correlated activity in V1, and the tuning similarity in orientation did so in V2 and V3. The superiority of tuning similarity factors was most pronounced at short retinotopic and/or cortical distances and held true irrespective of presence or degree of external visual stimulation. Our findings were robust, being replicated in another experiments conducted on a different pool of subjects and surviving an exhaustive set of control analyses, where alternative spatial metrics such as eccentricity or polar angle distances were applied. Our study incorporates and goes beyond previous human imaging studies by demonstrating, for the first time, that slow and large-scale neural co-fluctuations in human visual cortex are intrinsically tuned to visual features.

Title: Quantifying the links between electrical stimulation of the human primary visual cortex, size of affected cortical area, neuronal population activity, and subjective experience

Authors: J. WINAWER[1], *J. PARVIZI[2];
[1]New York Univ., New York, NY; [2]Neurol. and Neurolog. Sci., Stanford Univ., Stanford, CA

Abstract: Focal stimulation of the human cerebral cortex has long been known to elicit, or to interfere with, specific and complex behaviors and experiences, and as such has been a powerful tool for investigating the cortical basis for perception, thought and behavior. However, the spatial extent of cortical tissue affected by electrical stimulation remains unknown. Moreover, responses in the cortex have been characterized as arising from multiple types of neural signaling extending over different spatial scales and ranging from evoked stimulus-locked responses to induced asynchronous broadband activity. Bridging the behavioral and subjective changes elicited by electrical brain stimulation (EBS) with different signatures of cortical activity is essential for developing integrated theories of the structure and physiology of the human brain. Here, we measured different neural responses and the effects of EBS in human primary visual cortex in four patients implanted with intracranial electrodes. By combining stimulation, behavior, and retinotopic mapping in the same subjects, we show the relationship between the size of affected cortical area and the magnitude of electrical charge. Furthermore, we show that the spatial location of electrically induced visual sensations is precisely matched to the spatial receptive field of the cortical site when it is measured with broadband field potentials, and significantly less so with event related potentials. Together, these findings quantify the link between electrical brain stimulation, induced sensory experiences, and neural responses.

Title: Coaxial anisotropy shared between perceptual and cortical point spreads in human visual system

Authors: *J. RYU[1], S. LEE[2];
[1]Brain and Cognitive Sci., Seoul-City, Korea, Republic of; [2]Brain and Cognitive Neurosci., Seoul-City, Korea, Republic of

Abstract: A focal visual stimulus can evoke widespread neural activation far beyond the directly stimulated site referred to as "cortical point spread, CPS" and the lateral connections early visual cortex neurons have been proposed as a likely anatomical conduit. Consistently, studies on humans and non-human primates showed that the CPS spreads preferentially along with the axis of stimulus orientation—'coaxial anisotropy', dovetailing with the bias in spatial extension of horizontal connections. However, it remains unknown whether, and how if so, the coaxial anisotropy in CPS (CAI_C) relates to that in "perceptual point spread, PPS".
We acquired fMRI measurements from the early visual areas of subjects who viewed traveling Gabor arrays. The orthogonal combination of the drifting directions and stimulus orientations created the coaxial and orthoaxial conditions. We quantified CAI_C **(Fig 1B)** and it was robustly observed in all conditions for all the individuals (**Fig 1C**), and yet it varied substantially over individuals (+0 ~ +0.113).
To measure the PPS, we showed subjects a pair of Gabors and asked them to judge which one had a more circular envelope. We could compute the CAI of PPS (CAI_P) identical to that for CAI_C. The CAI_P was positive and showed substantial individual differences (+0 ~ +0.12). More importantly, the CAI_C was correlated with CAI_P over individuals (**Fig 2C**; r=0.873~0.878, V1>V2>V3). Our findings suggest that the CPS in V1 substantiates the perceived spatial spread of oriented stimuli.

Title: Investigating cortical feedback of objects and background scene to foveal and peripheral V1 using fMRI

Authors: *M. BENNETT, L. S. PETRO, L. MUCKLI;
Ctr. for Cognitive Neuroimaging, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: Introduction When discriminating abstract objects isolated in peripheral visual field, object information can be detected in non-stimulated foveal but not peripheral cortex (Williams et al., 2008). Conversely, complex natural scene information can be detected in non-stimulated peripheral cortex (Smith & Muckli, 2010; Muckli et al. 2015). This demonstrates cortical feedback contributions to object and scene representation in V1. Whether object and scene feedback are automatically directed to foveal versus peripheral V1, or if this is due to varying stimulus complexity/naturalism remains unknown. We addressed this question using computer-generated images of objects embedded in naturalistic scenes. **Methods** Nine subjects underwent

block-design fMRI (3T). Eight naturalistic computer-generated images variously combined objects and background scenes (Figure 1). The central portion and upper-right quadrant were occluded, preventing feed-forward stimulation of the ROIs, allowing isolation of feedback signals. Subjects discriminated either the scene or object. Multivoxel patterns (TR 2s; voxel-size $2mm^3$) from the ROIs were entered into support vector machine (SVM) classifiers. Bootstrapping determined above-chance group-level classification. **Results** In fovea (Figure 2), we classified object presence regardless of task (55.7%, 53.8%, collapsing task: 56.5%). Classifying object identity was only possible when collapsing task (55.9%). Also in fovea, we classified scene information during the scene task (56.7%) and when collapsing task (59.5%) but not during object task (52.2%). Therefore, the non-stimulated fovea contains object and task-dependent scene information. In periphery (Figure 3), no object information was detected. We classified scene information during object task (57.4%) and when collapsing task (55.3%), but not during scene task (54.6%). Therefore the non-stimulated periphery contains only scene information. **Conclusions** Our data suggest specialisation in cortical feedback to V1 cortex: scene information is fed-back diffusely to foveal and peripheral V1, whereas object feedback is directed to foveal cortex - possibly for high resolution scrutiny (Williams et al., 2008; Levy et al., 2001).

Title: Population coding in visual cortex underlies visual size perception

Authors: *C. MOUTSIANA[1], B. DE HAAS[2], A. PAPAGEORGIOU[4], N. FINLAYSON[2], D. SCHWARZKOPF[3];
[1]Dept. of Psychology, Kingston Univ. London, Kingston upon Thames, United Kingdom; [2]Exptl. Psychology, [3]UCL, London, United Kingdom; [4]Imperial Col., London, United Kingdom

Abstract: The subjective appearance of visual stimuli varies not only between participants but also across visual field locations. Here we used a newly developed psychophysics method, Multiple Alternatives Perceptual Search (MAPS), that efficiently measures perceptual biases when stimuli are simultaneously presented in different spatial locations. We found that judgments of the size of small visual stimuli are correlated with population receptive field (pRF) sizes in corresponding locations of V1. Our findings thus support a population coding model of size perception in which size is inferred from the spread of visual cortical activation. Bias estimates are very stable when measured dichoptically further corroborating the interpretation that they are at least in part mediated by visual cortex. In control experiments we further show that bias estimates from MAPS are similar to those obtained with traditional psychophysical methods. Finally, cueing spatial attention to a stimulus location enhances the magnitude of perceptual biases at the cued relative to non-cued locations.

Title: Retinotopically-specific variation in cortical thickness in V1 relates to performance on a central visual discrimination task

Authors: *D. LEE, W. K. BURGE, A. S. ELKHETALI, K. M. VISSCHER;
The Univ. of Alabama At Birminghan, Birmingham, AL

Abstract: The anatomy of primary visual cortex (V1) has been hypothesized to relate to visual behavior. Indeed, recent studies have examined the relationship of surface size of V1 to visual performance. However, these studies have not typically addressed the fact that different portions of V1 correspond to different locations within visual space. Anatomical variations across the visual cortex as a whole could give rise to a generalized visual improvement; conversely it could be the case that anatomical variation in V1 influences behavior in a retinotopically-specific manner. In this study, we examine how cortical thickness in segments of V1 corresponding to more central and more peripheral regions of space relate to visual performance in a central vision task.
Anatomical T1 weighted scans of participants (*n*=22) were collected and reconstructed to create regions of interest (ROI) corresponding to segments of V1 with varying visual eccentricity. For

the visual discrimination task, participants were presented with two sequential 500ms Gabor patches of different spatial frequencies and asked to determine which had the higher spatial frequency. Just noticeable difference (JND) thresholds were calculated as the difference in spatial frequency needed for participants to correctly perform the task 70% of the time. Thresholds were correlated with cortical thickness from ROIs for each participant.
We found that thicker V1 correlated to lower JND thresholds ($p < 0.05$), indicating that thicker cortex related to better visual discrimination ability. However, this relationship was specific to ROIs corresponding to central vision. Moving from centrally-representing to peripherally representing cortex, the correlation to behavior decreased. These results show that the thickness of V1 relates to visual behavior in a retinotopically specific way, and are an important step in better understanding experience-driven shifts in cortical thickness.

Title: Visual mental imagery in high-field fMRI

Authors: *M. A. VAN DEN BOOM, M. J. VANSTEENSEL, M. A. H. RAEMAEKERS, N. F. RAMSEY;
Brain Ctr. Rudolf Magnus / Neurol. and Neurosurg., Univ. Med. Ctr. Utrecht, Utrecht, Netherlands

Abstract: Communication Brain Computer Interfaces (BCIs) are developed to allow severely paralyzed people to communicate with the outside world. Using their brain signals to control a spelling device, people should be able to spell letters, words and sentences. An intuitive approach for a communication BCI could be based on visual mental imagery of symbols or letters. Previous 3T fMRI research has achieved recognition of two imagined symbols from visual cortex with 70 % accuracy. In the current study we examined the feasibility of decoding three visually imagined symbols from the visual cortex with the use of 7T fMRI.
Five healthy subjects participated in a 7T fMRI experiment (TR/TE: 1.5 s/25 ms; voxel size 1.5 mm). The experiment contained perceived and imagined tasks. During the perceived task (one run), at every trial, one of three symbols was shown. During the imagined task (two runs),

participants were required to imagine the symbol. The perceived task served as a reference for evaluating decoding performance. We used three symbols: a cross, a plus and a circle (visual angle ~11 degrees). Per task, 140 voxels with the highest t-values for each symbol were selected. A union of these voxels was then used as features in a Support Vector Machine. Leave-one-out cross validation was applied on all trials per task. We tested the classification score significance using a Monte Carlo simulation for each task. To check for the effect of subject head movement we investigated if there was a correlation (across subjects) between movement parameters and the classification scores.
The average classification score for the perceived task was 91.2 % (sd: 7.8 %) with all subjects significantly above chance level. The classification score for the first imagined run was 61,8 % (sd: 21.2 %) and that of the second imagined run 67.3 % (sd: 30%). In both imaged runs respectively 4 and 2 subjects were significantly above chance level. There was a negative correlation between the classification scores and subject head motion (translations r = -0.65, -0.50, -0.50, rotations r = -0.61, -0.46, -0,36).
Our preliminary results suggest feasibility of decoding visually imagined symbols from the visual cortex. The negative correlation between the classification scores and the head motion provides a possible explanation for the relative large variance in classification scores between the subjects. So far we have limited this study to three symbols, but considering our current results, it could be speculated that it is possible to decode a larger number of symbols as well with fair accuracy. In conclusion, our data suggests that using visual mental imagery for communication BCI purposes could well be feasible.

Title: Evoked and high-frequency markers of sustained visual perception in scalp EEG

Authors: *E. M. GERBER[1], L. Y. DEOUELL[2];
[1]Edmond and Lily Safra Ctr. for Brain Sci., [2]Dept. of Psychology and the Edmond and Lily Safra Ctr. for Brain Sci., Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: Little is known about the cortical activity that supports visual perception beyond the initial stimulus onset driven responses. In a previous study using intracranial electrocorticographic (ECOG) data in humans, we found that the ongoing presence of a sustained visual stimulus is accompanied by sustained high frequency broadband activity (>30 Hz, "gamma", HFBA) appearing predominantly in early visual cortex (EVC), as well as by sustained slow potentials appearing in a smaller subset of EVC sites. ECOG data has high spatial and temporal resolution but only sparsely samples the brain. In the current study, we show that similar duration-tracking sustained responses can be seen in scalp recorded HFBA as well as in the slow evoked potential. In a series of experiments we found sustained HFBA which is strongly lateralized to the hemisphere contralateral to the stimulus and is modulated by the position of the stimulus relative to the horizontal meridian. These features, together with a circumscribed occipital scalp distribution, indicate early visual cortex origin. Concurrently recorded high resolution eye tracking data provide conclusive evidence that this scalp EEG gamma response is indeed neural in origin and not a result of eye movement artifacts. Consistently across experiments, the high frequency response can be detected in only about a third of participants, likely due to individual differences in the projection of cortical dipoles to the scalp. Comparable to the intracranial findings, the scalp EEG high-frequency and slow sustained responses are topographically distinct, suggesting they reflect different cortical processes.

Title: Eccentricity-specific characteristics of V1 are altered following central vision loss

Authors: *W. BURGE[1], J. GRIFFIS[2], R. NENERT[3], M. DEFENDERFER[4], D. DECARLO[5], L. ROSS[6], K. VISSCHER[4];
[2]Psychology, [3]Neurol., [4]Neurobio., [5]Opthalmology, [1]Univ. of Alabama At Birmingham, Birmingham, AL; [6]Human Develop. and Family Studies, The Pennsylvania State Univ., State College, PA

Abstract: Central and peripheral vision have different functions. For example, central vision shows biases for processing detailed visual objects such as faces, while peripheral vision shows bias for processing more integrated visual objects such as buildings. After losing central vision, however, people must use peripheral vision for many tasks they used to rely on central vision for. Here, we address two linked hypotheses: that the structure and functional connectivity of primary visual cortex (V1) depends on eccentricity, and that these characteristics are altered following loss of central vision. For our functional analyses of healthy vision, we collected fMRI on a sample of 20 younger adults. For an anatomical analysis of healthy vision, we collected T1 MRI on a sample of 73 older and younger adults as well as utilizing the ABIDE and ADNI datasets. For our analyses of central vision loss, we collected T1 MRI and fMRI data from a group of 10 patients with Macular Degeneration (MD) who had lost central vision bilaterally, and their 10 matched controls. V1 was identified anatomically and segmented into central and peripheral portions using Freesurfer software. We tested how centrally-representing and peripherally-representing parts of V1 differed in cortical thickness and resting state functional connectivity in all groups. In healthy participants, central and peripheral V1 have striking differences in cortical thickness and functional connectivity between central and peripheral vision. The cortex was thicker in central V1 compared to peripheral V1. Further, central V1 was more strongly functionally connected to several fronto-parietal attentional regions. Conversely, peripheral V1 was more strongly functionally connected to the cingulo-opercular control network. Several differences were observed for participants who had lost central vision due to MD. Most strikingly, parts of peripheral V1 were significantly thicker in MD participants than controls. Consistent with this increase in thickness, MD participants' peripheral V1 had stronger functional connections to several cognitive control and higher order visual processing regions. Together, these findings suggest that the anatomy and connections of V1 differ between central and peripheral representations in a way that is consistent with their putative functions. Further, these anatomical and functional characteristics are altered following central vision loss. Our data are consistent with the idea that peripheral visual cortex structure and functional connections adapt to compensate for central vision loss.

Title: A cortical and cerebellar network for dynamic visual prediction in humans

Authors: *L. S. PETRO[1], F. M. CARVALHO[2], A. T. PATON[1], F. W. SMITH[3], L. MUCKLI[1]; [1]Univ. of Glasgow, Glasgow, United Kingdom; [2]Univ. of Sao Paulo, Sao Paulo, Brazil; [3]Univ. of East Anglia, Norwich, United Kingdom

Abstract: The brain uses memory to form internal representations of the environment. These internal models are hypothesized to engage mental time travel and to generate predictions of the environment. These predictions (of present or future context) are generated in high areas and carried to sensory cortex by feedback pathways. Investigating predictive processing in sensory cortex is essential for understanding the brain's modelling of the world. Feedback to V1 carries spatiotemporal predictions of sparse sensory inputs, such as the apparent motion illusion. This spatiotemporal motion prediction in V1 causes a reduced BOLD signal to the more predictable stimulus. We tested if predictions similarly alter processing in V1 in the context of complex scenes, which are the content of real-world predictions and may be used for cognitive tasks such as mental time travel. In 3T fMRI, 13 subjects saw movie clips consisting of a priming sequence, followed by a blank frame of 800ms, then a test frame. The test frame matched the expectation after the blank interval (800ms) or was from a later (4000ms) or earlier point (300, 600ms). Subjects mentally extrapolated the motion during the blank screen and rated the test frame as delayed or ahead of time. MRI parameters:18 slices; TR1s; isotropic voxel 3mm^3 (3x3x4mm^3 six subjects). We acquired T1 anatomical scans. We used general linear model deconvolution to estimate the BOLD response to the test frame conditions. In V1 and V3, we found a lower BOLD response to the 800ms frame compared to the 4000ms (t=2.24, p=0.02; t=2.07, p=0.04). In V1, V2 and V3 we found a lower BOLD response to the 600ms frame compared to the 4000ms, suggesting early visual cortex extrapolates motion from scenes with a precision spanning time delays of 600 and 800ms (t=2.18, p=0.03; t=1.99, p=0.05; t=2.2, p=0.03). In six subjects, a contrast of activation to the 600ms compared to the 4000ms frame revealed activity in the medial parietal cortex and medial temporal lobe. We find evidence that there is lower BOLD response to the 800ms test frame compared with the 4000ms condition in the cerebellum. Early visual cortex extrapolates motion from complex scenes with a precision spanning 200ms. We find that medial parietal cortex and medial temporal lobe engage in the prediction of dynamic scene inputs. The MPC and MTL are part of the default mode (Raichle at al., 2001) and

contextual association network (Bar, 2007), which have a role in translating internal models into predictions. We have evidence the cerebellum contributes to the cortical network for motion prediction. Internal models in the cerebellum may act alongside the cortex to predict the temporally-specific dynamics of our visual world.

Title: Matrix metalloproteinase-9 induced by light reintroduction reactivates plasticity in adult mouse visual cortex

Authors: ***S. MURASE**, E. M. QUINLAN;
Biol., Univ. of Maryland at Col. Park Dept. of Biol., College Park, MD

Abstract: Chronic monocular deprivation (cMD) induces severe amblyopia that is highly resistant to reversal in adulthood. However, binocular visual deprivation through dark exposure (DE) reactivates synaptic plasticity in the adult primary visual cortex (V1), promoting the structural and functional recovery of deprived eye visual responses. One attractive idea is that the extracellular matrix (ECM) contributes to the constraint of plasticity in adults by limiting morphological remodeling. We therefore hypothesized that degradation of the ECM may contribute to the reactivation of plasticity by DE in the adult V1. We focused on the activity of matrix-metalloproteinase-9 (MMP-9), an extracellular zinc-dependent endopeptidase degrades ECM proteins and participates in activity-dependent remodeling of dendritic spine morphology. Indeed, light reintroduction induces degradation of perineuronal net (PNN) in bionocular V1 (V1b), including PNN-rich layers 3 and 4. PNN-degradation by light reintroduction, measured by intensities of either WFA or anti-aggrecan IHC is completely blocked by infusion of MMP-9 inhibitor 1 (Millipore) to V1 (WFA: 92.8±14.8% and anti-aggrecan: 97.6±6.5%), compared to saline control (WFA: 54.0±6.9% and anti-aggrecan: 52.2±3.6%). In vivo delivery of an MMP-9 biomarker demonstrates that MMP-9 activity induced by light reintroduction co-localizes with markers of excitatory synapses. In particular, there is a two-fold increase by light reintroduction in the co-localization of MMP-9 activity with vesicle glutamate transporter 2 (light reared

control: 33.4±4.7% reintroduced to light after DE: 65.3±9.7%), suggesting that MMP-9 activity may mediate remodeling of thalamic input to V1b. To examine a known structural correlate of ocular dominance plasticity, dendritic spine densities of pyramidal neurons in layer 2/3 are analyzed. Spine densities of neurons in cMD hemisphere do not recover spontaneously, but do recover when reverse occlusion follows DE (0.77±0.065/micron to 0.95±0.080/micron). However, MMP-9$^{-/-}$ mice do not demonstrate structural plasticity with cMD or DE. Degradation of the PNN with the enzyme hyaluronidase rescues structural plasticity, resulting in an increase in spine density of neurons in non-deprived hemisphere (0.64±0.038/micron to 0.92±0.048/micron). Together, this suggests that the activity of MMP-9 plays a critical role in plasticity in response to DE.

Title: A crucial role for the fellow eye in the darkness-induced recovery of visual acuity in the amblyopic eye of felines

Authors: *D. E. MITCHELL, P. BOBBIE-ANSAH, K. R. DUFFY;
Dept of Psychology and Neurosci., Dalhousie Univ., Halifax, NS, Canada

Abstract: Following a short period of monocular deprivation (MD) imposed in the early postnatal life of kittens, there is a profound reduction of the vision of the deprived eye. The size of the reduction of vision as assessed by the loss of spatial acuity is dependent upon the animal's age at the time of deprivation and its duration. While some recovery of the acuity of this eye can occur, a substantial deficit in visual acuity usually remains with characteristics similar to those observed in human amblyopia. Recently we showed (Duffy & Mitchell, 2013) that a ten day period of total darkness introduced at between 3 and 4 months of age can induce recovery of the visual acuity of the amblyopic eye to normal levels in just 5-7 days without any decrement of the acuity of the fellow (stronger) eye. The speed and magnitude of this recovery suggest that neural connections with the fellow eye, that support normal vision retained by this eye following the

period of darkness, may play a crucial role in the recovery of visual acuity of the amblyopic eye. We investigated the possibility that activity in cortical cells mediated by neural connections from the fellow eye may serve to guide the darkness-induced recovery of the amblyopic eye. The possible role of the nondeprived eye as a mediator of visual recovery of the amblyopic eye was assessed by elimination of its potential role by occluding it immediately after the period of darkness.
The study was conducted on animals reared as before with a period of MD from P30-37 followed by a 10 day period of total darkness at P92. Immediately upon emergence from the darkroom at P102 days of age, the nondeprived eye was occluded for 11 days. Control kittens were reared identically with the exception that they were not exposed to darkness before the nondeprived eye was occluded at P102 for a similarperiod (16- 21days). In remarkable contrast to the rapid and complete recovery of the visual acuity of the deprived eye observed when both eyes are open after the period of darkness, occlusion of the nondeprived eye during this period appeared to block improvement of the acuity of the amblyopic eye beyond the very small changes observed in control animals that received a similar period of occlusion of the nondeprived eye without a prior period of darkness. It appears that the rapid recovery of vision of the amblyopic eye induced by darkness is dependent upon visually - driven neural activity mediated by the nondeprived eye. Additional observations from the animals that had the nondeprived eye occluded after the period of darkness suggest that darkness may be beneficial for only a limited time afterward.

Title: Recovery from the effects of long-term monocular deprivation following dark exposure or retinal inactivation

Authors: *K. DUFFY[1], M.-F. FONG[2], M. F. BEAR[2], D. E. MITCHELL[1];
[1]Dalhousie, Halifax, NS, Canada; [2]MIT, Boston, MA

Abstract: A brief duration of monocular deprivation (MD) beginning at the peak of the critical period in kittens can cause a visual impairment in the deprived eye (amblyopia), and can lead to pronounced shrinkage of deprived-eye neurons in the lateral geniculate nucleus (dLGN) that originates from synaptic changes within striate cortex. We recently demonstrated that either immersion in complete darkness (Duffy & Mitchell, 2013) or binocular retinal inactivation for 10 days following one week of MD promotes a rapid and full recovery of visual acuity, and stimulates a recovery of neuron soma size within the dLGN. In the current study we assessed the effectiveness of 10 days of darkness or retinal inactivation (with intravitreal TTX injections) to promote anatomical recovery from longer durations of MD that precipitate much larger anatomical deprivation effects. The cross-sectional soma size of neurons in the dLGN was measured using the nucleator stereology probe, and all measurements were made blind to rearing condition.

Comparison of the soma size of deprived and non-deprived neurons revealed that, as expected, the extent of deprived neuron atrophy increased as MD duration was extended to 6 weeks. Although substantial recovery of neuron soma size was observed when 6 weeks of MD was followed by darkness or binocular retinal inactivation, complete recovery was not achieved with either treatment. In an attempt to promote better recovery from the effects of 6 weeks of MD, we opened the deprived eye and inactivated only the fellow (stronger) eye for 10 days. Inactivation of the fellow eye led to a complete recovery of neuron soma size so that originally deprived and non-deprived neurons were equal in size and comparable to the size of neurons from normal controls. Importantly, 10 days of fellow eye lid closure (reverse occlusion) following the same duration of MD drove a smaller degree of recovery than 10 days of fellow eye inactivation. Furthermore, fellow eye inactivation was effective at promoting recovery in animals subjected to MD for even longer durations that extended to 18 weeks.

We conclude that while 10 days of darkness or binocular inactivation can promote substantial recovery from the anatomical effects of long-term MD, it nevertheless remained incomplete. However, full recovery following the same MD was achieved when the deprived eye was opened while the fellow eye was inactivated for 10 days.

Title: Waves of inter-individual variability during development of human visual cortex

Authors: *K. M. MURPHY[1], S. BESHARA[2], C. R. SIU[2], J. G. A. PINTO[2], D. G. JONES[3]; [1]Dept Psychol Neurosci & Behaviour, [2]McMaster Univ., Hamilton, ON, Canada; [3]Pairwise Affinity, Hamilton, ON, Canada

Abstract: The human visual cortex has tremendous capacity for plasticity, especially during development when visual experience drives maturation of cortical circuits. Studies of visual perception and neurobiological changes in V1 have identified infancy and childhood as stages of development when there are large steps towards a mature visual system. We have been studying development of excitatory and inhibitory receptor systems in human V1 have uncovered a new aspect of its development -- waves of inter-individual variability that occur during through infancy and childhood.

We used Western blotting of postmortem tissue samples from human V1 (n=30) ranging in age from 20 days to 80 years to quantify expression of a group of glutamatergic and GABAergic synaptic proteins. We measured expression of the proteins, plotted how they changed across the lifespan and then calculated the variability in a sliding window that included 3 adjacent cases. That inter-individual variability was analyzed using the Fano Factor where we calculated the Variance-to-Mean-Ratio (VMR) in the sliding window and plotted the VMR to visualize how variability of each protein changed across the lifespan. We found waves of high inter-individual variability during infancy and childhood that were not present in adults. Each protein had a different wave of variability. For example, Gephyrin the GABA receptor anchoring protein had high variability under 1 year of age while PSD95 was low at that time and then rose to have a wave of higher variability through childhood. Other glutamate receptor proteins had a progression of waves peaking during childhood starting with GluN1 and GluN2B at about 1 year, GluN2A at 1.5 years, GluA2 at 2 years and PSD-95 at 2.5 years.

These waves of variability are a new feature of human V1 development that may reflect stages of vulnerability or dynamics that drive maturation of an adaptive network of cortical circuitry. We think these waves both reflect and contribute to big steps in maturation of visual perception during infancy and childhood.

Title: Nicotinic activation of somatostatin inhibitory neurons by Lypd6-nAChRa2 system restores plasticity in adult visual cortex.

Authors: *M. SADAHIRO[1], M. P. DEMARS[2], P. N. BURMAN[2], A. ZIMMER[3], H. MORISHITA[2];
[2]Psychiatry, [1]Icahn Sch. of Med. At Mount Sinai, New York, NY; [3]Inst. of Mol. Psychiatry, Univ. of Bonn, Bonn, Germany

Abstract: Experience-dependent cortical plasticity declines into adulthood, posing a challenge for recovery of function. A network of inhibition is critical for plasticity, yet contributions of interneurons other than Parvalbumin interneurons have largely been unexplored. Here we show Lypd6, an endogenous positive modulator of nicotinic acetylcholine receptors, as a specific molecular target in Somatostatin interneurons to reactivate cortical plasticity in adulthood. Lypd6 decreases its expression in adult primary visual cortex in concert with declining ocular dominance plasticity. Overexpression of Lypd6 specifically in adult Somatostatin interneurons reactivates plasticity through α2 subtype of nicotinic receptor by activating Somatostatin interneurons which in turn inhibit Parvalbumin interneurons, a key early trigger of plasticity in juvenile cortex. Identification of the first Somatostatin interneuron-specific plasticity regulators provides novel therapeutic targets for disorders with limited recovery due to diminished plasticity such as amblyopia as well as for psychiatric disorders with deficits in Somatostatin interneurons.

Title: Neuronal responses correlated with shifts in interocular balance induced by short-term deprivation in adult macaque visual cortex.

Authors: *R. A. MILLER, III[1], M. BEGUM[2], D. TS'O[2];
[2]Neurosurg., [1]SUNY Upstate Med. Univ., Syracuse, NY

Abstract: Short-term monocular deprivation (STMD, depriving one eye for 1-3 hours, either total occlusion or pattern deprivation) disrupts interocular balance in adult humans, as measured psychophysically, and also in our present studies using anesthetized adult macaques, assessed with intrinsic signal optical imaging of the V1 ocular dominance columns. Surprisingly, in all these studies, the relative contribution of the deprived eye was elevated for more than an hour after deprivation ends. In addition, our V1 imaging studies show a rapid reduction in the contribution of the nondeprived eye during the deprivation of the other eye. Once the deprivation period ended, the nondeprived eye dramatically increased in strength, despite the stimulation to this eye remaining the same during the entire experiment.
We have now conducted multi-electrode recordings in V1 with the STMD paradigm. Single cell responses to monocular and binocular stimuli were measured before, during and after STMD. The single-unit recordings revealed several different types of cell responses. One class of neurons did not exhibit any striking changes in responses during STMD. These cells were often highly monocular. Another class of cells displayed a marked enhancement of responses in the deprived eye once the deprivation period ended, attaining activity levels beyond that of the pre-deprivation period and persisting for at least an hour. A third class of cells exhibited a surprising decline in responses during the deprivation period to stimulation in the non-deprived eye: in some cells, beginning gradually upon deprivation, while in others, curiously beginning sometime in the middle of the deprivation period. Responses to non-deprived eye stimulation began to return towards pre-deprivation levels once the deprivation of the other eye ended. This weakened response for the non-deprived eye during the deprivation period was striking. It cannot be explained by adaptation or fatigue in the eye or cortex. Another small population of cells showed deprivation responses more consistent with the classical notion of the non-deprived eye gaining in strength. Overall, the electrophysiological results show, in certain classes of V1 cells, response behaviors that may constitute components of the shifts in interocular balance induced by STMD observed in the imaging studies and psychophysically. The findings suggests a dynamic binocular mechanism for regulating interocular balance and gain that involves the neurons in V1.

Title: Time-course of the involvement of cholinergic receptors subtypes in a repetitive visual / cholinergic stimulation

Authors: ***M. GROLEAU**, M. CHAMOUN, M. BHAT, E. VAUCHER;
Ecole d'Optometrie, Univ. De Montreal, Montreal, QC, Canada

Abstract: Cholinergic stimulation coupled to visual exposure to a specific stimulus enhances the long-term cortical response to visual stimuli. However, there are a variety of cholinergic receptors subtypes in the visual cortex that play distinct and sometime opposite roles in the modulation of the visual cortex (V1) neurons. The weight of these different receptors in the different steps of cholinergic modulation of repetitive visual stimulation is still unclear. To determine which cholinergic receptors were involved in the increased cortical reactivity induced by cholinergic enhancement, RT-PCR was used. Cholinergic enhancement was performed either by an electrical stimulation of the basal forebrain or a pharmacological stimulation of the cholinergic system (donepezil, 1mg/kg, daily i.p. administration). A daily visual exposure of the rats to sine-wave gratings (training) was paired or not with this cholinergic enhancement. RT-PCR was performed without any visual exposure/cholinergic stimulation, or at 10 minutes, one week or two weeks of this visual/cholinergic training. V1, the frontoparietal cortex and the basal forebrain were analysed for the muscarinic receptors expression (M1, M2, M3, M4, M5), the nicotinic receptors subunits (α3, α4, α7, β2, β4) and NMDA receptors, GAD65 and ChAT. Statistical analysis was performed using Two-way ANOVA to evaluate the interaction between the treatment and the time-course for each cholinergic receptor tested and in each region evaluated. The results showed interactions in V1 between the treatment and the time-course. This suggests that when using the cholinergic enhancement treatments over time, the effect of the treatment is dependent of the number of visual exposure sessions and alters the mRNA expression of M1, M3, M4, β4, NMDA and GAD65. In the basal forebrain an interaction between the treatment and the time-course was observed for M3 and β4. In the frontoparietal

cortex, an interaction between the treatment and the time-course was detected only for the α3 nicotinic receptor. This suggests that the combination of cholinergic enhancement and visual exposure is specific to V1 and does not alter a control cortex. This study clearly shows that the involvement of the cholinergic receptors is involved in long-term changes related to plasticity processes sustaining perceptual learning.

Title: Protracted development of human V1: Glutamate receptors linked with plasticity and orientation selectivity

Authors: ***C. SIU**[1], S. BESHARA[1], D. G. JONES[3], K. M. MURPHY[2];
[1]MiNDS, [2]Psychology, Neurosci. and Behaviour, McMaster Univ., Hamilton, ON, Canada;
[3]Pairwise Affinity, Hamilton, ON, Canada

Abstract: Maturation of glutamate synapses in visual cortex regulates experience-dependent plasticity and drives development of receptive field properties to support visual perception. Human vision matures in stages that continue into adulthood, and that extended development has lead to the idea that V1 regulates an early stage while extrastriate areas mediate later stages of visual development. Very little is known, however, about the rate of development of glutamate receptors in human V1. This leaves unanswered if this neurobiological mechanism necessary for neuroplasticity matures early, or has lifelong changes in V1 that could support the dynamics of human visual perception across the lifespan.
Both plasticity and orientation tuning change across the lifespan so we quantified expression of 2 NMDA receptor subunits (GluN2A & GluN2B) involved in these functions. The developmental switch from GluN2B to GluN2A regulates the effect of visual experience on ocular dominance plasticity by controlling the synaptic modification threshold, while the increase in GluN2A controls maturation of orientation selectivity. We did Western blotting using 30 postmortem tissue samples from human V1 that ranged in age from 20 days to 80 years.
We found that GluN2B expression is relatively constant across the lifespan. In contrast, GluN2A expression is low in infancy, increases gradually to peak at ~30 years, then drops in aging. An

index of relative GluN2A:GluN2B expression shows a protracted shift that begins with more GluN2B early in infancy, switches to more GluN2A at 12 years, peaks at 40 years, then shifts in favour of GluN2B in aging. This age-related shift is driven by the loss of GluN2A.
The protracted GluN2A:GluN2B shift points to V1 involvement in the capacity for plasticity across the lifespan. The loss of GluN2A in aging provides a 'new' neurobiological mechanism for the loss of orientation tuning in aging V1 neurons. Perhaps this loss of GluN2A is preferentially on GABAergic neurons, identifying excitatory synapses as the site of age-related changes in inhibition in human V1. Together these results indicate it is time to formulate new hypotheses about the potential for plasticity in human V1 and the mechanisms that underlie age-related loss of visual perception.

Title: Postnatal systemic inflammation suppresses developmental cortical plasticity

Authors: ***M. R. SMITH**[1], P. BURMAN[2], M. SADAHIRO[2], B. A. KIDD[2], J. T. DUDLEY[2], H. MORISHITA[2];

Abstract: Childhood and adolescent critical periods of heightened neuroplasticity are essential for development of normal brain function and behavior. Disruption of these periods of developmental plasticity may alter the neurodevelopmental trajectory and contribute to brain-related disorders. Given the high prevalence of psychiatric and neurodevelopmental disorders, identifying disruptors of plasticity represents an essential step for developing strategies for prevention and therapeutic interventions. Applying a novel computational approach that systematically assessed connections among 436 transcriptional signatures of disease and multiple signatures of neuroplasticity, we identified inflammation as a common pathological process central to a diverse set of diseases predicted to dysregulate molecular processes associated with plasticity. To experimentally test the hypothesis that inflammation disrupts developmental plasticity *in vivo*, we used the ocular dominance model of experience-dependent cortical plasticity. We found that systemic lipopolysaccharide suppresses postnatal cortical plasticity with accompanying transcriptional changes in a specific set of molecular regulators of plasticity. These findings suggest inflammation in children may have unexpected negative consequences on the postnatal developmental trajectory by disrupting neuroplasticity during critical windows of development. Suppressed developmental neuroplasticity may in part underlie the pathophysiology of psychiatric and neurodevelopmental disorders associated with inflammation.

Title: Neuromodulator induced bidirectional changes in ocular dominance in the mouse primary visual cortex

Authors: *S. HONG, S. HUANG, A. KIRKWOOD;
Mind Brain Inst., Johns Hopkins Univ., Baltimore, MD

Abstract: Neuromodulatory signals mediated by G protein-coupled receptors are essential for the induction of experience-dependent cortical plasticity. *In vitro*, neuromodulators can exert a pull-push control of Hebbian plasticity, with receptors coupled to Gs and Gq11 respectively promoting the induction of LTP and LTD. Importantly, β-adrenergic receptors (coupled to Gs)

and 5-HT2c serotonergic receptors (coupled to Gq11) can provide a cellular substrate for reinforced learning as these receptors can transform the so-called “eligibility traces” into lasting LTP and LTD. We tested, therefore, whether the activation of these receptors *in vivo* can promote lasting bidirectional changes in visual responses. Using optical imaging of intrinsic signal we found that the pharmacological activation of 5-HT2c receptor, in conjunction with brief visual conditioning of one eye, induces LTD-like changes of the responses evoked by the conditioned eye only, thus shifting the natural ocular dominance balance. The same visual stimulation, but paired with activation of β-adrenergic receptors results in LTP-like changes, and the opposite ocular dominance changes. These results suggest that the pull-push regulation of Hebbian plasticity underlies the neuromodulation of experience dependent ocular dominance plasticity. Currently we are using optogenetics to evaluate the role of endogenous released noradrenaline and serotonin in this type of plasticity.

Title: The role of spontaneous correlations in structuring co-tuned networks in cortical development

Authors: *B. HEIN[1,2,3], G. B. SMITH[4], D. E. WHITNEY[4], P. HUELSDUNK[1,2,3], D. FITZPATRICK[4], M. KASCHUBE[1,2,3];
[1]Frankfurt Inst. For Advanced Studies, Frankfurt, Germany; [2]IMPRS for Neural Circuits, Max Planck Inst. for Brain Res., Frankfurt, Germany; [3]Goethe Univ., Frankfurt, Germany; [4]Max Planck Florida Inst. for Neurosci., Jupiter, FL

Abstract: In visual cortex, local networks of co-tuned neurons manifest in a columnar organization, but also form distributed circuits with distant, but similarly co-tuned neurons several millimeters away. It has been hypothesized that co-tuning between neurons in visual cortex might be dynamically established using patterns of spontaneous activity, however,

experimental evidence supporting this scenario is scarce. Here we combined chronic epifluorescence and two-photon imaging with quantitative analysis and modeling to dissect the organization of spontaneous activity in the early ferret visual cortex in relation to the developing networks of orientation selective domains which become apparent upon eye opening.
We find that by ten days prior to eye opening, cortical activity is already spatially coherent on a columnar scale. The local activity correlation structure resembles a Mexican-hat profile, an organization consistent with models for the activity dependent development of orientation domains. Remarkably, strong correlations were also present between cortical domains several millimeters apart, even at a stage in development when horizontal connections of layer 2/3 pyramidal cells remain primarily local. To understand how long-range correlations could arise in the early cortex from purely local connectivity, we generated a circuit model of rate units receiving weakly modulated random input drive with connectivity reflecting the experimentally observed Mexican-hat structure. This model produced modular activity patterns with long-range spatial correlations, arising through multi-synaptic heterogeneous recurrent feedback loops. Interestingly, although activity correlations in this model vary smoothly across the cortex, they are systematically punctuated by abrupt discontinuities, reminiscent of the fracture and pinwheel discontinuities found in the mature orientation map. Notably, we also observed such 'correlation fractures' in the structure of spontaneous activity *in vivo*, where they tend to co-align with pinwheel locations in the orientation preference map after eye-opening. Further, we find that several days prior to eye opening, long-range correlations in spontaneous activity were predictive of future tuning similarity in the mature orientation map, providing additional evidence for a developmental relationship between spontaneous activity and co-tuned networks. We conclude that the primitive circuits of the early cortex robustly generate both local and long-ranging structured correlations in spontaneous activity, which might form the basis for the development of co-tuned spatially distributed cortical networks.

Title: Temporary retinal inactivation promotes rapid recovery from monocular deprivation in mice and kittens

Authors: *M.-F. FONG[1], D. E. MITCHELL[3], K. R. DUFFY[3], P. NORTHRUP[3], Y. ATIYAS[1,2], F. M. VAN DESSEL[1,4], J. U. DEERE[1,4], M. F. BEAR[1];

Abstract: A brief period of monocular deprivation (MD) during early postnatal life drives structural and functional changes in the mammalian central visual pathway that lead to impaired visual acuity in the previously deprived eye. While MD is a classic paradigm for studying experience-dependent plasticity, it has also become an established model for study of the pathophysiology of amblyopia, a widespread form of human visual disability that arises due to imbalanced visual input between the two eyes during infancy or early childhood. Therefore, identifying strategies for reversing the consequences of early life MD are particularly relevant to developing targeted interventions for effective treatment of amblyopia. In this study, we tested the hypothesis that temporary inactivation of the retinas using tetrodotoxin (TTX) could promote recovery from MD in mice and cats. While long-lasting impairments in deprived eye vision following MD have been demonstrated in kittens, the stability of these deficits is not well characterized in mice. For this reason, we first conducted a longitudinal electrophysiological study to track visual ability in awake mice for several weeks following early life MD. Seven days of MD drove a profound reduction in visual cortical responsiveness to vision through the deprived eye that persisted for > 1 month after restoring binocular vision. However, the persistent reduction in deprived eye responses could be stably reversed when binocular visual experience followed temporary bilateral retinal inactivation. Further, in kittens, we found that bilateral retinal inactivation followed by a short period of binocular visual experience promoted fast recovery of the visual acuity of the deprived eye to normal levels. Finally, we show that even in the absence of subsequent visual experience, prolonged TTX treatment leads to recovery from the anatomical consequences of MD on the visual thalamus of kittens. We conclude that temporary retinal inactivation represents a highly efficacious strategy for promoting recovery from MD-driven visual impairments.

Title: Impact of PV neuron development on visual responses

Authors: *S. J. KUHLMAN, B. FEESE, N. MCGUIER, J. KAUTTONEN;
Carnegie Mellon Univ., Pittsburgh, PA

Abstract: During postnatal development, maturation of sensory circuits depends on the statistics encountered in the local environment. This is largely achieved by stimulus-instructed tuning of neuronal receptive fields. Such changes in tuning improve the information that is ultimately used to guide appropriate behavior and learning. The impact of visual experience on the maturation of cortical response properties varies among cell types contained within a microcircuit (Kuhlman et al. Nat Neurosci 2011). The differential impact of experience may support the division of labor among cell types that is essential for proper signal transformation and sensory encoding. The extent to which visual experience is required to maintain recently developed PV neuron response properties is unknown. Using two-photon guided cell attached recording of PV neurons in vivo we find that 1 day of binocular deprivation is sufficient to alter recently developed response properties. We are also exploring the impact that disrupted PV development has on population activity among excitatory neurons using calcium imaging in awake mice.

Title: Prominent role of MMP9 in the bidirectional regulation of visual cortex synaptic plasticity by visual experience.

Authors: *C. L. LANTZ, E. M. QUINLAN;
Dept. of Biol., Univ. of Maryland, College Park, MD

Abstract: Ocular dominance plasticity is robust in juveniles, but is significantly constrained in adults. We have previously demonstrated that dark exposure reactivates plasticity in the adult visual cortex, which can be harnessed by visual experience to drive recovery from amblyopia. One attractive candidate for the developmental constraint on ocular dominance plasticity is the maturation of the extracellular matrix, and its influence on excitability. Interestingly, the levels and activity of matrix-metalloproteinase-9 (MMP9), an activity-dependent protease known to degrade extracellular matrix components, is increased by light reintroduction following dark exposure (Murase et al., 2016).
Here we show that MMP9 is necessary for the reactivation of plasticity by adult dark exposure. Electrophysiological recordings in head-fixed awake mice revealed that pyramidal neurons in $MMP9^{-/-}$ adult cortex had increased visually-evoked spike rates (WT: 2.36 ± 0.8 Hz; $MMP9^{-/-}$: 3.75 ± 0.8 Hz). Despite this hyperexcitability, visual acuity (WT: 0.85 ± 0.04 cpd; $MMP9^{-/-}$: 0.78 ± 0.13 cpd) and contralateral bias (WT: 0.37±0.05; $MMP9^{-/-}$: 0.23 ± 0.04), as estimated by VEP amplitudes, were normal in $MMP9^{-/-}$ mice. However, dark exposure in adulthood, which reactivated robust ocular dominance plasticity in wild-types (post 3 day MD, Contra: 87.35 ± 20.4μV; Ipsi: 111.01± 0.24 μV; Bias: -0.133 ± 0.11), failed to activate plasticity in $MMP9^{-/-}$ adults (post 3 day MD, Contra: 86.40 ± 5.0 μV; Ipsi: 72.62 ± 11.8 μV; Bias: 0.11±0.03). Similarly, reducing excitability in $MMP9^{-/-}$ mice with diazepam, which rescued ocular dominance plasticity in other hyperexcitable transgenic lines such as $NARP^{-/-}$ mice, failed to activate plasticity (Pre- MD: 0.23±0.04, post 3 day MD:0.21±0.07), despite a diazepam mediated reduction in spike rates (Pre-MD: 2.75±0.15 Hz, post 3 day MD: 1.94±0.16 Hz). To ask if plasticity in $MMP9^{-/-}$ mice could be reactivated by degradation of the extracellular matrix, we delivered the enzyme hyaluronidase to adult primary visual cortex. Hyaluronidase rescued ocular dominance plasticity in $MMP9^{-/-}$ mice, revealed by a significant increase in the amplitude of non-deprived eye VEP following prolonged MD (Pre-MD: 152.3 ± 18.1 μV; post MD: 202.7± 21.6 μV). Together these data suggest that MMP9 plays a prominent role in the bidirectional regulation of synaptic plasticity in primary visual cortex by visual experience.

Title: Cross-modal plasticity at thalamocortical synapses

Authors: G. RODRIGUEZ[1], *H.-K. LEE[2];
[1]Biol., [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Loss of a sensory modality leads to widespread compensatory adaptation in the brain, which allows the remaining senses to guide behavior. We previously reported that such cross-modal plasticity is manifested as synaptic changes across different primary sensory cortices. In particular, in the spared sensory cortices we found strengthening of thalamocortical (TC) synapses as a result of sensory deprivation in adult mice. This was quite surprising in light of previous studies demonstrating that TC plasticity is lost after the second postnatal week of development in mice. Therefore, our observations indicate that cross-modal sensory deprivation may be able to recover synaptic plasticity mechanisms at TC synapses in adults. By combining primary visual cortical slice electrophysiology with optogenetic techniques, we are investigating the molecular and cellular mechanisms leading to TC synaptic potentiation in the primary visual cortex (V1) of deafened adult mice. In addition, we are determining *in vivo* functional changes caused by deafening in V1 of adult mice by measuring optical intrinsic signals during presentation of visual stimuli.

Title: Tuned inhibition model accounts for adaptation-induced tuning shifts in macaque V1 and V2

Authors: *D. J. THENGONE, Y. YU, J. VICTOR;
Brain and Mind Res. Inst., Weill Cornell Grad. Sch. of Med. Sci., New York, NY

Abstract: The visual system utilizes inputs from the recent past to adjust its representations of the sensory world. This ubiquitous property of sensory systems - adaptation - influences neural response characteristics including gain, stimulus preference, and degree of selectivity. To identify the specifics of adaptation-induced alterations in tuning properties, we measured and modeled the effects of adaptation on excitatory and inhibitory neurons in V1 and V2 of the primate visual cortex. We used a multitetrode array to record neuronal responses from neurons in V1 and V2 of 6 macaques under anesthesia and paralysis. We compared baseline orientation tuning curves to tuning curves measured after brief (400 ms) and prolonged (40 s) adaptation. Both durations of adaptation induced changes in bandwidth and tuning preferences in excitatory and inhibitory neurons. We found increases and decreases in bandwidth in both cell types, and shifts of the tuning preference either away from (repulsive) or towards (attractive) the adapting stimulus. Differences between V1 and V2 were relatively subtle. In V1, prolonged adaptation could either broaden or narrow the bandwidth of both cell types, while in V2, bandwidth changes were selective, with broadening in inhibitory cells and narrowing in excitatory cells. To account for the effects of adaptation on the orientation tuning of visual neurons, we considered several firing-rate models (80% excitatory neurons and 20% inhibitory neurons) of V1. The models are distinguished by the site of adaptation (post-synaptic vs pre-synaptic), and whether inhibitory neurons contribute to orientation selectivity. This results in four model classes: (1) untuned inhibition with postsynaptic adaptation; (2) tuned inhibition with postsynaptic adaptation; (3) untuned inhibition with presynaptic adaptation; (4) tuned inhibition with presynaptic adaptation. Neither model with post-synaptic adaptation (models 1 and 2) could account for changes in half-bandwidth or shifts in tuning curve peak. Pre-synaptic adaptation could induce such effects, but models differed in the kinds of tuning shifts they yielded. Specifically, if adaptation is pre-synaptic and inhibition is untuned (model 3), then adaptation to a non-preferred stimulus only produced repulsive shifts. In contrast, pre-synaptic adaptation with tuned inhibition (model 4) can lead to both repulsive and attractive shifts along with bandwidth decreases, similar to the experimental data. More broadly, our findings demonstrate that adaptation in inhibitory neurons is critical for shaping sensory representations as stimulus characteristics change over time.

Title: Changes in peripheral vision induced by simulated central field loss

Authors: *N. CHEN[1], K. SHIN[2], R. MILLIN[3], M. KWON[4], B. S. TJAN[5];
[1]Dept. of Psychology, Univ. of Southern C, Los Angeles, CA; [2]Dept. of Psychology, Univ. of Southern California, Los Angeles, CA; [3]Dept. of Psychology, Univ. of Washington, Seattle, WA; [4]Dept. of Ophthalmology, Univ. of Alabama at Birmingham, Birmingham, AL; [5]Dept. of Psychology, Neurosci. Grad. Program, Univ. of Southern California, Los Angeles, CA

Abstract: The human fovea serves both as the locus for fixations and the oculomotor reference for saccades. Training normally sighted adults with occluded central vision can reliably induce a preferred retinal locus (PRL) in peripheral vision for fixation with re-referenced saccades (Kwon, Nandy & Tjan, 2013, Curr. Biol.). Does the development of a PRL in peripheral vision alter the neural processing of the visual inputs? Crowding, the impediment of object recognition by clutter, is a hallmark of form-vision deficits in peripheral vision. Here we asked if the spatial extent of crowding can be altered as a consequence of the training-induced PRL. We trained nine human subjects using the object-following-and-visual-search task with a simulated central-field scotoma and a prescribed PRL. After 20 hours of training in 2-3 weeks, subjects' saccades were re-referenced to the prescribed PRL location in the presence of the simulated central scotoma. Before and after training, we measured the spatial extent of crowding behaviorally at two locations: the prescribed PRL location in the upper-left visual field and a symmetric "sideways" location in the upper-right field where one third of the saccade targets were presented during training. We found that training led to a shrinkage of the crowding zone along the radial axis at the PRL location, causing the crowding zone to become roundish, consistent with findings from patients with central field loss (Chung, 2013, J. Neurosci.). The crowding zone along the radial axis at the sideways location was also reduced. With fMRI measurements before and after training, we found a radial-specific reduction of crowding-related suppression (Millin et al., 2013, Cereb. Cortex; Kwon et al., 2014, J. Neurophysiol.) across visual areas V1-V4. However, this reduction, which parallels the behavioral finding, was observed only at the PRL location. These findings suggest that human crowding zones dynamically reorganize relative to the reference point of saccade, consistent with a theory that attributes crowding to image representation using saccade-biased image statistics (Nandy & Tjan, 2012, Nat. Neurosci.). By demonstrating that training with a simulated central-field scotoma facilitates peripheral vision

via reshaping the crowding zones, this study reveals the residual plasticity in adult peripheral vision and sheds light on new mechanisms of rehabilitations for patients with central field loss.

Title: *In vivo* visualization of multiple areas around the superior temporal sulcus of the common marmoset

Authors: *W. SUZUKI[1,2], T. TANI[2,1], T. BANNO[3,1], N. MIYAKAWA[1], H. ABE[2,1], T. HAYAMI[1], N. ICHINOHE[1,2];
[1]Natl. Ctr. of Neurol. and Psychiatry, Natl. Inst. of Neurosci., Kodaira, Japan; [2]Ichinohe group, Lab. for Mol. Analysis of Higher Brain Function, RIKEN BSI, Wako, Japan; [3]Dept. of Otorhinolaryngology:Head and Neck Surgery, Univ. of Pennsylvania Sch. of Med., Philadelphia, PA

Abstract: Superior temporal sulcus (STS) of humans and old world monkeys contains multiple cortical areas that have been recognized as regions for integration of dorsal/ventral visual pathways. Although the individual areas can be anatomically and physiologically distinct, they are folded in the sulcus, which makes it difficult to experimentally access especially *in vivo* in those species. A small New World monkey, the common marmoset (*Callithrix jacchus*) has a lissencephalic brain with those cortical areas exposed on the surface, and thus is an adequate primate model to examine the functional roles of each area for the information processing in the STS. In the present study, to identify the multiple areas around the STS *in vivo*, we applied optical intrinsic signal imaging (OISI) technique to the marmoset STS and visualized the spatial organization in activities of the multiple visual cortical areas when several kinds of visual stimuli were presented. A large region of the caudal STS was exposed and illuminated with a band-passed light of 535 nm center wavelength. The stimulus evoked signals were defined by the changes in backscattered light following a visual stimulus presentation. First, we visualized retinotopic organization in the signals evoked by flashing random dots appeared within annuluses for eccentricity (~14 degree) or those within wedges for polar-angle (45-degree step).

A visual field sign map was computed from the evoked signals and showed two retinotopically organized areas in the STS; MT cluster and FSTd. Second, to identify motion sensitive areas we presented moving random dots with a uniform motion or expansion/contraction. The moving dots evoked signals in a larger region in the STS, including the MT cluster and FSTd. Especially, moving dots that expanded from a center to the periphery evoked the maximum responses in the MT cluster and a distinct area dorsal to the MT cluster that would correspond to MST. Third, movies showing marmoset grasping action evoked signals in a further large region that extended ventrally and rostrally from the one evoked by the moving random dots. We observed an additional distinct area rostral and ventral to the FSTd that would correspond to FSTv. Finally, we confirmed that the evoked optical signals reflected cell responses using multi-unit recording. Thus, we conclude that OISI is an optimal tool to visualize multiple areas in the STS on the lissencephalic cortical surface of marmosets. By identifying multiple STS areas *in vivo* with OISI, we will be able to advance the study in the STS to understand hierarchical information processing for integration between dorsal and ventral pathways.

Title: Spiking irregularity in V2 neurons of amblyopic monkeys

Authors: *Y. WANG[1], B. ZHANG[2], X. TAO[3], G. SHEN[3], E. L. SMITH, III[1], Y. M. CHINO[1]; [1]Col. of Optometry, Univ. of Houston, Houston, TX; [2]Col. of Optometry, Nova Southeastern Univ., Fort Lauderdale, FL; [3]Baylor Col. of Med., Houston, TX

Abstract: Experiencing interocular decorrelation of cortical inputs early in life can cause compromised binocular vision and often amblyopia, a developmental disorder of spatial vision. According to recent perceptual studies, abnormally enhanced ‘noise’ in the visual system is thought to prevent amblyopic humans from reliably discriminating visual stimuli. However, the

neural basis for such high-level of noise in amblyopes is not known. By using established optical means we created macaque models of anisometropic amblyopia exhibiting a range of visual deficits (e.g., amblyopia index of 0.3-0.8). We recorded from a population of neurons in visual area V2 of anesthetized monkeys. We quantified the spiking noise (variability) in response to brief (640 ms) sine wave gratings that were optimized for orientation and spatial frequency for each unit and varied for contrast between 5% and 80%. To assess spiking noise, we quantified the *spiking irregularity* by calculating the square of the coefficient of variation (CV^2) and the *trial-to-trial variability* of the spike count by calculating the mean-matched Fano factor (FF) for individual neurons. We found: 1) Average spike count was significant higher in amblyopes only at high contrast (50-80%). 2) Spike count dynamics was abnormal in that the onset latency was shorter and the response decay following the transient discharge was delayed or absent in amblyopic neurons. 3) Average operational CV^2 was significantly higher in amblyopes only at high contrast. 4) Average mean-matched FF was 'normal' in amblyopic V2 neurons at high contrasts while significantly elevated at lower contrasts (10-25%). 5) Average CV^2 of individual monkeys were well correlated with their depth of amblyopia (amblyopia index). 6) However, the average mean-matched FF of individual monkeys were not well correlated with their amblyopia index values. 7) Importantly, the average CV^2 of individual monkeys, but not mean-matched FF, was highly correlated with the prevalence of binocularly suppressive neurons. These results suggest that the increased spiking irregularity (CV^2) and spike count dynamics, linked to a high level of binocular suppression in V1 and V2, adversely affect the information processing in V2 and presumably, visual areas downstream from V2. We conclude that the observed spiking irregularities in V2 may be involved, at least in part, with reducing the visual performance of amblyopic monkeys in simple or complex visual tasks.

Title: In-vivo visualization of myelin, color- and disparity-biased stripes in monkey area v2 using sub-mm resolution (f)mri at 3 tesla

Authors: *X. LI[1], J. ARSENAULT[1,2], T. JANSSENS[1], Q. ZHU[1], W. VANDUFFEL[1,2,3]; [1]Res. Group Neurophysiology, KU Leuven, Leuven, Belgium; [2]A. A. Martinos Ctr. for Biomed. Imaging, MGH, Charlestown, MA; [3]Dept. of Radiology, Harvard Med. Sch., Boston, MA

Abstract: Cytochrome oxidase stainings revealed three types of stripes in macaque and human area V2. The widths of these stripes are roughly 1 - 1.5 mm in macaque and 2.5 - 3.5 mm in human. Stripes of the same kind are seperated from each other by ~4 mm in macaque (Roe and Ts'o 1997) and ~7 mm in human (Nasr et al. 2016). Different functional properties are attributed to thin and thick dark stripes, for example based on separated color, direction, and disparity-selective cells (Chen et al. 2008, Tootell et al. 2004). Nevertheless, the stripes remain difficult to segregate using conventional fMRI due to their size. Recently, an fMRI study (Nasr et al. 2016) using high field (7T) and 1 mm isotropic voxels exquisitely revealed this stripe-like functional organization in human area V2. Here, we visualized the stripes in awake macaques using sub-mm resolution and conventional field fMRI (3T). We used the same isoluminant color and achromatic radial grating stimuli as in our previous double-label deoxyglucose study (Tootell et al. 2004) to detect the color-biased thin stripes. A size-matched binocular disparity defined radial sine-wave grating and its monocular counterpart was used to activate the disparity-biased stripes. Furthermore, myelination density mapping using T1- and T2-weighted MRI with 0.4 mm isotropic voxel size was acquired in an attempt to visualize the pale stripes which are more myelinated compared to thin and thick stripes (Horton and Hocking 1997). During the functional scans, monkeys fixated at the center of the stimulus. Contrast-enhanced fMRI data with 0.6 mm isotropic voxels (EPI, TR 3 s) was acquired using implanted phased-array receive coils developed in our lab (Janssens et al. 2012). To minimize image artifacts caused by monkey motion, several image processing algorithms were implemented, including an optimized GRAPPA algorithm for image reconstruction (Hoge et al. 2009), a B-spline grid based nonlinear registration algorithm for EPI to EPI distortion correction and a fieldmap-based distortion correction algorithm for EPI to structue registration. Finally, a GLM denoising algorithm (Kay et al. 2013) was used to reduce physiological and other nuisance noise in the temporal domain. We found stripe-like color activations interdigitated with disparity activations in retinotopically-defined area V2, which are reproducible across monkeys and across scan sessions of the same monkeys. Furthermore, we observed higher myelinated stripes largely separated from color- and disparity-selective stripes. These results show that high-resolution 3T fMRI can be reliably used to study in-vivo submillimeter-scale functional organizations of the primate brain.

Title: A retinotopic proto-organization in IT present at birth

Authors: *M. J. ARCARO, J. L. VINCENT, P. SCHADE, K. SRIHASAM, M. S. LIVINGSTONE;
Neurobio., Harvard Med. Sch., Boston, MA

Abstract: In adult primates, inferior temporal cortex (IT) is subdivided into domains selectively responsive to particular categories, such as bodies, places, and faces. Notably, the locations of these domains are consistent across individuals, suggesting a common constraint on their development. Recent experiments from our lab demonstrated that novel domains could be formed in IT of juvenile monkeys in response to intensive experience (Srihasam et al. 2014). The locations of these training-induced domains were also consistent across individuals and depended on the stimulus set, not on the degree of expertise or the symbols' functionality. Taken together, these data suggest that a pre-existing, "proto-" organization in IT guides and constrains the spatial organization of developing domains.

To look for any such proto-organization, we imaged monkeys longitudinally starting as early as 1-week through two years of age. Previously, our lab found that visual responsiveness and category-selectivity in IT are not detectable with fMRI until several months of age (Vincent et al. 2015, SfN). While evoked responses were not detectable in newborns, it is possible that early functional organization of IT could be reflected in patterns of synchronous signal fluctuations. To identify the organization of IT in newborns, we used correlation analyses on data collected during resting states and while monkeys viewed static and dynamic images.

We observed significant correlations between IT cortex and primary visual cortex as early as 1-week of age. The correlations in IT were retinotopically organized, with the fovea of V1 most strongly correlated with the lower bank of the STS, and peripheral portions of V1 most strongly correlated with ventral portions of IT (as well as parietal cortex). The portions of IT that correlated at birth with the fovea of V1 later in development showed selectivity to foveal stimulation (vs. peripheral) and faces (vs. objects) in the same monkeys. Taken together, these results suggest that a retinotopic organization of IT is present at birth (if not beforehand), and may provide the scaffolding for functional domain development in IT.

Title: Convolutional network modeling of the primate dorsal and ventral visual streams

Authors: *B. P. TRIPP;
Systems Design Engin., Univ. of Waterloo, Waterloo, ON, Canada

Abstract: Convolutional neural networks (LeCun et al., 1990, NIPS) are a kind of artificial neural network that has a number of parallels with the primate visual cortex. These include deep structures with retinotopic connections, in which abstract representations emerge in later stages. Notably, in addition to structural similarities, convolutional networks perform as well as humans in object recognition in natural scenes. Furthermore, convolutional networks trained for object recognition have been found to predict activity in the inferotemporal cortex and V4 (Yamins et al., 2014, PNAS). Similar networks also perform well in depth and optic flow estimation, and other visual tasks. Convolutional networks also differ from the visual cortex in important ways, for example they have traditionally lacked recurrent connections and attention mechanisms. However, such details have been incorporated in more recent networks. The “dropout” regularization method, which is very effective in these networks, is on a continuum with Poisson spike variability. Also, importantly, there is growing hardware and software support for fast simulation of very large convolutional networks. For these reasons, convolutional networks may serve as a good starting point for large, integrated models of the whole visual cortex. A preliminary attempt to develop such a model will be presented. The model approximates the structure of a large network that includes multiple early, dorsal, and ventral visual areas. It exhibits features of neural activity in each of these areas, and performs a variety of visual processing, including estimation of self-motion and grasp affordances.

Title: Revealing Details: spatial-frequency selective domains for a coarse-to-fine processing in macaque V4

Authors: *Y. LU[1], J. YIN[1], Z. CHEN[1,2], Y. LIU[1,2], H. GONG[1,2], L. QIAN[1], X. LI[1], I. M. ANDOLINA[1], W. WANG[1];
[1]Inst. of Neuroscience, CAS, Shanghai, China; [2]Univ. of Chinese Acad. of Sci., Shanghai, China

Abstract: Spatial vision is critical for primates to see effortlessly. One seemingly paradox in the primate ventral stream concerns the increasing complexity of encoded features while spatial frequency (SF) selectivity decreases drastically along the hierarchy. However this inconsistency does not appear to affect our sight, because at the highest levels of the ventral stream neurons are capable of invariantly encoding complex patterns or figures with high spatial resolution. Straddling a unique position along the ventral stream, how does V4 serve as a connecting link between the preceding and the following processing stages for spatial vision? Combing simultaneously intrinsic-signal optical imaging of V1, V2, and V4, anatomical CTb injections and electrophysiological neuronal recordings in awake macaques, here we discovered that neurons with low and high SF preferences clustered into columns in V4 but not in V1 and V2. These isolated high SF preference domains (SFPD) were surrounded by numerous low SFPD. CTb injections in V4 showed that neural projections to high SFPD come not only from V2 but also from V1, suggesting an extra spatial integration directly from primary visual cortex. Neuronal responses within the high SFPD favored local features, whereas those within low SFPD signaled the orientation of global patterns. By analyzing response latency, we found neurons located in high SFPD (SF≥4c/d) responded substantially later than those in low SFPDs (SF≤1.5c/d) to their preferred SF (60.3±5.8ms versus 50.7±7.2ms, N=186 versus N=198, $P<0.001$, t-Test). This suggests a non-parallel spatial analysis by neurons in low and high SF channels, supporting a role in coarse-to-fine (global ⇨ local) processing occurring at this intermediate processing stage of the ventral stream. Our findings demonstrate an unexpected columnar organization of neurons with low and high SF preferences in macaque V4. The differential processing of local and global patterns at different spatial scales with different processing time windows across these domains shed light on spatial analysis along the visual hierarchy, and helps us to better understand the integration of local spatial features into global representations.

Title: Feedback signals from higher-order visual cortex affect spike-responses of neurons in the 'intermediate' area in the pattern-processing stream

Authors: ***J. Y. HUANG**[1], C. WANG[2], B. DREHER[2];
[1]Discipline of Biomed. Sci., The Univ. of Sydney, Lidcombe, Australia; [2]Discipline of Anat. and Histology, The Univ. of Sydney, Sydney, Australia

Abstract: In domestic cat, a subset of neurons in the postero-temporal visual (PTV) cortex - a higher-order pattern/form-processing area sends direct 'feedback' projection to the ipsilateral cytoarchitectonic area 19 (area V3). Reversible inactivation of PTV achieved by cooling it to 10°C, silences spike-activity of neurons in the area - no feedback signals to area 19. In anesthetized and immobilized cats, the background spike-activities and spike-responses to visual stimuli of single area 19 neurons were recorded extracellularly before, during cooling and after rewarming of ipsilateral PTV to physiological temperature. Transient inactivation by cooling of PTV very rarely resulted in significant reductions in background spike-activity of area 19 cells. By contrast, in a substantial proportion of area 19 neurons, transient inactivation of PTV resulted in: i) significant reversible changes in peak magnitude of spike-responses to visual stimuli (35.5%; 10/28); ii) substantial reversible changes in their direction selectivity indices (43%; 12/28) and iii) reversible, upward shifts in their preferred stimulus velocities (37%; 7/19). However, substantial ($\geq 15^{\circ}$) shifts in preferred orientation and/or substantial ($\geq 20^{\circ}$) changes in width of orientation tuning curves were less common (26.5%; 4/15). Thus, higher-order pattern/form-processing visual cortical signals tend to play an important role in determining the spike-responses and some 'motion-related' receptive field properties of a proportion of neurons in area 19 - an 'intermediate' form-processing visual area.

Title: Interactions between macaque retinotopic areas and IT for segmenting and recognizing objects in a visual scene

Authors: *J. K. HESSE, D. Y. TSAO;
Biol., Caltech, Pasadena, CA

Abstract: Segmentation of the visual scene and recognition of the objects therein are two interdependent problems that are hard to solve separately from each other. When trying to segment a scene, it is helpful to already know the present objects and their shapes. However, for recognizing an object in clutter, one would like to consider its isolated segment alone to not get confounded by features of other objects.
Using fMRI in macaque IT we found that segmenting the scene is indeed crucial for successful recognition: By changing the texture of an occluder we controlled the segmentability of a face stimulus while keeping the features of the face identical and found that responses in face patches drop significantly when the face is rendered unsegmentable.
To study the interaction between recognition and segmentation, we next looked for areas involved in segmentation. Presenting stimuli containing distinct figures defined by luminance, texture, motion or disparity revealed a set of distinct patches in retinotopic areas that were activated significantly more by the figure stimuli than by their respective background control stimuli. We targeted these different patches with multi-site electrophysiological recordings to compare their information about figure-ground segmentation by presenting figure stimuli across multiple positions and trying to decode from neuronal responses whether different regions of the scene belong to a figure, background or a border belonging to either side of a figure.
The different levels of figure-ground information encoded in each patch indicate to which extent different retinotopic areas are involved in segmentation and may thereby aid recognition in IT.

Title: Theta-rhythmic spiking of visual cortical area V4 neurons arises from receptive field center-surround interactions

Authors: *R. KIENITZ[1], J. T. SCHMIEDT[1], K. A. SHAPCOTT[1], K. KOUROUPAKI[1], M. C. SCHMID[2];
[1]Ernst Strüngmann Inst. (ESI) For Neurosci., Frankfurt, Germany; [2]Inst. of Neurosci., Newcastle Univ., Newcastle upon Tyne, United Kingdom

Abstract: Rhythmic modulation of neural activity is an important aspect of brain function. However the generative mechanisms underlying many brain rhythms in the awake state are not fully understood. A study by Rollenhagen et al. (2005) had shown that theta (~4 Hz) rhythmic spiking in inferotemporal cortex (IT) may result from a finely tuned balance of excitation and inhibition between two neural populations representing separate visual objects. In cortical area V4, we recently found that theta (~4 Hz) rhythmic spiking is elicited by the presentation of a Kanizsa illusion, when illusion inducing stimuli were positioned around the neuron's receptive field (RF) center (Cox et al., 2013). The aim of our present study was to test whether rhythmic theta spiking in V4 can be explained by interactions between the excitatory RF center and its inhibitory surround.
To this end we recorded multi-unit activity (MUA) and local field potential (LFP) using chronically implanted "Utah" arrays in area V4 of two awake macaque monkeys performing passive viewing tasks.
As a first step we assessed the extent of the RF center and surround subregions by increasing simple visual stimuli in size up to ~7° diameter. As expected, enlargement of a black disc (gray background) up to an optimal size (~2-3°) resulted in elevated firing rates while further increase reduced the neuronal firing again (normalization), likely due to an increasing inhibitory drive from the neuron's suppressive surround (e.g. Desimone, Schein, 1987). Under these conditions with a single homogeneous stimulus no rhythm emerged. However, when we stimulated the neuron's center and surround independently using two spatially separated and simultaneously presented stimuli (e.g. a 2° disc and a 6° annulus separated by a gap at 4°), neurons started to engage in ~4 Hz rhythmic spiking. Similarly, theta spiking was also observed for single large stimuli, when a black center was accompanied by a white surround, or vice versa (gray background).

Finally, taking advantage of the array's spatial coverage, we positioned two smaller stimuli such that each of them stimulated the center of one and the surround of the other neuronal population, respectively. We found that temporary excitation of one group was accompanied by inhibition of the other group, yielding two populations of neurons oscillating in an anti-phase theta rhythm. Taken together, we found that spiking activity in extrastriate area V4 switches from a tonic to a 4-5 Hz rhythmic firing mode during the presentation of multiple or heterogeneous visual stimuli. This can be explained by inhibitory center-surround interactions.

Title: Effect of adapter duration on repetition suppression in macaque inferior temporal cortex.

Authors: ***P. KURAVI**, R. VOGELS;
K.U.Leuven, Leuven, Belgium

Abstract: Repetition suppression, the attenuation of neural activity for a repeated visual stimulus, is a well-known phenomenon in the inferior temporal (IT) cortex of the rhesus monkey. A previous adaptation study of primary visual cortex, V1, suggests that prolonged exposure to the adapter stimuli strengthens the adaptation effect in comparison to a brief exposure of the same stimuli. Here we investigate whether this property of V1 neurons prevails in macaque IT, an area hierarchically at a higher stage. To determine this we presented an adapter stimulus for durations ranging between 300 and 3000ms followed by a test stimulus of 300ms, with an interstimulus interval of 300ms. Single units were recorded from the rostral lower bank of the superior temporal sulcus during passive fixation. Two stimuli (A, B) were selected from a set of

52 images of various object categories, based on their response strength. These stimuli were either presented in repetition trials, i.e. repetition of the same stimulus (AA, BB), or in alternation trials, i.e. alternation of the stimuli (AB, BA). Our data show repetition suppression for both the short (300ms; $p < 0.0001$, 60 units) and long adapter durations (3000ms; $p< 0.0001$, 60 units). However, in contrast to V1, the degree of repetition suppression did not differ significantly between adapter durations (300 vs. 3000ms, n.s., 60 units). To examine whether the repetition suppression effect in IT was inherited from early visual areas, we performed an independent set of recordings where the adapter (300 or 3000ms duration) and test stimuli were presented either at the same or different locations, above or below the fixation dot, at an eccentricity of 5 visual degrees. We observed a significant repetition suppression effect for both adapter durations when test and adapter stimuli were presented either at the same or a different location ($p's < 0.001$, 38 units). The suppression effect didn't differ between 300 and 3000ms adapter durations when presented at the same or at a different location (n.s, 38 units). As a control, we performed additional single and multi-unit recordings where an adapter of 300ms was repeated 7 times with an interstimulus interval of 150ms (multiple adapter condition), followed by a 300 ms test stimulis, in addition to single 300 and 3000ms adapters (as above). We found that the multiple adapter showed the strongest suppression effect ($p < 0.0001$, 41 single units and $p < 0.0001$, 37 multiunits) although the stimulus exposure duration (adapter, 7 * 300 = 2100ms) was less than that of the 3000ms adapter condition. These surprising data constrain computational models of stimulus selective adaptation in IT (see Giese et al., SFN abstracts, 2016).

Title: A cross-validated cytoarchitectonic atlas of the human ventral stream

Authors: *M. ROSENKE[1], K. S. WEINER[1], M. BARNETT[1], M. FROST[2], K. ZILLES[3,4], K. AMUNTS[4,5], R. GOEBEL[2,6], K. GRILL-SPECTOR[1,7];
[1]Psychology, Stanford Univ., Stanford, CA; [2]Psychology and Neurosci., Maastricht Univ., Maastricht, Netherlands; [3]C. and O. Vogt Inst. for Brain Research, Heinrich Heine Univ. Düsseldorf, Dusseldorf, Germany; [4]Inst. for Neurosci. and Med. (INM-1), and JARA Brain, Res.

Ctr. Jülich, Jülich, Germany; [5]Univ. Hosp. Aachen, RWTH Aachen, Aachen, Germany; [6]Netherlands Inst. for Neurosci., Amsterdam, Netherlands; [7]Stanford Neurosci. Inst., Stanford, CA

Abstract: Eight cytoarchitectonic regions (cROIs) have been identified in the human ventral stream extending from primary visual cortex to higher visual areas (Amunts et al., 2000; Rottschy et al., 2007, Caspers et al., 2013; Lorenz et al., 2015). Four areas are located in occipital cortex (hOc1, hOc2, hOc3v, hOc4v) and four areas are located on the fusiform gyrus (FG; FG1-FG4). Based on these cytoarchitectonic delineations, the goal of the present study is to create a cross-validated cytoarchitectonic atlas of the human ventral stream. To do so, each of the eight cROIs was projected to the cortical surface of each subject's brain, from which we generated a group map of each cROI by transforming individual subjects' cROIs into a common anatomical space. We tested three types of alignments: (1) volume-based alignment to the MNI template, (2) cortex-based alignment (CBA) to the Freesurfer average brain (CBAfs), and (3) CBA to the group average of the nine postmortem brains (CBApm). Across alignment techniques, we compared (1) the consistency of a cROI averaged across subjects and (2) the ability to predict the location and spatial extent of a cROI in a new subject. Results show that group cROIs generated using CBAfs or CBApm have higher across-subject consistency and higher predictability compared to volume alignment ($F(2,13) = 80.4$, $p < .001$; average predictabilities: MNI: .21.11, CBApm: .54, CBAfs: .55). However, there were no significant differences across CBAfs and CBApm. Additionally, while the group hOc1 showed the highest between-subjects consistency and predictability, FG cROIs did not show lower consistency or predictability compared to occipital cROIs hOc2-hOc4v. Addition of other anatomical landmarks to the CBA further improved the group cROIs: (1) Adding the collateral sulcus increased the between-subject consistency of FG1 and FG3 ($p<.001$) and (2) adding the anterior tip of the mid-fusiform sulcus reduced inter-subject variability of the FG3/4 boundary ($p<.001$). Overall, these results suggest that CBA generates more accurate atlases of the cytoarchitectonic structure of the ventral stream by preserving the location of cROIs relative to the cortical folding. This atlas will be freely available and can be used to compare functional activations in typical and atypical populations to cytoarchitectonic partitions.

Title: Impact of visual cortico-striatal loop disruption on neural processing within the parahippocampal place area

Authors: *S. NASR[1,2], H. D. ROSAS, 02129[3,2];
[1]Athinoula A Martinos Ctr. for Biomed. Imaging, Charlestown, MA; [2]Harvard Med. Sch., Boston, MA; [3]Martinos Ctr. for Biomed. Imaging, Charlestown, MA

Abstract: Visual perception is often considered as the product of a multi-stage feedforward neural processing in which visual information is relayed from thalamus to the early visual areas and then to a sequence of higher, more selective visual regions within the temporal visual cortex. However, this neural processing is not purely feedforward. Rather, neuroanatomical studies in non-human primates (NHPs) have shown that almost all visual regions project back to striatum (mainly to caudate nucleus), which is connected to thalamus and together generate the Visual Cortico-Striatal Loop (VCSL). Despite perceptual and navigation impairments in patients with striatum atrophy (e.g. in Huntington's disease (HD)), the relevance of VCSL on cortical visual processing is not fully understood. In this study, we examined the contribution of VCSL on visual processing using fMRI and behavioral tests in healthy controls and HD patients. Experiment 1 (n=31), tested the level of functionally connectivity between caudate and temporal visual areas. Results showed a significantly stronger functional connection between caudate and the Parahippocampal Place Area (PPA) compared to other visual areas including V1, FFA and RSC ($p<0.05$). Experiment 2 (n=43) tested visual stimulus selectivity of caudate. Consistent with its functional connection to PPA, caudate showed a scene-selective response. Experiment 3 tested the impact of VCSL disruption on neural processes within PPA. We found that in HD patients (n=16), compared to healthy matched controls (n=18), scene-selective activity in PPA was reduced significantly ($p<0.0001$). This impairment was more prominent in the portion of PPA that showed a stronger functional connection to caudate. In contrast to PPA, the level of face-selective activity in Fusiform Face Area (FFA) and Amygdala remained intact between HD patients and controls. In behavioral level, consistent with decrease in PPA selective response, HD patients (n=12) compared to controls (n=12) showed a lower shape comparison performance for houses and simple objects. In contrast, we did not find a significant difference between spatial comparison performance of HD patients and controls ($p=0.11$). These results suggest a direct impact of VCSL on perceptual categorization and generation of 'selective' activity within PPA. These findings also broaden our understanding of neurodegenerative disorders (e.g. Huntington's, Alzheimer's and Parkinson's diseases) in which caudate degeneration has been shown.

Title: Does the dorsal medial visual area represent a unique target of the koniocellular pathway?

Authors: *B. MOORE[1], J. D. BOYD[1,2], O. P. ROY[1,3], J. A. MAVITY-HUDSON[1], V. A. CASAGRANDE[1];
[1]Vanderbilt Univ., Nashville, TN; [2]Univ. of British Columbia, Vancouver, BC, Canada; [3]Univ. of Virginia Hlth. Syst., Charlottesville, VA

Abstract: The primate visual system exhibits a well-studied division of labor whereby projections from the lateral geniculate nucleus (LGN) terminate in separate compartments of primary visual cortex (V1) with the parvocellular (P) pathway synapsing in the ventral tier of layer 4, the magnocellular (M) pathway terminating in the dorsal tier of layer 4, and the koniocellular (K) pathway synapsing in the cytochrome oxidase (CO) blobs of layer 3B. Even after V1, the M and P pathways appear to differentially extend to extrastriate visual areas with the P pathway targeting the second visual area (V2) and the M pathway predominately acting on the Middle Temporal (MT) visual area (Casagrande & Kaas, 1994). These differences offer clues concerning the role of different extrastriate areas. With this in mind and given that various hypotheses have been put forward about the role of the dorsal medial (DM) visual areas (Rosa et al., 2009), we asked whether the projections to DM, the likely homologue of area V3a or V6 in macaques, are from a specific layer of V1. To reach this goal, we conducted a retrograde tracer study and examined the labeled cells in V1.
Area DM was anatomically identified in a population of bush babies and pressure injections of cholera toxin subunit B conjugated to 7nm colloidal gold (CTB-Au) were made at a depth of 100μm. Each subject received multiple 1μL injections placed 500-700μm apart covering the entirety of DM in one hemisphere. After a 3 day survival period, the animals were perfused and posterior cortex was flattened into a block that was sectioned tangentially into 50μm sections. Tissue slides were imaged, posterized, and divided into blob and interblob regions (Shipp &

Zeki, 1989). A computerized image quantification system was used to calculate the area of blob and interblob regions as well as to count the number of labeled cells occurring within these regions.
Results show that the labeled cells tightly correlate with CO blobs throughout the entirety of V1. This finding suggests that DM may be driven by input from the K pathway - at least in bush babies. It is noteworthy that although CO blobs are often considered uniquely composed of color selective cells, bush babies only have a single cone type resulting in color blindness. The presence of blobs in these animals can be explained by the hypothesis put forward by Allman & Zucker (1990) who proposed that CO blobs take a more generalized role in processing surface features which include color, texture, and contrast. This suggests that the K pathway could serve as the first step in surface context information that eventually drives area DM. More analysis is needed to further elucidate the functional role of this extrastriate area.

Title: A deep convolutional energy model of V4 accurately predicts responses to natural movies

Authors: *M. D. OLIVER, J. GALLANT;
UC Berkeley, Berkeley, CA

Abstract: Area V4 is an important intermediate stage of visual processing. However, it has been very difficult to characterize and model the tuning properties of V4 neurons. For example, no current models of V4 neurons can accurately predict responses to natural images. This is in stark contrast to models of V1 and MT, where responses can be predicted well. V4 neurons have large, nonlinear receptive fields, and this makes it difficult to estimate their tuning properties using conventional methods; modeling V4 amounts to solving a high-dimensional non-linear regression problem with limited data.
To effectively attack this problem, we first sought to collect as much data as possible by

chronically implanting electrode arrays in area V4 of two macaque monkeys. Neurons were recorded while the awake animals viewed clips of large, full color natural movies. The chronic recordings were stable enough that neurons could often be held for several days. This allowed us to collect responses to hundreds of thousands (up to over 1 million) of distinct movie frames, for hundreds of different V4 neurons.
We then used several different neural network architectures to fit the data obtained from each V4 neuron. The training signals for each fit neural network were the stimulus movie and the response from one neuron. The most successful neural network architecture that we tested was one that combined insights from the cortical magnification factor, the Adelson-Bergen energy model, the scattering transform and deep convolutional neural networks. We call this the deep convolutional energy model. This model is simple and interpretable, and it predicts V4 responses significantly better than previous models. The predictions of deep convolutional energy models fit to V4 neurons stimulated with natural movies approach the prediction performance of the best current models of V1 and MT neurons. The models trained on natural movies also accurately predict V4 responses to various types of synthetic stimuli similar to those used in previous studies of V4. Finally, the trained V4 models can also be used to generate optimal stimuli for each neuron, which provides important insights about the representation of visual information in area V4.

Title: Proliferation of macromolecular tissue in human cortex underlies development of face processing

Authors: *J. GOMEZ[1], M. BARNETT[1], V. NATU[1], A. MEZER[2], K. S. WEINER[1], K. AMUNTS[3], K. ZILLES[4], K. GRILL-SPECTOR[1];

Abstract: Computations performed by a given cortical region are a product of its underlying cytoarchitecture and likely sculpted through development. Yet, how does cortical tissue change as brain function and behavior improve from childhood to adulthood? Human high-level visual cortex, with its prolonged development and causal role in perception, provides an ideal test bed to answer this question. We employ novel quantitative magnetic resonance imaging (qMRI) to quantify the volume and composition of brain tissue, such as the lipids and cholesterol in cell walls, dendrites, and myelin (measured through proton relaxation time: T1, and macromolecular tissue volume: MTV). Combining qMRI, functional MRI, and visual recognition behavior in a large sample of children (n=26, 5-12 years old) and adults (n=26, 22-28 years old), we make unprecedented measurements of the tripartite relationship between structure, function, and behavior in the developing brain. We find differential development of ventral high-level visual areas involved in face and place recognition, where development of face-selective regions (red in Fig. 1), but not place-selective regions (yellow in Fig. 1), is predominated by lowered T1, which is indicative of macromolecular tissue proliferation. These anatomical developments are correlated with specific increases in functional selectivity to faces in face-selective regions (Fig. 1B) as well as improvements in face recognition ability (Fig. 1C). Ultimately, this development leads to differentiated tissue properties between face- and place-selective regions in adulthood, which we validate with postmortem cytoarchitectonic measurements in independent brains. These results suggest a rethinking of fine-grained anatomical development of cortex, as macromolecular tissue proliferation implicates a different neural mechanism of development during childhood than infancy pruning. We offer a new model by which behavior emerges from an interplay between structural and functional changes in the cortex.

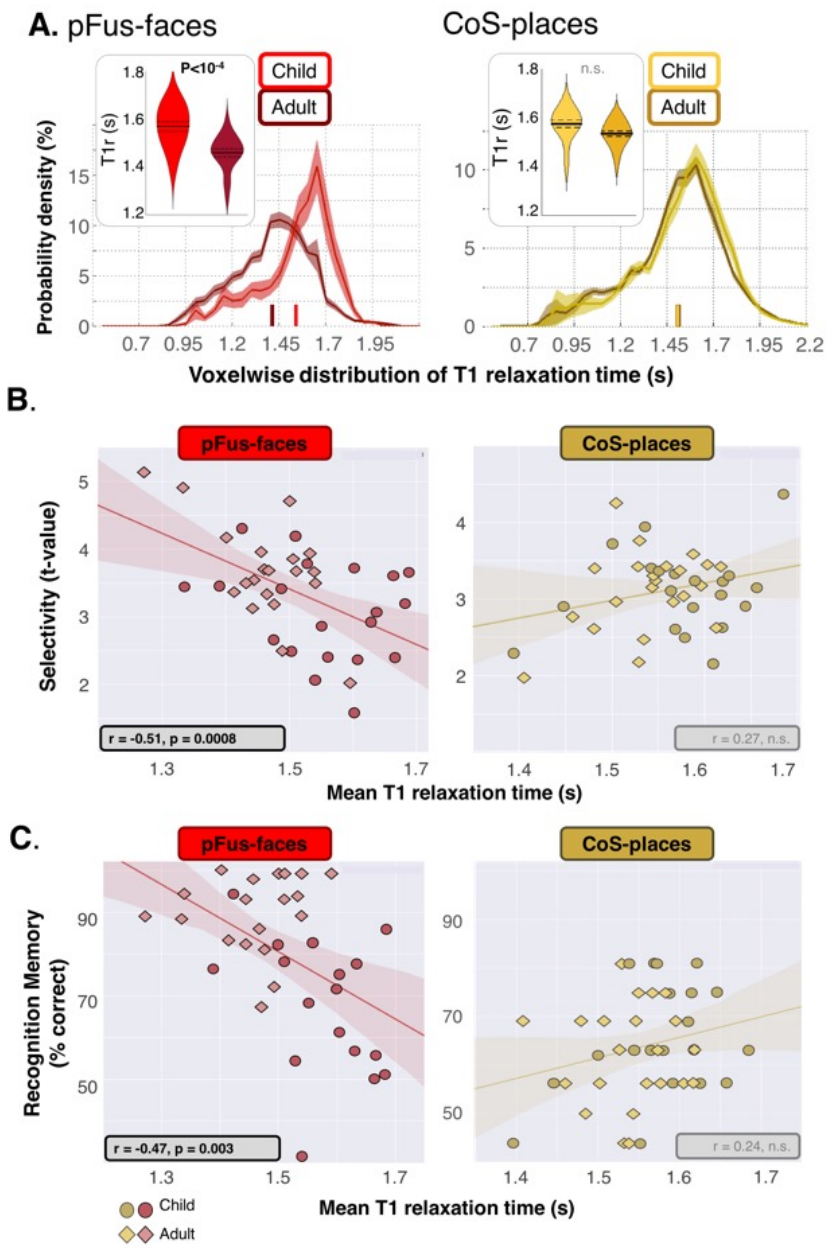

Figure 1: Proliferation of cortical tissue in face-selective regions impacts function and behavior. **(A)** T1 relaxation times averaged within a region of interest (inset violin plots) or shown as voxelwide distributions across subjects (lower curves, shaded region is standard error), for either a face-selective region on the posterior fusiform gyrus (pFus-faces, red) or a place-selective region in the collateral sulcus (CoS-places, yellow). Data are averaged across 20 children and 20 adults for pFus-faces and 20 children and 22 adults for CoS-places. **(B)** *Left:* pFus-faces mean t-values for the contrast faces versus all other stimuli plotted against pFus-faces mean T1 relaxation time. Each point is a subject (circles: children; diamonds: adults. Line of best fit plotted with 95% confidence obtained from bootstrapping. *Right:* same as left, but for places vs. other stimuli in CoS-places. **(C)** *Left:* face recognition memory vs. pFus-faces mean T1 relaxation. *Right:* place recognition memory vs. CoS-places mean T1 relaxation time.

Title: Sensitivity of v2 neurons to curvatures in infant monkeys

Authors: ***B. ZHANG**[1], Y. WANG[2], X. TAO[2], G. SHEN[2], E. L. SMITH, III[2], I. OHZAWA[3], Y. CHINO[2];
[1]Col. of Optometry, Nova Southeastern Univ., Davie, FL; [2]Univ. of Houston, Houston, TX; [3]Osaka Univ., Osaka, Japan

Abstract: Non-human primates can discriminate texture-defined form as early as 6-8 weeks of age despite their relatively low visual acuity. The sensitivity to texture-defined form is influenced by the ability to extract the appropriate image properties, to integrate these properties, and to segment the shape that is represented. The neuronal mechanisms underlying this remarkable visual capacity of infant primates have not been extensively studied. In adult monkeys, neurons in 'extrastriate visual areas are thought to act as "integrators" of local stimulus information that is processed by V1. As a result, V2 and in particular, V4 neurons become sensitive to angled contours that make up critical aspects of global shape by efficiently linking local feature information. Our previous developmental study on the receptive-field subunits of V2 neurons (Zhang et al, 2013) implied that V2 neurons in infant monkeys can encode angles or curvatures. In this study we tested this idea more directly by using two-dimensional dynamic noise stimuli and a new analytical method called "Transform Domain Reverse Correlation (TDRC)", which computes spike-triggered average of stimuli after transforming them into curvature domain. The resulting map reveals the stimulus selectivity of individual neurons for angled or curved contours. Unit recordings were made in V2 of anesthetized infant macaque monkeys (4, 8, and 16 weeks) and adult monkeys. We found: 1) Signal strength and reliability (Zmax) for infant neurons were not significantly different from that for adults. 2) The optimal curvature tuning widths were similar in infants and adults. 3) The variance of curvatures of subunits for infant monkeys was lower in infants than in adults. 4) There was no bias in optimal

curvature direction in any age group, and 5) Most importantly, the percentage of neurons that were sensitive to curvatures was similar in infants and adults. The results suggest that as early as 4 weeks of age, about 40% of V2 neurons in non-human primates are sensitive to angled or curved contours in image sub-regions. Our results provide a physiological substrate for the aforementioned perceptual finding that infant monkeys are capable of discriminating texture-defined visual borders as early as 6 weeks of age (El-Shamayleh et al, 2011) and that human infants can detect texture-defined patterns as early as 3-5 months of age (roughly equivalent to 3-5 weeks in non-human primates)(Norcia et al, 2005; Sireteanau et al, 2005).

Title: Neural mechanisms for visual object detection in *Drosophila*

Authors: *M. KELES, M. A. FRYE;
UCLA, Los Angeles, CA

Abstract: A visual object is perceptually distinguished from the moving visual surround by optical disparities such as relative motion, size, texture, and brightness. Visual circuits must implement the parametric detection of these cues. Although the neural circuitry for motion vision is well studied in the mammalian retina and the fruit fly optic lobe, the neural mechanisms for object detection are not well resolved in either system. Behavioral analysis in *Drosophila* reveals robust visual perception of salient objects such as conspecifics and landscape features. Neurogenetic and physiological experiments have recently demonstrated that the neural circuits for motion vision that supply the lobula plate of the optic lobe are dispensable for intact object vision, indicating a separate neural pathway. Using 2-photon GCaMP imaging, we hypothesized that neurons in the lobula compartment of the optic lobe are selective object detectors. To test this hypothesis we have investigated a specific class of lobula columnar neuron, LC-11. We show that LC11 dendrites and axons respond only to the motion of small, solid, high-contrast objects, with little or no responses to elongated bars or panoramic gratings. We show that the receptive field of each cell in the columnar palisade is tuned to an object subtending 8-degrees

with suboptimal yet robust activation of an object subtending less than one inter-receptor angle, and is activated by non-directional motion of a dark object within its 20-degree functional receptive field (1/3rd the size of the anatomical receptive field). Blocking inhibitory ionic currents with PTX abolishes object selectivity and releases responses to large moving features and gratings. All LC11 axon terminals ramify within a compact glomerulus in the central brain, where retinotopy is lost. We suggest that strong activation of the LC11 glomerulus conveys the perception of a small object moving across the ipsilateral frontal eye. Future research will focus on the use of this information by downstream circuits.

Title: A fusion mechanism for depth cues in monkey MT?

Authors: *M. ARMENDARIZ[1], H. BAN[2,3], A. WELCHMAN[4], W. VANDUFFEL[1,5,6];
[1]KU Leuven, Leuven, Belgium; [2]Natl. Inst. of Information and Communications Technol., Osaka, Japan; [3]Osaka Univ., Osaka, Japan; [4]Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom; [5]Dept. of Radiology, Harvard Med. Sch., Boston, MA; [6]Massachusetts Gen. Hosp., Boston, MA

Abstract: To reconstruct the third dimension from flat retinal images, the brain exploits a range of monocular and binocular depth cues. However, the neural mechanisms underlying cue integration is still poorly understood. Traditionally, this process has been broadly conceived in modular terms, with the independent processing of individual cues followed by a combination stage in which the influence of each cue reflects the reliability with which it is encoded. Computational and recent imaging studies in humans suggested the existence of a fusion mechanism that combines the information of different depth cues (Ban et al. 2012; Murphy et al. 2013). In particular, the latter studies showed, rather unexpectedly based on previous monkey research, that area V3B/KO may house neurons coding for a fusion mechanism of different depth cues. To investigate cue integration in monkeys using exactly the same paradigm as in Ban et al. (2012), we performed an equivalent fMRI study. Specifically, we showed monkeys a set of stimuli representing near or far depth planes defined by motion parallax, binocular disparity and the combination of both in either a congruent (i.e. the two cues signal the same depth planes) or incongruent fashion (i.e. the two cues signal different depth planes). We used a linear support

vector machine to classify between near and far patterns in retinotopically defined regions of interest (ROI) of visual cortex. To quantify differences in prediction accuracies across conditions and to assess fusion, we conducted three test for cue integration: integration index, congruent vs incongruent cues and transfer index (similar to Ban et al. 2012). We found that fMRI responses are more discriminable when the two cues signal depth concurrently, and that depth information provided by one cue might be diagnostic of depth indicated by the other. We revealed that monkey area MT shows fMRI signals consistent with a fusion mechanism of independent depth cues. In fact, these results may reconcile the human imaging data with previous monkey electrophysiological studies implicating area MT in depth perception based on motion and binocular disparity signals (Nadler et al. 2008; Nadler et al. 2013; DeAngelis et al. 1998). In general, our findings together with those obtained in humans provide evidence for a fusion mechanism for depth perception in the dorsal stream of primates. The fusion of depth cues, however, appears to be computed in different areas in humans (V3B/KO) and monkeys (MT). Therefore it is tempting to speculate that human V3B/KO may have been part of the MT cluster in an ancestor of monkeys and humans which has drifted in a caudo-dorsal direction during human evolution.

Title: Neural representation of occluded objects in macaque V4

Authors: ***S. D. ZHU**[1], L. ZHANG[1], R. VON DER HEYDT[1,2];
[1]Krieger Mind/Brain Inst., [2]Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: In everyday vision objects often occlude one another from sight. Despite this erratic inflow of visual information, we perceive objects as permanent. Evidence from human and animal behavioral studies indicates that occluded objects are still represented in the brain, and

imaging studies found correlating activity in several cortical areas. Finding persistence of border ownership signals O'Herron & von der Heydt (Neuron 61;801-9, 2009) speculated that activity might persist in hypothetical "grouping cells" that link distributed features to objects. However, grouping cells have not been demonstrated and the neural mechanism of object permanence remains poorly understood. Here we searched for object-related activity in macaque V4, a candidate area for grouping cells. Monkeys performed a visual foraging task in which they sequentially fixated individual figures of an array of 10 figures in search for reward. The array was constructed so that, in most cases, fixating one figure would bring another figure into the receptive field (RF) of the neuron under study, in other cases, a region of uniform background. During the presentation of the array, a grating of parallel opaque stripes drifted over the array, variably occluding some figures, each for about 0.25s. To a human observer, the 10 objects appeared permanent despite the transitory occlusions. We measured the firing rates following the saccades that brought a figure into the RF during phases of visibility (VIS) and during phases of occlusion (OCC), and compared both with the activity following the saccades that brought no figure to the RF during the corresponding phases (NOF). The difference VIS-NOF is the representation of a visible object and the difference OCC-NOF is the representation of an occluded object ("permanence activity"). Note that this cannot be persistence of responses, because before these saccades the RF 'saw' the same random mix of stimuli in both OCC and NOF. We calculated a permanence index PERMI = (OCC-NOF)/(VIS-NOF). Preliminary results indicate that V4 cells show robust permanence activity (PERMI=0.53, SEM=0.08, N=40) whereas such activity is weak in cells of V1/V2 (PERMI=0.22, SEM=0.09, N=13). We conclude that V4 may contribute to the perceptual capacity for object permanence.

Title: Dual mechanisms of pattern completion in macaque identified by removal of visual area TE

Authors: *J. M. FREDERICKS, M. A. G. ELDRIDGE, K. A. LOWE, B. J. RICHMOND; NIMH, NIH, Germantown, MD

Abstract: Introduction: Bilateral removal of temporal lobe area TE causes impairments in discriminating categories and pairs of patterns. Here we explore whether monkeys with bilateral area TE removals are impaired in tests of pattern completion and figure-ground discrimination.
Methods: Three control monkeys and three monkeys with bilateral TE ablations were tested on a cat vs. dog categorization task comprising 440 unique stimuli per session. Monkeys were trained to touch a bar to initiate a trial, and release the bar during one of two intervals; early (signaled by a red central dot) if they identified the stimulus as cat, or late (signaled by a green central dot) if the stimulus was identified as dog. A correct response resulted in the delivery of a liquid reward, an incorrect response led to a time-out. Once the animals performed this simple categorization task we introduced visual noise.
Results: Monkeys were presented with interleaved trials of foreground and background noise (11 levels, from 0 - 100 %) that was generated by replacing randomly chosen stimulus pixels with a randomly chosen greyscale pixel. In the absence of noise, the performance of monkeys with TE removals was moderately degraded relative to that of controls. The presence of background noise did not further degrade the ability of the TE-lesioned monkeys to categorize stimuli, indicating that TE is not necessary for figure-ground discrimination as configured in this experiment. Increasing levels of foreground noise caused decreased accuracy of categorization in both experimental and control groups. As foreground noise increased from 0 - 40% noise, the performance of control and TE-lesioned monkeys degraded in parallel. Beyond 60% foreground noise, control monkey performance dropped abruptly becoming indistinguishable from that of monkeys with ablations; at 90% foreground noise both groups were performing at chance levels.
Discussion: Pattern completion appears to depend on two mechanisms. A TE-independent mechanism supports a basic ability to perform categorization at modest levels. A TE-dependent mechanism confers a substantial advantage at lower noise levels.

Title: Spiking neuronal network for optimal context integration in vision

Authors: ***J. LEE**[1], R. IYER[2], S. MIHALAS[2];
[1]MAT, Allen Inst., Seattle, WA; [2]Allen Inst. for Brain Sci., Seattle, WA

Abstract: Neurons in the primary visual cortex (V1) predominantly respond to a patch of the visual input, their classical receptive field. These responses are modulated by the visual input in the surround. This reflects the fact that features in natural scenes do not occur in isolation: lines, surfaces are generally continuous. There is information about a visual patch in its surround. This information is assumed to be passed to a neuron in V1 by neighboring neurons via lateral connections. The relation between visual evoked responses and lateral connectivity has been recently measured in mouse V1. By combining natural scene statistics, mouse V1 neuron responses and their connectivity, we are interested in addressing the question: Given a set of natural scene statistics, what lateral connections would optimally integrate the cues from the classical receptive field with those from the surround?
First, we assumed a neural code: the firing rate of the neuron maps bijectively to the probability of the feature the neuron is representing to be in the presented image. We generated a database of features these neurons represent by constructing a parameterized set of models from V1 electrophysiological responses. We used the Berkeley Segmentation Dataset to compute the probabilities of co-occurrences of these features. We computed the relation between probabilities of feature co-occurrences and the synaptic weight which optimally integrates these features. The relation between evoked responses and connectivity which leads to optimal context integration is qualitatively similar to the measured one, but several additional predictions are made.
We implemented the predicted optimal connectivity in a spiking model of the visual processing in mouse. The network has the capacity to infer from context when presented with images with gaps. We hypothesize that this computation: optimal context integration is a general property of cortical circuits, and the rules constructed for mouse V1 generalize to other areas and species.

Title: Familiarity sculpts figure ground selectivity through inhibitory interactions in monkey inferotemporal cortex

Authors: *N. RATAN MURTY[1], S. P. ARUN[2];
[2]Ctr. for Neurosci., [1]Indian Inst. of Sci., Bangalore, India

Abstract: Contours in the visual world are inherently ambiguous, and are assigned to either side through a process known as figure-ground segmentation. In the high level visual areas responsible for recognition such as the inferior temporal cortex, neurons are sensitive to the outcome of figure-ground organization, implying that segmentation precedes recognition. But can recognition processes influence segmentation? To address this issue, we recorded extracellular neuronal responses from 116 visual neurons in the anterior inferior temporal cortex from 2 monkeys (60 from M1 and 56 from M2) that were familiarised in a counter-balanced fashion 1) to only one side 2) to both sides and 3) to neither side of arbitrary contours. We observed many more neurons that preferred the unfamiliar side over the familiar side of each contour. However, neurons that preferred the familiar side of the contour showed enhanced selectivity for the familiarised side during the early part of the visual response (50-150ms post stimulus onset). Both effects were present only when one side was familiar but not when both sides were familiar or unfamiliar. These effects were also specific to putative inhibitory but not putative excitatory neurons. Taken together, our results show that familiarity sculpts figure-ground selectivity through inhibitory interactions.

Title: Neural model for stimulus-specific adaptation of neurons in area IT

Authors: *M. A. GIESE[1], P. KURAVI[2], R. VOGELS[2];
[1]Hertie Inst. For Clin. Brain Sci. / CIN, Tuebingen, Germany; [2]Dept. Neuroscience, KU Leuven, Lab. Neuro en Psychofysiologie, Leuven, Belgium

Abstract: Many neurons in visual cortex show adaptation effects for repeated stimulation, providing a potential neural basis for repetition suppression effects in fMRI studies and high-level after-effects observed in behavioral studies. A variety of theoretical explanations has been discussed, which so far have been difficult to distinguish without detailed electrophysiological data. Recent electrophysiological data on the adaptation of shape-selective neurons in inferotemporal cortex (area IT) provides substantial constraints that narrow down the spectrum of possible computational mechanims. We propose a biophysically plausible neurodynamical model that reproduces these results. METHODS: Our model consists of a neural field (neural mass model), which models the population activity dynamics of shape-selective neurons in area IT, and integrates several adaptive mechanisms: (i) spike-rate adaptation; (ii) input fatigue adaptation, modeling adaptation in synaptic inputs and earlier levels of the visual hierarchy; (iii) a firing-rate fatigue mechanism that depends on the output firing rates of the neurons. RESULTS: The model reproduces the following experimental results: (i) Shape of typical PSTHs of IT neurons (Kaliukhovich & Vogels, Cereb. Cortex, 2011); (ii) temporal decay of adaptation with number of stimulus repetitions (Sawamura et al., Neuron, 2006); (iii) dependence of adaptation on effective and ineffective adaptor stimuli, which stimulate the neuron strongly or only moderately (deBaene & Vogels, Cereb. Cortex, 2011); (iv) dependence of the strength of the adaptation effect on the duration of the adaptor (see Kuravi & Vogels, SFN abstracts, 2016). All proposed mechanisms are necessary to account for the data. CONCLUSIONS: A mean field model that includes several physiologically plausible adaptive processes provides a unifying account for critical experimental observations on the adaptation of IT neurons.

Title: Building object view invariance in a newly-discovered network in inferior temporal cortex

Authors: *P. BAO, D. Y. TSAO;
Biol., Caltech, Pasadena, CA

Abstract: Object recognition in primates is mediated by hierarchical, multi-stage processing of visual information within occipital and inferior temporal (IT) cortex. Insight into the functional organization of IT has rapidly accumulated in recent years. It is known that IT contains several networks that process specific categories (e.g., faces, bodies, scenes) or stimulus dimensions (e.g., color, curvature). Furthermore, at least in the case of the network for face processing, the nodes appear to be organized hierarchically, e.g., neurons in the middle faces patches are tuned for specific facial views, while those in the most anterior patch are tuned for the identity of faces in a view-invariant way. However, there remains a fair amount of IT cortex that doesn't belong to any known network, raising the question: are there any new, undiscovered networks not yet accounted for by existing functional parcellation studies? If so, what are these networks processing and how are they organized? To address this question, we exploited the technique of electrical microstimulation combined with simultaneous functional magnetic resonance imaging. Electrical microstimulation of a region of macaque IT cortex not belonging to any known network produced strong activation in three patches that also didn't overlap with any known networks. We targeted single-unit recordings to these three patches, while monkeys viewed an image set consisting of 51 objects with 24 views for each object; the objects included faces, animals, houses, vegifruit, vehicle, and man-made objects. The monkey was rewarded with juice for fixating the center of the images. Average responses across neurons from the three patches revealed high similarity in object preferences between the patches, further confirming these patches belong to a common network; for example, all three patches showed the smallest response to faces. We determined high- and low-preference objects based on mean singe-unit responses from cells in the three patches, and then performed an fMRI experiment contrasting responses to these high- and low-preference objects; this revealed the same network as the original microstimulation+fMRI experiment. Representational similarity analysis on population single-unit responses in each of the three patches revealed the most view-invariant representation in the most anterior patch, and the least view-invariant representation in the posterior patch, suggesting that, analogous to the face patch network, view-invariant object representation is built up hierarchically within this new network.

Abstract: Primates can easily recognize objects in their complex environment. The ability is thought to be achieved by hierarchical information processing along the ventral stream, which starts from the primary visual cortex and ends at the anterior inferior temporal cortex (ITC). In computer vision, convolutional neural networks (CNNs) have achieved nearly human-level performance for object category recognition tasks. CNNs are hierarchical learning models originally developed by inspirations from the primate ventral stream. Previous studies indicate a hierarchical similarity between CNNs and the primate ventral stream, where features extracted at lower and higher layers of CNNs can be employed to better predict neural responses measured at lower and higher areas in the ventral stream, respectively. However, a more detailed analysis of the relationships between CNN features and neural responses expressed in other domains than space is required to establish more biologically plausible models, because neural information processing in the brain may occur simultaneously in space, time and frequency domains. In this study, we simultaneously recorded the cortical potentials of 128 channel electrocorticogaphy (ECoG) covering from macaque's posterior to anterior ITC while presenting natural images consisting of 12 categories, each of which contains 1000 examples. We then extracted features at each layer of a pre-trained CNN model (VGGNet-16) from the same images. Using the CNN features, we estimated encoding models to predict ECoG features at each electrode location, time window and frequency. Finally, we tested prediction accuracy of each model while conducting permutation tests. Comparing the prediction accuracy among CNN layers, we found that, in space domain, ECoG features measured in posterior and anterior electrodes were better predicted from CNN features extracted at lower and higher layers, respectively. Moreover, in time domain, ECoG features extracted in earlier and later time windows were better predicted from lower and higher layers, respectively. Finally, in frequency domain, ECoG features extracted in gamma and

theta bands were better predicted from lower and higher layers, respectively. Our results indicate that feature representations extracted at different CNN layers are related to particular subspaces of space, time and frequency domains of neural responses measured along the primate ITC.

Title: A simple, wireless system for remote, high-throughput behavioral testing of nonhuman primates

Authors: *E. B. ISSA, K. M. SCHMIDT, 02139, S. OHAYON, J. J. DICARLO;
Brain and Cognitive Sci., Massachusetts Inst. of Technol. Dept. of Brain and Cognitive Sci., Cambridge, MA

Abstract: Behavioral training and testing of animals in their home environment allows simultaneous measurements across many animals with little time required of lab personnel. This approach has been widely adopted in rodent work; however, in-colony behavioral testing is less widespread in nonhuman primate work. Here, we have developed an in-cage, touchscreen system that because of its low cost, scalability, and overall simplicity can be widely adopted by the primate community. The web-based system uses a single client-side web application that can run on any device (tablet, laptop, smartphone) and on any operating system. Recent advances in Javascript made it possible to deliver auditory and visual stimuli at high temporal precision and to leverage smart Bluetooth closed-loop communication with peripheral devices from within the web browser. Behavioral performance is monitored in near-realtime through the cloud from a web page which can be viewed on any device including a smartphone. To date, we have used this system to collect ~1 million behavioral trials on a visual object recognition task across multiple subjects and across different nonhuman primate species (macaques and marmosets). We have found that animals will often perform more trials and work for more fluid reward in the colony setting compared to a lab setting. When animals were brought to lab for physiological

testing, we found a rapid switch of effector from reaching movements (touchscreen) to eye movements (camera-based eye tracking) while retaining task knowledge suggesting that home cage, touchscreen testing is an efficient method for training naïve animals when precise eye tracking is not required. Future extensions of this system will include RFID-based subject identification so that each animal can activate the touchscreen ("log-in") loading their specific task in a group housed setting.

Title: Image-grain comparison of core object recognition behavior in humans, monkeys and machines

Authors: *R. RAJALINGHAM[1], E. B. ISSA[2], K. KAR[2], K. SCHMIDT[2], J. J. DICARLO[1]; [1]Brain and Cognitive Sci., [2]MIT, Cambridge, MA

Abstract: Humans can rapidly and accurately recognize objects in spite of high variation in viewing parameters (e.g. position, pose, and size) and background conditions. To uncover the algorithms underlying this ability, quantitative benchmarks of human behavior can be used to test animal, neural, and computational vision systems. Recently, we compared the core object recognition behavior of humans against that of monkeys and machines and found that monkeys not only matched human-level performance but also exhibited a pattern of object confusions that was indistinguishable from humans, a pattern that was also shared with high performing object recognition models (convolutional neural networks, CNNs). Object-level confusions, however, fail to capture image-level variation as each object can produce myriad images under variations in viewing parameters, with some images being more challenging than others. Here, we obtained the much larger datasets that are required to measure object recognition behavior at a higher resolution, the image-grain. This allowed us to systematically ask whether human, monkey and machine vision systems differ in their pattern of image-by-image performance.We tested object recognition performance on a binary choice match-to-sample paradigm using brief presentations

of images of 3D objects rendered with high viewing parameter variation on natural backgrounds. To collect large behavioral datasets, we used high-throughput psychophysical techniques: Amazon Mechanical Turk for humans, and a novel home-cage behavioral system ("MonkeyTurk") for monkeys. Over a million behavioral trials across hundreds of humans and five monkeys were aggregated to characterize each species on each image. To test multiple layers of high-performing CNN models on the same tasks, we trained linear classifiers on the model features. Our results show that monkeys are highly consistent with the pooled human in their pattern of image difficulties and are indistinguishable from individual human subjects. In contrast, all tested CNN models were significantly less consistent with the pooled human. This gap in consistency at the image level, though small, could not be easily attributed to our choice of linear classifiers, training images, viewing parameters or retinal sampling. Thus, current CNN models may not perfectly capture the representations that underlie core object recognition behavior in humans and monkeys. Moreover, these results show that high-resolution, image-grain behavioral measures serve as stronger constraints than object-level measures for uncovering mechanistic models of human visual object recognition.

Title: A stimulus-driven analysis of convolutional neural network models of visual cortex

Authors: *M. MCGILL[1,2], D. TSAO[3], P. PERONA[4];
[2]Computation and Neural Systems, [3]Biol., [4]Electrical Engin., [1]Caltech, Pasadena, CA

Abstract: Convolutional neural networks (CNNs) trained for object recognition are useful tools for reasoning about the primate ventral visual stream. For a given stimulus, the activity of a CNN layer is predictive of neural activity in the corresponding brain region(s). This suggests that CNNs may perform object recognition using similar mechanisms to those used by the primate visual system, and that studying CNNs may yield hypotheses to test in biological systems. As artificial neural networks are universal function approximators, the space of algorithms that may use for recognition is large and the transformations that images undergo while moving through network layers are poorly understood. Existing analyses characterize single-unit receptive fields but fail to describe the computations being performed by CNN layers as populations, operating

on natural images. To better understand how the representations of natural images are transformed by CNNs, we study (1) the image information that can be decoded from each layer's activity, (2) how sensitive each layer is to object transformations (e.g. shifts and rotations), and (3) how clusters of image representations warp, split, and merge moving from earlier through later layers.

Title: Object classification and separation of object manifolds in the human brain

Authors: ***C. JEW**[1], X. WANG[2], R. D. S. RAIZADA[1];
[1]Brain and Cognitive Sci., [2]Biomed. Engin., Univ. of Rochester, Rochester, NY

Abstract: No two instances of an object projected onto a person's retina are ever the same. An object's position, size, pose, or illumination are features that change from one image to the next depending on the viewer's perspective or the environment's conditions. The set of these different views is known as a viewpoint manifold. Manifolds have been applied in the field of computer vision to perform object recognition and pose estimation, but can the same or similar methods also be applied to brain patterns as a way to uncover how objects might be neurally represented? In computer vision, Murase and Nayar (1995) proposed a way to compress a set of images of the same object in order to represent the varying images within a lower-dimensional subspace than the retinal or pixel-level representations. All the images of the same object within this lower-dimensional space make up that object's manifold. For example, within the manifold for a mug, a snapshot of the mug at 10 degrees will occupy a point along the manifold that is closer to the point that represents the same mug rotated at 15 degrees than the point at which the same mug is rotated at 45 degrees. A point's position along the manifold represents a specific view or image of the object. If two objects' manifolds are separable within the same subspace, then the objects can be easily recognized. If the manifolds are tangled, however, transformations must be carried out on the manifolds to separate them (DiCarlo & Cox, 2007).
Participants' brain patterns were collected during a functional magnetic resonance imaging (fMRI) paradigm in which they observed four tools rotating individually on the screen. Multi-class classification of the objects with cross-validation is performed using the brain patterns for all objects within regions of interest extracted based on the Harvard-Oxford atlas. For each

classifier, a subset of the brain patterns corresponding to a portion of the rotation is withheld as the test set. We find the greatest classification accuracy in the temporo-occipital portion of the inferior temporal gyrus and the lowest accuracy in occipital pole. After performing classification, we then examine the manifolds for each of the objects based on the brain patterns elicited within the most and least accurate regions. We hypothesize that regions that are more successful at classifying the objects will also demonstrate greater separation between the manifolds within the low-dimension subspace. We find no evidence to support this hypothesis after performing principal components analysis on the brain patterns; instead, the manifolds appear tangled in all regions we examine. Other dimensionality reduction methods are now being tested.

Title: Manifolds of tool-graspability and viewpoint in the human brain

Authors: ***X. WANG**, C. JEW, R. RAIZADA;
Univ. of Rochester, Rochester, NY

Abstract: Consider an object, such as a spoon, which at a coarse-grained level can be viewed simply as an oriented bar, but at a finer-grained level is a tool with a graspable handle at only one of its two ends. When an object of this sort rotates though 360 degrees, a brain region which represents it merely as an oriented bar, ignoring which end has the handle, will perceive this as two full rotations, as 0, 180 and 360 degrees would all look the same. In contrast, a brain region which is sensitive to the object as a 3D shape with a handle at one end will treat this as only one single rotation (DiCarlo and Cox 2007, Murase et al 1995, Elgammal & Lee 2004, Rahami 2005). We investigated this question by extracting object viewpoint manifolds from multivoxel patterns of fMRI activation in people viewing movies of slowly rotating tools: a spoon, fork, knife and scissors.
We tested this new representation structure by analyzing fMRI data of people observing those four continuous rotating tools. We addressed the following key questions: what do the manifold representation structures look like for different brain regions under those stimuli? What methods can we apply to select voxels that are sensitive to either rotations or shapes? Can we estimate rotation angles using manifolds from certain brain areas? Can we classify different objects based on manifold structures in certain areas?

fMRI images were first preprocessed and normalized to standard MNI templates. We then divided the registered fMRI volumes into 48 regions based on Harvard-Oxford atlas (from FSL package). Since the fMRI task paradigm has constant-periodic (T = 60 s), in order to select voxels whose signal changes are temporally correlated with rotation task frequency, we proposed a voxel selection method based on ranked Fourier Power spectrum. We then constructed manifold structures for both full ROIs and voxels selected within in each ROI using principal component analysis (PCA). We found lower level visual regions can be represented by manifolds that are merely sensitive to symmetrical elongated shapes. We also find regions that are sensitive to objects' graspability based on their corresponding manifold structures.

Title: Neural representation of action-related object pairs in human visual cortex

Authors: ***R. WANG**, Y. XU;
Harvard Univ., Cambridge, MA

Abstract: Objects are not shown in isolation; instead, they appear in pairs with contextual association (e.g., a cake and a platter) or interact with each other in a predictable action-related manner (eg., a pitcher and a cup). Using fMRI MVPA, we previously reported that contextual association significantly affected object pair representation in posterior fusiform gyrus (pFS), an object-related processing region. Here we examined how and where action-related information within an object pair is represented and whether or not it is represented similarly as the contextual association between objects. We measured responses in human retinotopically defined early visual areas, object-related processing regions in lateral and ventral occipital regions, and action-related processing regions in visual cortex (defined by contrasting action-related object pairs with their constituent objects shown in isolation). We manipulated contextual association and action-related interaction between the objects in the pair. For the contextual association manipulation, a pair of objects could be either contextually congruent (e.g., a pitcher and a cup) or incongruent (e.g., a pitcher and a nail). For the action manipulation, a pair of objects could appear either in a familiar action colocation (e.g. a pitcher pointed towards a cup), an unfamiliar

action colocation (e.g., a pitcher pointed away from a cup), or a non-action colocation (e.g., a pitcher and a cup appeared side by side). To investigate the effect of contextual association and action-related interaction, in a given brain region, we measured the Euclidean distance between the voxel response patterns of an actual pair and the averaged voxel response patterns of the constituent objects shown in isolation. Replicating our previous results, in both pFs and action-related processing regions, we found that contextually associated non-action pairs were more dissimilar to the average of their constituent objects than pairs containing two unrelated objects. Interestingly, this contextual effect disappeared in contextually associated action pairs in action-related processing regions, resulting in a significant interaction between contextual congruency and action-related colocation. These results suggest that whereas contextual association integrates objects to form an integrated whole, action-related interaction breaks such integration, likely providing our visual system more independent access to the individual objects for the purpose of action perception and planning.

Title: The cortical network of usability evaluations for unknown tools

Authors: ***M. A. GANN**, M. HIMMELBACH;
Hertie-Institute For Clin. Brain Res., Tuebingen, Germany

Abstract: In daily life we are surrounded by different tools. Most often, we encounter familiar tools, and we can retrieve information about them from our semantic knowledge. Sometimes, however, we are confronted with new and unfamiliar tools. We must analyze and interpret their properties and infer a possible use. We assumed that such sensory and cognitive processing of unfamiliar tools will place a higher demand on a previously reported left-hemispheric network comprising the IFG/vPMC, anterior and dorsal IPL, and posterior ITG/IOG. In contrast, retrieving the well-known functionality of highly familiar tools should result in higher demands on the posterior MTG which has been associated with the retrieval of information from semantic networks before.
We asked 25 healthy participants to decide whether visually presented tools were useful in

various mechanical tasks. Brain activity was measured with 3T BOLD fMRI. We used a multiband EPI sequence with TR = 670 ms. Tools were either highly familiar or unfamiliar according to a preceding behavioral study.
The analysis indeed showed higher activation for unfamiliar than for familiar effective tools in the left IFG, left SMG, left MOG and left IOG/ITG. Exploiting our relatively high temporal resolution, we examined the time courses of significant clusters that had been identified in the whole brain analysis. Temporal parameters indicated a temporal order of signal increases in the abovementioned areas, which might represent different processing steps from visual processing to decision making.

Title: Impairment of tool evaluation in patients with apraxia

Authors: ***M. HIMMELBACH**, M. BARABAS, A. KIRSCHNER;
Hertie-Institute For Clin. Brain Res., Tuebingen, Germany

Abstract: Using objects as tools in everyday situations is usually based on previously acquired knowledge about the typical tools we use. However, when we do not have specific tools at hand or are confronted with new problems that we did not experience before, we have to understand the tool and the respective problem and think about mechanical solutions. Clinical tests in apraxia patients focus on practical demonstrations of typical tool knowledge through tool use pantomimes and real tool use but neglect mechanical thinking and reasoning. Our study focused on deficits of mechanical reasoning in patients who showed tool-related disorders in standard tests of limb apraxia. We devised a large set of typically well known and usually unknown tools. We created combinations of tools and problems that were orthogonalized with respect to the factors familiarity and effectivity. Healthy adults and patients with apraxia were instructed to rate the familiarity and effectivity of tools relative to a given problem. As expected, patients with limb apraxia reliably identified well known typical tools and typical tool/problem combinations. Despite of this rather good performance based on tool knowledge, the patients showed an impairment in mechanical reasoning in comparison to healthy adult controls. Deficits in tool

understanding and mechanical reasoning represent an underdiagnosed component of apraxia. They might play a more important role than hitherto assumed. Investigations in patients with respective disorders can provide important insights into the neuronal implementation of this cognitive process.

Title: White matter connectivity of the dynamic object perception network

Authors: *J. A. PYLES, M. J. TARR;
Dept. of Psychology, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Dynamic objects are ubiquitous in our visual environment. We previously identified a network of brain regions across occipitotemporal cortex recruited during the perception of dynamic objects and provided evidence that most of these regions encode information about dynamic objects invariant across changes in viewpoint, articulation and size (Pyles & Tarr 2013, 2014). Here we investigate how the functional regions of this network are structurally connected. We combined fMRI with diffusion-weighted imaging and deterministic fiber-tracking to identify the white matter connectivity between these regions. Dynamic object-selective regions were identified using a unique fMRI localizer that incorporated short animations of moving, articulating novel objects, contrasted with phase scrambled versions of the same animations. We also ran a MT/MST motion localizer, retinotopy, and a biological motion localizer. Structural connectivity was assessed with multiband diffusion spectrum imaging using a 253 direction sequence reconstructed using a generalized q-imaging method (Yeh, Wedeen, & Tseng, 2010). Consistent with our previous results, during the viewing of dynamic objects we observed the recruitment of large regions of occipitotemporal cortex, substantially overlapping with LOC and hMT+. Dynamic objects also recruited regions of parietal cortex not active when using static objects. These functionally-identified areas as well as results from retinotopy, the MT/MST localizer, and the bio-motion localizer were then used as regions of interest for deterministic fiber-tracking to map the white matter connections between these areas. Results reveal short range connections between nearby regions selective for dynamic objects as well as connectivity

to retinotopic cortex. Fiber streamlines originating in the region overlapping with LOC and hMT+ complex showed longer range connections to anterior temporal lobe and frontal lobe. Critically, differences were seen in the connectivity of the static object selective LOC versus the more superior dynamic object selective regions. A contrast between the connectivity of the dynamic object perception and the bio-motion networks further refines the nature of both networks. Finally, we illustrate the relationship of these tracts to the inferior longitudinal fasciculus and the vertical occipital fasciculus, tracts connecting dorsal and ventral cortex (Yeatman et al. 2014). In sum, our findings provide new insights into the structural connectivity of the dynamic object perception network, and its relationship to other visual regions.

Title: How does movement affect object recognition?

Authors: ***D. BURK**, D. SHEINBERG;
Neurosci., Brown Univ., Providence, RI

Abstract: As we move throughout the world, our brains continuously acquire sensory information to make predictions based on what we see. For example, an animal hopping in a foggy park could be perceived as a rabbit, even when the rabbit's form is too far away to be visible. More generally, objects often have stereotypical movements, but it remains unknown how a particular movement becomes associated with an object, and how movement is used in recognition. Previous research has shown that the brain associates features (e.g. color, shape, size) to create a unified percept of an object. This percept can be retrieved when the appropriate group (or possibly a subset) of features is encountered again. We ask whether movement can be used as diagnostic information similar to other features. Specifically, we aim to address (1) under what circumstances a stereotyped, translational movement pattern (e.g. zig-zag, arc, line) associated with an object could aid its identification and (2) the neural mechanisms underlying this behavior. We developed a match-to-sample task for human and non-human primates that

requires the use of movement information to perform object recognition under variable perceptual noise. We manipulate movement-object associations and spatiotemporal characteristics of the movement patterns to demonstrate how these parameters affect recognition. Initial behavioral data suggests that objects can be recognized by their movement patterns and that movement can improve object recognition in the presence of noise, whether the mapping is one object per one movement pattern or many objects sharing a common movement pattern. Computational analysis of the movement trajectories shows a relationship between features of the movement patterns and recognition difficulty. The analysis also provides useful predictions for behavior (reaction times, accuracy) and neural activity in areas sensitive to object features (IT) and movement (MT, MST). Here we aim to demonstrate the learning of associations between movements and objects and real-time acquisition of these associations for object recognition.

Title: Localizing functional regions of interest based on responses to dynamic naturalistic stimuli

Authors: *S. A. NASTASE[1], J. S. GUNTUPALLI[1], J. V. HAXBY[1,2], Y. O. HALCHENKO[1]; [1]Dept. of Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Ctr. for Mind/Brain Sci. (CIMeC), Univ. of Trento, Rovereto, Italy

Abstract: In human neuroimaging, functional regions of interest (ROIs) are typically localized by contrasting responses to several classes of controlled stimuli (e.g., faces, houses). However, the stimulus information driving this localization is also embedded in rich, naturalistic stimuli, albeit in a more complex way. Prior work has demonstrated that dynamic movie stimuli drive neural responses that are consistent across participants and encode extensive perceptual and semantic information. Here we introduce a framework for localizing functional ROIs using naturalistic stimuli: we use machine learning algorithms to assign each voxel in the brain to canonical functional ROIs (e.g., the fusiform face area, FFA, and parahippocampal place area, PPA) based on voxelwise response profiles to a dynamic movie stimulus. In contrast to typical multivariate pattern analyses, in this scenario each voxel is a sample in a feature space where each dimension represents the voxelwise response amplitude for a given time point in the movie stimulus. Framing the problem in this way results in highly correlated features (i.e., time points),

a large pool of samples (i.e., voxels), and very unbalanced class frequencies—of the total number of voxels in the brain, very few are members of any given functional ROI. To cope with these challenges, we used stochastic gradient descent to fit a linear SVM with samples weighted proportionally to class frequency. We are able to classify voxels from the whole brain as belonging to FFA or PPA with high accuracy (FFA: 98.9%, PPA: 98.6%) in left-out participants, correctly identifying 86.6% of voxels belonging to FFA, and 86.9% belonging to PPA. Interestingly, although some proportion of misclassifications are due to noise, some false positives can be interpreted as voxels with similar response profiles to ROI voxels that are not typically assigned to the manually-defined ROI based on conventional univariate contrasts. This approach circumvents the need for anatomical alignment across participants, as voxels can be assigned based purely on their response profiles. We compare these predicted ROI assignments to predictions based on anatomy alone. Anatomical information can be incorporated into the algorithm to improve localization, but at the expense of not discovering voxels with similar tuning at unexpected locations. Overall, our findings suggest that functional ROIs can be accurately identified in novel participants based on voxelwise responses to naturalistic stimuli.

Title: Intrinsic activity of the human brain and stimulus semantics are reflected in patterns of brain activity evoked by natural vision.

Authors: ***D. KIM**[1], K. KAY[2], G. SHULMAN[3], M. CORBETTA[3];
[1]Biomed. Engin., Washington Univ. In St. Louis, Saint Louis, MO; [2]Radiology, Univ. of Minnesota, Twin Cities, MN; [3]Neurol., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Resting state activity in the human brain is organized in a finite number of brain networks (so called resting state networks, RSNs). The topography of RSNs is highly similar to the patterns of co-activation and functional connectivity (FC) observed during sensory, motor and cognitive tasks (Fox et al., 2006; Smith et al., 2009; Cole et al., 2014; Wilf et al., 2015). The strong spatial correlation (ρ =~0.90) between the spatial topography of resting (intrinsic) and

task-evoked (extrinsic) FC has supported the hypothesis that patterns of synchronized intrinsic activity function as spatiotemporal priors for behaviorally relevant task evoked activities (Raichle, 2011; Petersen & Sporns, 2015; Lewis, 2009).
We compared the FC of intrinsic activity and task-evoked (extrinsic) activity during observation of movie clips (natural vision task) in a Human Connectome Project (HCP) 7 Tesla MRI dataset (11 Subjects, aged 20 ~ 35). Importantly, extrinsic FC was measured after statistically removing the contribution of intrinsic activity based on the temporal correlation of inter-regional signal time series averaged in different group of subjects (inter-subject functional connectivity, ISFC). Under these conditions, the correlation between extrinsic and intrinsic FC was reduced but remained significant ($\rho = 0.59$). Correspondingly, we found a large-scale difference in the spatial topography of extrinsic and intrinsic FC. Intrinsic FC showed the previously reported groupings of externally-oriented (e.g. vision, auditory, somatosensory, motor, dorsal attention) vs internally-oriented (e.g. default mode, fronto-parietal control, cingulo-opercular) networks (Fox et al 2005). Extrinsic FC, however, grouped visual and dorsal attention networks separately from the other networks. This result indicates a systematic difference between the topography of resting and movie-evoked FC, following the removal of the intrinsic component from the movie-evoked activity.
In preliminary work we have also analyzed the contribution of the semantic content of each movie to the topography of FC evoked by the movie. Each frame of each movie was categorized using binary semantic codes (see methods in Huth et al., 2012), yielding a frequency vector for each movie that indicated the number of frames in which each semantic feature was present. Movies that showed a similar semantic content, as indexed by a high correlation between their frequency vectors, showed a similar topography of movie-evoked FC, as indexed by a high spatial correlation between their FC matrices.

Title: The neural semantic representations of fine-grained object categories

Authors: *M. KUMAR[1], K. D. FEDERMEIER[2], L. FEI-FEI[3], D. M. BECK[2];
[1]Neurosci., [2]Psychology, Univ. of Illinois at Urbana-Champaign, Urbana, IL; [3]Computer Sci., Stanford Univ., Stanford, CA

Abstract: When we view a picture or read a word, we evoke its meaning (semantics) based on prior knowledge of the concept. We previously showed that pictures and words describing scene categories evoke similar representations in the inferior frontal gyrus, precuneus, angular gyrus and ventral visual cortex. Similar results have been seen for objects such as tools and animals. Here we ask whether these similarities extend to fine grained distinctions ? To examine the nature of differences and similarities between fine grained concepts, we examine the neural activity for pictures and words using a classifier to decode the BOLD signal within modalities and across modalities via multivariate pattern analysis (MVPA). We used picture stimuli of animate and inanimate exemplars from twenty-four categories derived from six classes (big cats, insects, birds, vehicles, tools and fruits. Each class comprised of a diverse set of stimuli (e.g. big cats: tiger, leopard, panther, lion). Word stimuli were approximate "captions" of the types of pictures used for the same category (e.g. 'a panther hunting at night'). In the fMRI experiment, subjects passively viewed first all the word stimuli for all twenty-four categories and then the picture stimuli for the same categories. A whole brain MVPA searchlight with six-way classification was performed. The six-way results from cross-decoding (training on the word stimuli and testing on the picture stimuli) showed similarities across words and pictures in the left precuneus. The results for picture decoding revealed a distributed set of brain regions including the ventral occipito-temporal cortex, parahippocampal gyrus, precuneus, and angular gyrus. These results suggest that like scenes, objects representations evoked by words and picture evoke similar representations even at a fine-grained level.

Title: Human scene-selective cortex represents the statistical distribution of object and action categories in natural movies

Authors: U. KELES[1], D. STANSBURY[2], J. L. GALLANT[2], *T. CUKUR[1];
[1]Bilkent Univ., Ankara, Turkey; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: Three scene-selective regions in the human brain, PPA, RSC and OPA (also known as TOS), are assumed to represent both low-level spatial and high-level semantic information about visual scenes (Kveraga, Bar; 2014). Previous studies on low-level representations argued that these regions represent features related to global spatial layout rather than constituent local features (Epstein, Kanwisher; 1998). It is thus possible that semantic representations in these areas also reflect holistic information that cannot be described as a simple sum of the information provided by the constituent objects and actions. To test this hypothesis, we assessed the semantic representations of natural scenes in PPA, RSC and OPA using two distinct encoding models: a scene-category model reflecting holistic co-occurrence statistics of objects-actions, and a parts-of-scenes model expressing scenes as additive combinations of constituent objects-actions. Human subjects viewed natural movies containing 1705 object-action categories for 210 min. Functional MRI was used to record whole-brain BOLD responses. Voxel-wise encoding models were fit to measure tuning for semantic features. The latent semantic features of the two models were extracted via separate learning algorithms applied on a large database of movie scripts. Latent Dirichlet allocation (Blei, 2003) was used to learn topical scene-category features (e.g. city street) that encapsulated co-occurence statistics of objects-actions. Nonnegative matrix factorization (Lee, Seung; 1999) was used to learn parts-of-scenes features (e.g. car or driving) that reflect additive object-action components of scenes. Voxel-wise models were fit by projecting the stimulus onto semantic features and applying regularized regression. Prediction accuracy was taken as the correlation coefficient between recorded and predicted responses on held-out data. To reveal whether scene-selective cortex represents holistic semantic information beyond what can be ascribed to a sum of information from constituent objects-actions, we compared the prediction accuracy of the two encoding models. In PPA, RSC and OPA, we find that the scene-category model outperforms the parts-of-scenes model, and that it explains significant variance in BOLD responses after accounting for the parts-based model ($P<0.05$, signed-rank test). Yet, we find no significant difference between model performance in other ventral-temporal ROIs. These results suggest that semantic representations in scene-selective cortex reflect holistic scene-category information that cannot be explained by a sum of constituent parts.

Title: Human scene-selective areas represent the distance to and orientation of large surfaces

Authors: *M. D. LESCROART[1], J. L. GALLANT[2];
[1]Helen Wills Neurosci. Inst., [2]UC Berkeley, Berkeley, CA

Abstract: A network of areas in the human brain—including the Parahippocampal Place Area (PPA), the Occipital Place Area (OPA), and the Retrosplenial Complex (RSC)—respond to images of visual scenes. However, it is still unclear whether these areas represent 3D features related to scene structure or low-level 2D features related to spatial frequency. To better characterize the representation of visual features in PPA, OPA, and RSC, we define feature spaces that quantify scene structure and spatial frequency, and use them to predict brain activity in scene-selective areas. We fit these models to BOLD fMRI data recorded while human subjects viewed movies of a virtual world rendered with 3D graphics software. We used meta-data from the graphics software to define a scene structure feature space that quantifies the distance to and orientation of large surfaces in each movie frame. This feature space uses continuous parameters based on 3D data (surface normals and depth maps) rather than human-assigned categorical labels such as “open” or “closed”. We also used a Gabor wavelet feature space to quantify variation in spatial frequency in each movie frame. We fit models for both feature spaces for every voxel in the brain using L2-regularized regression, and evaluated each model based on how much response variance it predicts in a withheld data set.
We found that the scene structure model explains more response variance in scene-selective areas than the Gabor wavelet model. Furthermore, a variance partitioning analysis revealed that the scene structure model explains a significant amount of *unique* variance that cannot be explained by the Gabor wavelet model. Having validated the scene structure model, we investigated the information it captured by performing principal component analysis (PCA) on the weights of the scene structure model for voxels in scene-selective areas. We found that the first PC distinguishes scenes with enclosing structure (walls and ceilings) from completely open or close-up scenes with no structure. The second PC distinguishes near scenes from far scenes. These results suggest that PPA, OPA, and RSC represent conjunctions of the distance to and orientation of walls, ceilings, and other large objects in scenes, independent of low-level features captured by the Gabor wavelet model. Finally, we used the model weights and a structural prior

to generate reconstructions of the backgrounds in each segment (TR) of the stimulus movies. The reconstructions demonstrate that our scene structure model captures an unprecedented level of information about the geometry of the local visual environment from scene-selective areas.

Title: Neural representation of spatial boundary cues in visual cortex

Authors: *R. CHENG[1], K. FERRARA[2], S. LEE[3], S. PARK[1];
[1]Cognitive Sci., Johns Hopkins Univ., Baltimore, MD; [2]Ctr. for Brain Plasticity and Recovery, Georgetown Univ., Washington D.C., DC; [3]Ctr. for Mind/Brain Sci., Univ. of Trento, Trento, Italy

Abstract: Boundaries are crucial for defining the spatial constraints of an environment, but what are the essential features of a boundary? Developmental studies have demonstrated that not all environmental structures can define an effective boundary (Lee & Spelke, 2011). Four-year-old children were shown the location of a hidden toy in a rectangular arena. After disorientation, they were able to search the correct location and its geometric equivalent location when the arena was marked by continuous, 2cm-tall “curb” structure, but not by isolated columns connected together by a suspended string. This contrast suggests that horizontal continuity could be an important element of what defines a spatial boundary cue. Recent neuroimaging work has shown that the parahippocampal place area (PPA) is sensitive to the presence of vertical boundary structure in visually-presented scenes (Ferrara & Park, 2014). In the present study, we ask whether there exists a neural representation that distinguishes between boundaries with varying degrees of horizontal solidity. The horizontal solidity of boundaries was manipulated by varying the amount of vertical elements (i.e., poles) that extended in horizontal space in artificial scene images. The number of poles increased in a logarithmic scale across conditions: an open field (0 poles), 3 poles, 9 poles, 17 poles, 33 poles and 65 poles (Wall). Participants (N=11) viewed these conditions in blocks of 12 s while performing a one-back repetition task. We measured univariate and multivariate response in two scene-selective regions: PPA and Occipital Place Area (OPA). To evaluate the nature of boundary representation in these two regions, we created

three hypothetical models to test whether a region is sensitive to 1) the presence of vertical structure in a scene 2) the continuity of horizontally extended structures, and 3) the amount of poles along the horizontal extent of the boundary. With these models, we ran within-subject multiple linear regressions on the similarity matrices generated from multi-voxel pattern activity in PPA and OPA. We found that PPA is sensitive to the presence of poles in a scene boundary (beta=0.38, p=0.003) but doesn't distinguish between boundary conditions made up of different numbers of poles (beta=0.043, p=0.26). On the other hand, OPA tracks the amount of poles that make up the boundary (beta=0.17, p=0.004) and it is also sensitive to the continuity of these structures (beta=0.26, p=0.014). Taken together, these results provide insight to the defining geometric features of scene boundaries and how these features are represented differently across scene-selective regions in the brain.

Title: The effect of consecutive TMS-fMRI on the contralateral preference for scenes within scene-selective occipital place area

Authors: *E. H. SILSON, I. I. A. GROEN, C. I. BAKER;
Lab-Brain & Cog, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: Despite demonstrating selective responses to single stimulus categories, several regions of human occipitotemporal cortex have been shown recently to exhibit significant biases for the contralateral visual field (Silson et al., 2015; 2016). Notwithstanding different representations of eccentricity (foveal or peripheral) across category-selective regions, contralateral biases have been identified within object-, body, face- and scene-selective cortices. Such biases mirror those present in antecedent visual cortex and suggest that underlying retinotopic organization may constrain the function of category-selective regions. Here, we used consecutive TMS-fMRI to examine how causal interference of scene-selective occipital place area (OPA) alters the responses elicited therein by contralaterally presented scenes and faces. Given previous reports that TMS to category-selective regions results in a local attenuation of the fMRI response, we hypothesized that TMS of left and right OPA would result in reduced fMRI responses to scenes, but not faces, in the contralateral visual field. Healthy volunteers (n=18) were scanned on a 3T scanner (3x3x4 voxels, whole brain coverage) in three separate

counterbalanced sessions in which they performed four runs of a fixation task both before and after 60 seconds of theta-burst stimulation (30% max output, 50Hz, 900 pulses). In each run, scene and face stimuli (5x5 degrees), centered at 5 degrees eccentricity along the horizontal meridian, were presented into either the left or right visual fields in blocks. Importantly, the specific scene and face stimuli were different between pre and post runs to limit any stimulus specific habituation. In each session participants were removed from the scanner midway in the experiment and received either stimulation of left OPA, right OPA or no stimulation but with a decoy coil placed over right OPA. Target sites (peak voxel for scene > face) and ROIs were based on functional localizers in an independent scanning session. When considering our stimulation sites and their preferred category only, consistent with previous work, we observe decreased fMRI responses to contralaterally presented scenes following TMS, but this effect was limited to right OPA. Beyond this restrictive analysis however, these effects were also present for ipsialterally presented scenes and faces and moreover, were distributed across large swaths of cortex. These data suggest the effects of theta-burst stimulation on fMRI responses shows limited spatial specificity.

Title: The effect of consecutive TMS-fMRI on scene representations in high-level visual cortex

Authors: *C. I. BAKER, E. H. SILSON, I. I. A. GROEN;
Lab. Brain and Cognition, NIH, Bethesda, MD

Abstract: An extensive neuroimaging literature supports the presence of multiple scene- and face selective regions in high-level visual cortex, which are thought to constitute distinct visual processing networks. Whilst combined transcranial magnetic stimulation (TMS) and fMRI experiments on the face network have demonstrated causal interactions between face regions (Pitcher et al., 2007, 2014), much less is known about the scene network. Here, we used consecutive TMS-fMRI to examine to what extent causal interference with neural activity in a posterior node in the scene network, the Occipital Place Area (OPA), affected representations of visual stimuli in scene-selective regions. We tested whether TMS to OPA affected fMRI

responses in OPA itself, as well as the more downstream Parahippocampal Place Area (PPA) and retrosplenial complex (RSC). In addition, we included two control conditions: an active TMS condition, in which we stimulated the Occipital Face Area (OFA) instead, as well as a no stimulation condition. Healthy volunteers (n=16) were scanned on a 3T scanner (3x3x4 mm voxels, whole brain coverage) in three separate counterbalanced sessions in which they performed eight runs of a 2-back repetition task on 20 s blocks of visual stimuli separated by 8 s fixation gaps. Midway in each session, participants were removed from the scanner to receive 60 seconds of theta-burst stimulation (30% max output, 50Hz, 900 pulses) to either right OPA or right OFA, or no stimulation with a decoy coil placed over right OPA. Target sites (peak voxel for scene > face or vice versa) and ROIs were based on functional localizers from an independent scanning session. In each run, participants were presented with blocks of stimuli from eight different scene categories (man-made open, man-made closed, natural open, natural closed) used in a previous study (Kravitz et al., 2011), as well as images of isolated faces, buildings, and man-made and natural objects. Univariate analysis of fMRI response magnitude revealed distributed effects of TMS across multiple stimulus categories in both scene- and face-selective regions. Whole brain analyses indicated that in general, TMS to OFA induced stronger reductions than TMS to OPA, possibly due to its position near the foveal confluence. Together, these data suggest that the effects of theta-burst TMS on fMRI responses can be widespread and not necessarily restricted to a single visual processing network or stimulus category.

Title: The role of the occipital place area in guiding eye movements through scenes

Authors: G. L. MALCOLM[1], E. H. SILSON[2], J. R. HENRY[2], *J. E. INGEHOLM[2], C. I. BAKER[2];
[1]Dept. of Psychology, Univ. of East Anglia, Norwich, United Kingdom; [2]Lab. of Brain and Cognition, NIH / NIMH, Bethesda, MD

Abstract: Despite huge variability in the visual properties of every environment, we are very efficient at processing scenes and finding semantically meaningful consistencies. Scene

processing is supported by cortical regions, which exhibit preferential responses to scenes compared to objects or faces: parahippocampal place area (PPA), retrosplenial complex (RSC) and occipital place area (OPA). Typically, these regions have been studied in terms of what visual information they are responsive to, within the context of scene recognition or navigation. In the present study we move beyond these tasks to investigate eye movement guidance within scenes. Eye movements rely on a scene's visual representation to direct saccades, and thus foveal vision. Here we focus on the contribution of OPA, which is i) located in occipito-parietal cortex, likely feeding information into parts of the dorsal pathway critical for eye movements, and ii) contains strong retinotopic representations, predominantly of the contralateral visual field (Silson et al., 2015). Specifically, we examined how disrupting OPA, via transcranial magnetic stimulation (TMS), affects eye movements while participants (n = 24) searched scenes. Scenes consisted of indoor and outdoor settings, with object position controlled across all four visual quadrants. Scenes were displayed for 1s, followed by two objects presented either side of fixation. Participants indicated which object had been in the previous scene. On half of the trials, participants received repetitive TMS: a five pulse train over 500ms, starting at scene onset. Half of the participants received TMS to rOPA and half to rOFA (occipital face area), which also exhibits a bias for the contralateral visual field. If OPA plays a causal role in the guidance of eye movements within scenes, then TMS to rOPA, but not rOFA, should disrupt the distribution of fixations throughout the scene. In particular, given the contralateral representation within OPA, we predicted that participants should be biased to make eye movements toward the ipsilateral visual field (here, right visual field) following rOPA, but not rOFA stimulation. There was an overall left-to-right pattern in eye movements across all conditions as participants explored the scenes, despite every trial starting with a central fixation cross. Critically, the average fixation position for participants in the rOPA condition was biased toward the ipsilateral visual field. Further, this bias was stronger than either control trials or following rOFA stimulation. These results indicate that OPA might represent local scene information facilitating eye movement guidance

Title: The encapsulated structure of the scene network facilitates scene recognition

Authors: *X. HAO[1], X. WANG[1], X. Z. KONG[1], J. LIU[2];
[1]State Key Lab. of Cognitive Neurosci. and Learning, [2]Sch. of Psychology, Beijing Normal Univ., Beijing, China

Abstract: Humans have an impressive ability to recognize real-world scenes. Previous neuroimaging studies have found that the visual system contains a dedicated scene network (SN) for scene recognition, commonly consisting of the parahippocampal place area (PPA), the retrosplenial complex (RSC), and the transverse occipital sulcus (TOS). These studies mainly focus on the functional characteristics of a specific region within the SN, but the knowledge about how these regions work collaboratively to facilitate scene recognition is limited. The present study characterized the within-network connectivity (WNC, integration) and between-network connectivity (BNC, segregation) of the SN, and then examined their association with behavioral performance in scene recognition in a large sample of participants (N = 228). First, we identified the SN as a set of voxels that responded selectively to scenes over objects with a functional localizer, and the non-scene network (NSN) as the rest of the voxels in the brain. For a voxel in the SN, the WNC was calculated as the averaged functional connectivity (FC) of the voxel to the rest of the SN voxels, whereas BNC was the averaged FC of the voxel to all of the NSN voxels. We found that 85.7% of the voxels in the SN had a significant larger WNC value than BNC value, suggesting that the SN is a relatively encapsulated network. *Then,* we examined the behavioral relevance of the SN by associating the WNC and BNC of the SN with behavioral performance in recognizing scenes based on either local information (location) or global information (configuration). We found that (1) individuals with stronger WNC in the right TOS or weaker BNC in the bilateral TOS and mPFC were more sensitive to configural changes of scenes, and (2) individuals with weaker BNC in the mPFC had a larger location effect. *In short,* our study demonstrated the integration and segregation of the SN could benefit behavioral performance in scene recognition, suggesting the critical role of interaction of local regions in scene recognition.

Title: S100B modulates functional connectivity of key regions for human scene/place recognition

Authors: *S. XU[1], X.-Z. KONG[2], J. LIU[1];
[1]Sch. of Psychology, [2]State Key Lab. of Cognitive Neurosci. & Learning, IDG/McGovern Inst. for Brain research, Beijing Normal Univ., Beijing, China

Abstract: Spatial navigation is crucial for living, and PPA (the parahippocampal place area), OPA (the occipital place area) and RSC (the retrosplenial cortex) have been demonstrated playing pivotal role in human spatial navigation, especially in scene/place recognition. Previous studies have shown that the S100B gene is causally related to spatial navigation performance and affects local neural activation of these regions during place-recognition and navigation tasks. The present study further asked whether S100B modulates inherent functional connectivity of these regions. Using PPA, OPA and RSC as seed regions, the present study calculated voxel-wise functional connectivity across the brain using rs-fMRI (resting-state functional magnetic resonance imaging) data obtained from a large sample of young healthy participants (N = 243), generating a set of connectivity maps reflecting the strength of the functional connectivity between a given voxel and each of the seed regions. We first examined the spatial correspondence between each of these rs-fMRI functional connectivity maps and the S100B gene expression map in postmortem brains from the Allen Brain Atlas. Then, we identified brain regions whose functional connectivity with any of the seed regions was modulated by individual serum level of S100B and S100B gene polymorphisms. The results revealed that (1) Regional S100B expression was negatively correlated with regional strength of functional connectivity with PPA and RSC. (2) Significant correlations were found between individual S100B serum level and functional connectivity with the seed regions in various cortical and subcortical regions. (3) These correlations mainly located in the putamen, the paracingulate gyrus and the

cingulate gyrus for PPA and RSC, and in the occipital regions for OPA. (4) Similar results emerged in correlating functional-connectivity with S100B genotypes. The present study provided the first evidence that S100B gene modulates the functional connectivity of regions critically involved in human spatial navigation, especially in scene/place recognition. These findings advanced our understanding of genetic modulation on the inherent functional connectivity in functionally specific neural networks.

Title: Effect of stochastic mastoid vibration on perception of vestibular recognition of rotary motion

Authors: ***R. KABBALIGERE**[1], F. KARMALI[2], B. LEE[1], C. LAYNE[1];
[1]Hlth. and Human Performance, Univ. of Houston, Houston, TX; [2]Massachusetts Eye and Ear Infirmary, Boston, MA

Abstract: Stochastic resonance (SR) is a phenomenon that is known to improve the strength of a weak signal in the presence of suitable amounts of non-zero level of external noise in non-linear sensory systems. There are numerous studies that have studied the effect of SR on sensation in the auditory, visual, proprioceptive and vestibular systems. This study tested the effect of stochastic vibration applied to the mastoids on vestibular perception of rotation in the dark, and particularly direction recognition thresholds and biases. In direction recognition paradigms, threshold represents the width of the Gaussian cumulative probability distribution and is linearly proportional to the standard deviation of the underlying noise. Bias is defined as an offset from zero and corresponds to the stimulus to which subjects respond correctly 50% of the time. Direction recognition threshold and bias for yaw rotation at 1Hz in 9 healthy subjects was measured with and without bilateral mastoid vibration. The vibratory stimulus consisted of band-passed white noise in the range of 1Hz-500Hz and maximum amplitude of 0.635 mm. The results showed that SR vibration significantly reduced bias magnitude when compared to baseline ($p=0.05$) but had no effect on recognition thresholds. Additionally, the effect of SR on bias was found to depend on the baseline thresholds. Subjects who had greater baseline thresholds were found to be more responsive to SR and showed greater reductions in bias. This finding may be related to the fixed level of the vibratory stimulus and points to the importance of

individualizing the stimulus level as a function of one's baseline thresholds. The presence of perceptual bias in healthy subjects has been linked to the imbalance in neural activities and firing rates of the left and right semicircular canals (SCCs). Our results suggest that SR vibration applied on the mastoid can be effective in reducing the asymmetry in neural activity of the SCCs and promote coordinated functioning between the SCCs.

Title: Dynamics of eye movements and secondary vestibular neurons during prosthetic vestibular stimulation.

Authors: *C. PHILLIPS, L. LING, K. NIE, A. NOWACK, J. T. RUBINSTEIN, J. O. PHILLIPS;
Otolaryngology - HNS, Univ. of Washington, Seattle, WA

Abstract: Background: Recent research and development on new modalities for the treatment of vestibular loss have yielded vestibular prosthetics employing electrical stimulation of the semicircular canal (SCC) ampullae. These devices, currently under investigation in both human subjects and animal models, are effective in eliciting eye movements comparable, broadly, to those produced naturally through the vestibulo-ocular reflex (VOR). Here we examine the dynamics of eye movements elicited by such stimulation and compare them to dynamics of secondary vestibular neurons.
Methods: Rhesus monkeys were implanted unilaterally with a multichannel vestibular neurostimulator with stimulating electrodes in the perilymphatic space adjacent to the SCC ampullae. In addition, animals were implanted with 2D scleral search coils for the recording of eye movements and recording chambers with access to the vestibular nuclei. Eye movements and

secondary vestibular neurons were recorded in response to steady-state and current amplitude modulated (AM) trains of stimulation delivered to individual SCC ampullae.
Results: Steady-state stimulation elicits directionally appropriate nystagmus the velocity of which can be controlled parametrically by modulating either pulse rate or current amplitude. Short (2s) steady-state stimulation does not elicit a nystagmus with a constant velocity, but instead exhibits temporal dynamics. Sinusoidal AM stimulation produce nystagmus with a sinusoidal velocity profile. However, this velocity profile displays a phase shift and an amplitude that varies with the envelope frequency of stimulation, between 0.1 and 20 Hz. Steady state electrical stimulation of SCC afferents elicits phase locked activity of secondary vestibular neurons, that exhibit temporal dynamics.
Conclusions: These results illustrate significant differences between nystagmus elicited by prosthetic stimulation of the vestibular periphery and that elicited naturally, by rotations of the head. These results suggest that qualities of prosthetic vestibular stimulation that differ from natural stimulation have significant effects on information processing by the vestibular system.

Title: Relationship between vestibular evoked compound action potential responses and electrically elicited VOR.

Authors: A. L. NOWACK[1], L. LING[1], K. NIE[1], C. PHILLIPS[1], *J. O. PHILLIPS[2], J. RUBINSTEIN[1];
[2]Oto-HNS, [1]Univ. of Washington, Seattle, WA

Abstract: Background: Previous studies have shown that vestibular evoked compound action potentials (vECAPs) recorded from a fully implantable vestibular prosthesis provide a good measure of the activation of the vestibular afferents by biphasic pulse electrical stimuli. These recordings demonstrate long lasting electrical activation of nerve fibers in rhesus monkeys, and declining activation of over time in human subjects. However, recent studies have shown that dramatic dissociations of vestibular evoked behavior, such as the electrically evoked vestibulo-ocular reflex (eVOR), and vECAP responses can occur in some situations. For example, following ototoxic lesion of vestibular hair cells, vECAP responses decline whereas eVOR slow phase velocities increase. To further examine the relationship between vestibular evoked responses and behavior, we examined the relationship between vECAP threshold and amplitude gain, and the slow phase velocity of eye movements evoked by electrical stimulation in 10 rhesus monkeys.
Methods: Rhesus monkeys were implanted with a multichannel vestibular neurostimulator, with stimulating electrode arrays in the perilymphatic space adjacent to the ampullae of the three semicircular canals of one ear. In addition, animals were implanted with scleral coils for eye position recording. Eye movements were recorded in response to trains of biphasic stimulation delivered to individual SCC ampullae. vECAPs were recorded in response to stimulation at the same current levels in each canal. Both intracanal (stimulation and recording electrode in the same canal) and intercanal (stimulation and recording electrode in separate canals) recordings were obtained.
Results: vECAP threshold and gain showed a highly variable correlation with elicited slow phase eye velocity across canals or across animals. Canals with the most robust vECAP response were not those with the highest elicited slow phase velocities. Reduced vECAP responses did not reliably predict reduced or absent slow phase velocities. The correlation between vECAP responses and behavioral response were not stable over time in individual animals.
Conclusions: These results illustrate significant differences between elicited slow phase eye velocity and vECAP response during prosthetic vestibular stimulation, and suggest that the afferent pool sampled with the vECAP may significantly different than the full complement of afferents that are recruited to elicit the eVOR.

Title: Single-unit activity of chinchilla vestibular afferent neurons in response to passive rotation and prosthetic electrical stimulation

Authors: *P. REN;
otolaryngology, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Bilateral loss of vestibular sensation due to ototoxic injury or other insults to both labyrinths is disabling. Affected individuals suffer chronic disequilibrium, increased risk of falls and unstable vision during head movements typical of common daily activities like walking and driving. The vestibular nerves are intact in many such cases, so an implanted stimulator encoding signals from a head-mounted motion sensor can excite the vestibular nerve and - if it creates the right pattern of activity on the nerve's five branches - restore sensation of head movement. However, the current spread or imprecise electrode placement can reduce MVP efficacy through spurious activation of non-target axons, resulting in misalignment between the actual and perceived axes of head motion. Effects of current spread can be inferred from misalignment of vestibulo-ocular reflex (VOR) responses, and we have used that technique fruitfully in chinchillas and rhesus monkeys. However, VOR measurements are an imprecise proxy for

current spread. In contrast, single unit recording from individual vestibular afferent neurons provides a much more precise assay of current spread and, consequently, can provide the information necessary to optimize design of electrode arrays for a vestibular implant. The goal of the present study was to characterize activity of vestibular afferents in response to passive whole-body rotation and prosthetic electrical stimulation, thereby establishing a normative data set for subsequent study of current spread within the labyrinth. We measured single-unit neuronal activity of >200 vestibular afferents in chinchillas, including >50 otolith units. Sensitivity was measured to tilts and to passive sinusoidal rotation (0.5~5Hz). Sensitivity increased as a function of rotation frequency. Vestibular afferent activity was also modulated by prosthetic electrical stimulation, with probability of firing increasing with increasing pulse amplitude and charge/phase. Activity of non-target neurons (i.e., vestibular afferents from an end organ other than the one targeted by prosthetic current delivered by a given stimulating electrode) was modulated by current spread, in qualitative agreement with model predictions.

Title: The subadditive integration of neural responses to passive head rotation and galvanic vestibular stimulation in the vestibular nuclei

Authors: *G. KIM[1], E. JEON[3], K.-S. KIM[3], S. LEE[2];
[1]Inha Univ., Inchon-City, Korea, Republic of; [2]Electronic Engin., Inha Univ., InCheon, Korea, Republic of; [3]Otolaryngology-Head & Neck Surgery, Inha Univ. Hosp., InCheon, Korea, Republic of

Abstract: For the head orientation and body postural balance in three dimensional (3D) space, the vestibular system perceives the motion information with six degrees of freedom (three for angular and another three for linear motions) to designate the simultaneous changes acting on the

head. The sensed information is generally composed of multidimensional active or passive stimuli in a natural condition, and the information is known to be subadditively integrated in the central nervous areas. On the other hand, galvanic vestibular stimulation (GVS) has been widely used to directly excite the vestibular afferent neurons, but its central integration with the kinematic stimuli has not been thoroughly studied. Here, we investigated the integration of neural information caused by one of kinematic stimuli and GVS in the vestibular nuclei (VN) using a combined stimulus, which consists of horizontal head rotation (yaw) and GVS. Twenty six vestibular responses were recorded in the lateral vestibular nuclei from twenty healthy guinea pigs, using chronic extracellular recording by tungsten electrodes (5-7MΩ). All vestibular units (15 regular and 11 irregular neurons) for this study responded to both types of stimuli, horizontal head rotation and GVS. We designed three separate types of stimuli, *pure head rotation, pure GVS,* and *combined stimulus*, to excite the vestibular neurons in the VN. To assess the features of neural responses to the stimuli, a sinusoidal curve fitting was applied, and the amplitudes and baselines in the fitted sine wave were calculated. Two comparisons were conducted; one was based on the amplitudes during the head rotation and the combined stimulus while the other was based on the baselines during GVS, the head rotation and the combined stimulus. The former showed that the integrated neural information of the head rotation and GVS was reduced in the VN ($p<<0.01$, binomial cumulative distribution) indicating the information of two stimuli was subadditively integrated. The latter also demonstrated a similar result, attenuating the neural information related with baselines in the combined stimulus ($p=0.038$, binomial cumulative distribution). In conclusion, the subadditive neural integration was maintained when combining the neural responses to the kinematic stimulus and GVS in the VN.

Title: Neural correlates of transmastoid galvanic vestibular stimulation in alert primates: Linking vestibular afferent activation to perceptual, ocular and postural responses

Authors: *A. KWAN[1], D. E. MITCHELL[2], P. A. FORBES[3,4], J.-S. BLOUIN[4], K. E. CULLEN[1,2];
[1]Biomed. Engin., [2]Physiol., McGill Univ., Montreal, QC, Canada; [3]Biomechanical Engin., Delft Univ. of Technol., Delft, Netherlands; [4]Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: Every day we rely on our vestibular system for our sense of balance as we move around in the world. Physiologically, the vestibular sensors in the inner ear detect and convert head motion into a neural signal, which is then carried by the primary vestibular afferents to the central nervous system. Because the application of self-motion stimuli to activate the vestibular system often also results the unavoidable activation other sensory inputs (i.e., tactile and proprioceptive), investigating the vestibular system in isolation is challenging. In this context, an increasingly popular tool to artificially activate the human vestibular system is galvanic vestibular stimulation (GVS), in which electrical stimulation is applied between surface electrodes on the mastoid processes behind the ears. To date, however, while the effects of GVS, including the perception of self-motion, eye movements, and postural sway have been well described, their neuronal correlates remain unknown. Specifically, the link between the dynamics of the activation of the vestibular afferents and these GVS-responses has not been established. Here, in order to link the neuronal mechanisms mediating behavioural responses during GVS, we recorded both eye movements and vestibular afferent activity while GVS was applied between surface electrodes on the mastoid processes of alert macaques. First, we recorded eye velocity during sinusoidally modulated GVS, as monkeys fixated a target. We found that the eye movements evoked in alert macaques show similar patterns compared to those reported in humans. Notably, the gain of torsional eye velocity relative to peak GVS current amplitude remained relatively constant as a function of frequency. Next, and even more importantly, our single unit recording experiments revealed that GVS during these same paradigms similarly activated semicircular canal and otolith afferents. Strikingly, the gain and phase of regular afferents of both organs showed comparable trends (i.e., increasing) as a function of frequency, and irregular afferents of both organs showed comparable trends as a function of frequency (i.e., also increasing but gains were greater relative to those of regular afferents). Similar frequency responses were observed during broadband noise stimulation, suggesting that afferents responses to GVS were largely linear. Taken together, these results reveal the neural correlates underlying GVS-evoked perceptual, ocular and postural responses - a fundamental step into understanding the effect of this technique required to advance its clinical and biomedical applications.

Title: Customizing transcutaneous electro-cortical stimulation: An objective thresholding technique using sinusoidal galvanic vestibular stimulation and lateral body sway

Authors: *H. A. TRIER[1], S. B. DOUGLAS[1], C. ZUMARAN[1], A. L. ALCHEHAYED[1], J. M. SERRADOR[2,3], S. J. WOOD[1];

Abstract: Galvanic vestibular stimulation (GVS) involves the application of low-intensity transcutaneous direct current stimulation to the mastoid processes or earlobes. At low levels of stimulation (≤1 mA) stochastic GVS stimulation has been shown to improve balance function, while higher levels have been used to disrupt function as an analog of clinical dysfunction. However, individual sensitivity and response to GVS varies. The present study established a protocol for determining an individual threshold level for GVS based on participants' postural sway responses. Young adult participants attended three one-hour sessions spaced evenly across one week, and in each session wore inertial motion sensors (MTi, Xsens Technologies, The Netherlands) on head and torso. A light foam board with an attached third sensor was held by participants to indicate direction and amplitude of perceived motion. A sinusoidal stimulus with frequency of 0.1 Hz and intensity of 0.1-1.7 mA was applied bilaterally across electrodes attached to each earlobe in increasing and then decreasing increments of 0.1 mA. During each three-minute trial, participants stood with their feet together and eyes closed while indicating perceived motion with the handheld sensor and verbal reports. The narrow stance width resulted in predominantly lateral sway in phase with the sinusoidal stimulus that was reliably detected from the roll position of the inertial sensors. Simultaneous subjective reports were less consistent than the postural sway measures. We propose this simple thresholding technique should be implemented using portable technologies to customize stimulation levels when employing transcutaneous electro-cortical stimulation interventions.

Title: Plasticity within vestibular reflex pathways: Implications for use of vestibular prostheses

Authors: *D. E. MITCHELL[1], C. C. DELLA SANTINA[2], K. E. CULLEN[1];
[1]Dept. of Physiol., McGill Univ., Montreal, QC, Canada; [2]Dept. of Otolaryngology - Head & Neck Surgery, Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Whether it is the generation of a simple reflex behavior or an elaborate gymnastic routine, plasticity within motor pathways is required for the accurate execution of movements. Linking synaptic plasticity with changes in motor performance requires understanding how synaptic efficacy influences behavioral responses. The vestibular system plays a vital role in gaze and postural stabilization, through the vestibulo-ocular reflex (VOR) and vestibulo-spinal reflexes, respectively. Notably, the relative simplicity of vestibular pathways and their precise behavioral readout make it an excellent model system for studying the mechanisms underlying the fine tuning of motor performance. In this study, we examined the neural correlates of behavioral plasticity induced by applying temporally precise electrical stimulation to vestibular afferents in alert rhesus monkeys. To link changes in neuronal activity with changes in motor performance, we recorded eye and head movements driven by the VOR and vestibulo-spinal reflexes, respectively, as well as the activity of neurons that drive these reflexes during behaviorally relevant stimulation of the vestibular nerve. Responses of neurons in direct VOR and vestibulo-spinal pathways were decreased following behaviorally relevant patterns of vestibular nerve activation in awake behaving animals. Specifically, stimulation of the vestibular nerve resulted in a decreased efficacy of the synapse between vestibular afferents and first-order central neurons (i.e. long term depression (LTD)). The attenuation of these pathways was sufficient to cause a reduction in evoked VOR and vestibulo-spinal reflex responses. Interestingly, we found evidence of nearly instantaneous complementary changes in the strength of indirect inhibitory brainstem pathways, which worked to offset the reduced sensitivity of first-order central neurons. Therefore, rapid plasticity at the first central vestibular synapse can fine-tune motor performance, while complementary plasticity within indirect inhibitory brainstem pathways ultimately contributes to ensuring a robust behavioral output. Taken together, these findings provide evidence that vestibular prosthetic stimulation induces LTD at the synapse between vestibular afferents and first-order central neurons. Fortunately, our results also reveal

that changes at this synapse induced by stimulation are balanced by the complementary enhancement of local inhibitory pathways within the vestibular nuclei that contribute to ensuring a relatively robust behavioral performance.

Title: Distribution of vestibulosympathetic input to spinal glutamatergic interneurons

Authors: *G. C. WALTER, M.-C. PERREAULT;
Physiol., Emory Univ., Atlanta, GA

Abstract: Changes in body position during movement recruit neural circuits that help maintain balance and blood pressure. The vestibular system, via the vestibulospinal and vestibulosympathetic pathways, is thought to participate in both (Yates et al 2014). The goal of the present work is to assess the extent to which vestibulosympathetic control is mediated via spinal glutamatergic interneurons (INs). To do this we combined vestibular nerve ($VIII^{th}$ n.) stimulation and single-cell calcium imaging in ex-vivo brainstem-spinal cord neonatal preparations from vGluT2:GCaMPx transgenic mice. In these mice, $vGluT2^{+}$ INs genetically encode calcium sensors and their activity can be probed optically. Individual $vGluT2^{+}$ INs were visualized from the cut surface of the Th10 spinal segment. The current threshold (T) was defined as the minimum current intensity at which $VIII^{th}$ n. stimulation evoked calcium responses in CaGDA-preloaded sympathetic preganglionic neurons (SPNs). Only responses evoked by 2T stimulation are reported here. We analyzed vestibular-evoked responses in 240 $vGluT2^{+}$ INs (n=11). These $vGluT2^{+}$ INs were spatially distributed along the entire dorsoventral extent of Th10, with 115 located dorsally in lamina I-V and 125 located ventrally in lamina VI-X. Remarkably, while ventrally located $vGluT2^{+}$ INs were generally responsive to $VIII^{th}$ n. stimulation, dorsally located $vGluT2^{+}$ INs were not (92% vs 12% of responsive $vGluT2^{+}$ INs, respectively). Stimulation of sensory afferents in the Th10 dorsal root evoked responses in all the dorsally located $vGluT2^{+}$ INs tested (41/41, n=2), suggesting that their lack of responsiveness to vestibular inputs was genuine. Then, we wanted to determine whether vestibulospinal or vestibulosympathetic inputs were responsible for vestibular-evoked responses in the ventrally

located vGluT2^{+} INs. For this we took advantage of the difference in funicular trajectories of the vestibulospinal and vestibulosympathetic descending axons (VF+VLF vs DLF) and compared the responses of vGluT2^{+} INs to VIIIth n. stimulation before and after unilateral VF+VLF lesion (38, n=2). Compatible with *vestibulospinal* activation, we found that 35% of the vGluT2^{+} INs that responded to VIIIth n. stimulation before the lesion were no longer responsive to the stimulation after the lesion. Compatible with *vestibulosympathetic* activation, the remaining 65% still responded to VIIIth n. stimulation after the lesion. Our findings indicate that vestibular-responsive vGluT2^{+} INs are clustered in the ventral spinal cord and that a substantial proportion are involved in mediating vestibulosympathetic responses.

Title: Light-sheet based whole-brain neuronal activity recording during vestibular stimulation in zebrafish larvae

Authors: *V. BORMUTH, R. CANDELIER, G. DEBREGEAS, G. MIGAULT;
Lab. Jean Perrin, Univ. Pierre Et Marie Curie, Paris, France

Abstract: Light-sheet microscopy allows cell resolved whole-brain calcium imaging at several brain scans per second in zebrafish larvae. Currently this technique is not compatible with dynamic stimulation of the vestibular system. We developed an ultra stable miniaturized light-sheet microscope that can be rotated while performing whole-brain recordings. Rotating the microscope rotates the fish and stimulates the vestibular system while imaging always the same plane in the brain. We demonstrate volumetric whole-brain neuronal activity recordings during vestibular stimulation. We mapped the brain activity with cellular resolution of the vestibule-ocular reflex.

Title: Evolution of spatiotemporal dynamics from otolith sensory afferents to cortex

Authors: ***S. LIU**[1], J. LAURENS[1], R. CHAN[1], X. YU[1], D. DICKMAN[1], G. C. DEANGELIS[2], D. E. ANGELAKI[1];
[1]Dept. of Neurosci., Baylor Col. of Med., Houston, TX; [2]Dept. of Brain and Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: Sensory signals are transformed as neural activity is relayed from sensors through pre-thalamic and thalamic nuclei to cortex. To explore how temporal dynamics and directional tuning are sculpted in hierarchical vestibular circuits, we compared response properties of macaque otolith afferents with those in vestibular and cerebellar nuclei, as well as five cortical areas (parieto-insular vestibular cortex, visual posterior sylvian area, ventral intraparietal area, dorsal medial superior temporal area, and frontal pursuit area) to identical motion stimuli. Transient translational stimuli were presented along 26 headings in 3D, including all combinations of azimuth and elevation in increments of 45°. To characterize spatiotemporal response properties, we developed 3D tuning models where the temporal profiles of the velocity (V), acceleration (A) and jerk (J) component of the motion stimulus were multiplied by independent spatial tuning curves. Neural responses were fit with models of increasing complexity incorporating one ('V', 'A', 'J' models), two ('VA', 'VJ', 'AJ' models) or three ('VAJ' model) components. We found that 52% of otolith afferents were best fit by the A model and 30% by the AJ model, whereas only 19% were best fit by the VAJ model. This indicates that acceleration responses are dominant in otolith afferents. In contrast, 7% of (including vestibular/cerebellar nuclei and the 5 cortical areas) were best fit by the V model, 19% and 11% by the VA and VJ models, and 59% by the VAJ model , indicating that velocity responses were common in central cells. These analyses reveal that a remarkable spatio-temporal transformation takes place between the otolith afferents, which carry cosine-tuned linear acceleration and jerk signals that are spatially aligned, and their targets in the brainstem and cerebellum, where neurons exhibit non-linear, mixed selectivity for multiple temporal components of the stimulus. Furthermore, the velocity, acceleration and jerk components of response for central neurons

often show dissimilar spatial tuning, being encoded in a strongly non-linear and non-separable manner . Our analysis also shows that little further processing occurs downstream, such that similar spatio-temporal properties are found in brainstem/cerebellar nuclei and multiple cortical areas. These results suggest that the first synapse represents a key signal transformation, shaping how self-motion is represented in central vestibular circuits and diverse cortical areas.

Title: Modulatory role of orexin on synaptic transmission in the central vestibular system

Authors: ***Y. JIANG**[1], T. LAM[1], C. MA[1], D. SHUM[1], J. WANG[2], Y. CHAN[1];
[1]Sch. of Biomed. Sci., The Univ. of Hong Kong, Hong Kong, China; [2]Nanjing Univ., Nanjing, China

Abstract: Orexin is known to modulate synaptic plasticity in the hippocampus and contribute to social memory in adult rodents. While orexin neurons in the lateral hypothalamus project to the vestibular nucleus (VN), the role of orexin in the maturation of vestibular functions remains unexplored. We hypothesized that orexin modulates synaptic transmission in the VN, regulating the expression of vestibular-related behaviors during postnatal development. Our immunohistochemical results showed that orexin receptors and orexin-immunopositive neurons are present in the VN. Also, pharmacological perturbation of orexin receptors in the VN of neonatal rats led to impairment in developmental acquisition of vestibular-related behaviors, such as air-righting reflex. To understand the role of orexin on synaptic transmission in the VN, we employed *in vitro* whole-cell patch-clamp technique to study the action of orexin on the excitability of neurons in the medial vestibular nucleus (MVN) of rats at postnatal day 14. Treatment with orexin led to reductions in both the amplitude and frequency of miniature inhibitory postsynaptic current (mIPSC). This suggests that orexin decreases presynaptic release of inhibitory transmitters and postsynaptic depolarization within the MVN. Notably, we found that agonist of orexin 2 receptor reduced the frequency but not amplitude of mIPSC. All in all, we demonstrated that orexin suppresses synaptic inhibition on MVN neurons. We further

investigated whether orexin-modulated mIPSC is mediated by $GABA_A$ receptors or glycine receptors. With the use of bicuculline and strychnine, we observed that orexin decreased mIPSC mediated by $GABA_A$ receptors, but not glycine receptors. Taken together, our findings provide us with fundamental knowledge about the modulatory role of orexin in GABAergic transmission in the VN and its impact on postnatal refinement of neural circuit for vestibular-related behavior.

Title: Temporal whitening of natural self-motion stimuli by early vestibular pathways

Authors: *K. E. CULLEN[1], D. E. MITCHELL[2], A. KWAN[3], J. CARRIOT[4], M. J. CHACRON[2];
[2]Physiol., [3]Biomed. Engin., [1]McGill Univ., Montreal, QC, Canada; [4]Physiol. and Pharmacol., Univ. of Western Ontario, London, ON, Canada

Abstract: Understanding how the brain generates appropriate behavior and accurate perception in response to incoming sensory signals remains a fundamental challenge in neuroscience. The common wisdom is that neural coding strategies are adapted to the statistics of the sensory signals found in the natural environment. Specifically, early sensory pathways are thought to efficiently process natural stimuli by matching their tuning properties to their statistics, thereby removing redundancy and thus maximizing information transmission. If this is the case, neural tuning should be inversely proportional to stimulus power, such that the resulting neural response is independent of frequency (i.e. “whitened”). To date, however, there has been no experimental demonstration that such a match exists. Here we show for the first time how whitening is achieved by sensory pathways. Specifically, we recorded from vestibular neurons during natural self-motion and found that whitening occurs sequentially, beginning at the level of the sensory periphery, and is then further refined centrally. Notably, individual neurons at the first central stage of processing suggested exceptional whitening that could not be explained solely by considering their tuning properties. We found that the apparent whitening observed for central neurons was due to a close match between their comparatively high resting discharge variability

and their high-pass tuning, and self-motion statistics. Our results therefore show that neural variability contributes to the "whitening" observed in the response spectra for natural vestibular stimuli, and suggest that this is the case for other sensory systems.

Title: Central vestibular neurons integrate inputs from limb and labyrinth in an additive manner

Authors: *D. M. MILLER[1], C. D. BALABAN[1], W. M. DEMAYO[2], G. H. BOURDAGES[1], B. J. YATES[1], A. A. MCCALL[1];
[1]Otolaryngology, Univ. of Pittsburgh, Pittsburgh, PA; [2]The Commonwealth Med. Col., Scranton, PA

Abstract: The maintenance of balance is an inherently multimodal process. Vestibular and proprioceptive afferent information is processed by the central nervous system and used to generate an estimate of body position and movement in space that shapes corrective postural reflexes to external perturbations. Our group recently demonstrated in decerebrate and conscious cat preparations that hindlimb somatosensory inputs converge with vestibular afferent input onto neurons in multiple CNS locations that participate in balance control. While it is known that head position and limb state modulate postural reflexes, the combined influences of the two inputs on the activity of vestibular nucleus (VN) neurons is unknown. In the present study, we compared the responses of VN neurons to vestibular and hindlimb stimuli delivered separately and together in conscious cats. Extracellular single-unit recordings were obtained from neurons in the caudal aspects of the VN complex. Sinusoidal whole body rotation in the roll plane was used as the search stimulus. Units responding to the search stimulus were tested for their responses to 10° ramp-and-hold roll body rotation (vestibular stimulation), 60° extension hindlimb movement, and both movements delivered simultaneously. Composite response histograms were fit by a model of low and high pass filtered limb and body positon signals using least squares nonlinear

regression. Most neurons that responded to vestibular and limb stimulation did so in an additive fashion. VN neurons that exhibit these integrative properties likely participate in adjusting vestibulospinal outflow in response to limb state.

Title: Monosynaptic viral tracing reveals direct inputs to mouse efferent vestibular neurons

Authors: M. A. MATHEWS[1], A. MURRAY[2], *A. J. CAMP[1];
[1]Univ. of Sydney, Sydney University, Australia; [2]Univ. Col. London, London, United Kingdom

Abstract: *Background:* Many sensory modalities are modulated by efferent input from the central nervous system (CNS), allowing central influence of sensory inflow. One prominent example of this is the efferent vestibular system, despite intensive physiological investigation though, the underlying mechanisms and purpose of central nervous control of the peripheral vestibular labyrinth remain hypothetical. Previous work has demonstrated that activation of the cholinergic efferent vestibular nucleus (EVN) (located in the brainstem) directly modulates peripheral vestibular end organs including hair cells as well as vestibular primary afferent fibres. While more recent investigations have exposed facets of the underlying physiological and anatomical properties of the EVN, a lack of understanding regarding EVN circuit dynamics makes it impossible to link vestibular efferent activity to behaviour. *Objective:* Here we sought to determine the context within which the EVN is activated by tracing the monosynaptic inputs to this group of neurons. *Methods:* We used monosynaptic rabies tracing to determine the direct inputs to EVN neurons. In mice (n = 3) expressing Cre under the control of the choline acetyl transferase (ChAT) promotor we expressed the rabies glycoprotein (G) selectively in EVN neurons. Following G expression, we injected glycoprotein-deficient rabies (RABVdeltaG) virus expressing a fluorescent protein into the horizontal and posterior semicircular canals in the inner ear of the same animal. Histological analysis was performed to identify the direct inputs to EVN neurons. *Results:* We observed direct inputs from neighbouring vestibular nuclei including the medial and lateral vestibular nuclei, as well as from regions of the reticular formation and other parts of the brainstem. *Conclusions:* The identification of direct monosynaptic inputs to mouse EVN neurons with rabies virus will allow us to expand hypothesis regarding EVN function. In

addition, this method will allow us to manipulate EVN neurons, or their inputs, via electrical, chemical or optogenetic methods providing a means to systematically explore the context-dependent modulation of peripheral vestibular function.

Title: Convergence of linear acceleration and yaw rotation signals in the vestibular nucleus

Authors: B. ABBATEMATTEO[1], L. H. CARNEY[1], M. WEI[2], *S. D. NEWLANDS[2];
[1]Biomed. Engin., [2]Otolaryngology, Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: Linear acceleration signals carried by vestibular afferents innervating the utricle and yaw rotation velocity signals carried by afferents originating from semi-circular canals converge upon neurons in the vestibular nucleus. The majority of non-eye movement neurons in the vestibular nucleus receive these convergent signals. Canal-otolith interactions have been shown to be non-linear in these neurons, but the mechanisms that produce these convergent responses are poorly understood. Earlier studies of convergent responses have not allowed systematic, independent manipulation of the frequency and amplitudes of the translational and rotational signals. The goal of the present study is to characterize the convergent responses. Awake, behaving macaques were placed on a turntable mounted on a horizontal sled. The rotation and translation motors were independently controlled. First, the unimodal responses to sinusoidal translational and rotational stimuli were characterized. Then, responses to combined stimuli (2 or 0.3 Hz translation at 0.1g with 2, 0.5, or 0.3 Hz superimposed rotation at 30, 60 or 90°/s) were then compared to the unimodal responses in the time and frequency domains. The discrete Fourier transform was applied to Kaiser-filtered instantaneous firing rates to identify magnitude and phase of the translation and rotation frequency components of the convergent response. It was determined that convergent responses are sub/super additive dependent upon stimulus intensity and acceleration directional heading. Frequency components of each stimulus mode were present (e.g. the 2 Hz translation and 0.5 Hz rotation) in the convergent response, as well as interactions (e.g. 1.5 and 2.5 Hz components), suggesting a nonlinear, multiplicative combination. Response phase to each stimulus mode were often different between unimodal and

convergent trials. These data provide tests of models for convergent interactions, such as simple gating, addition, coincidence detection, and divisive normalization. The divisive normalization model was extended into the time domain to model instantaneous firing rates. The magnitudes of frequency components present in the convergent responses were best modeled by divisive normalization; however, the phases of the components in the convergent responses were not easily explained using any of the existing simple neural models.

Title: Behavioral expression of orexin-modulated transmission in the vestibular nucleus of postnatal rats

Authors: *U. LAM[1], C. MA[1], D. SHUM[1], J. WANG[2], Y. CHAN[1];
[1]Sch. of Biomed. Sci., Univ. of Hong Kong, Hong Kong, Hong Kong; [2]Sch. of Biol. Sci., Nanjing Univ., Nanjing, China

Abstract: Orexin is known to participate in body balance and motor coordination via modulating synaptic transmission in the central vestibular system of adult animals. We hypothesize that orexin also regulates the maturation of vestibular functions during postnatal development. To test whether neonatal perturbation of orexinergic synapses in the vestibular nucleus (VN) exerts any effect on the acquisition of vestibular-related behaviors, we blocked or activated orexin receptors in the VN of postnatal day (P) 1 rats by implanting drug-containing Elvax slice onto the dorsal surface of VN for slow release of the drug to the underlying VN. Pharmacological intervention was achieved by loading the slices with orexin, orexin receptor antagonist (SB334867) or orexin receptor agonist ([Ala11, D-Leu15]-orexin-B). Specific behavioral tests including negative geotaxis (a graviceptive response), surface righting and air righting were performed on these rats at different postnatal stages until adulthood. Neonatal treatment with orexin receptor antagonist accelerated acquisition of negative geotaxis, surface righting, as well as air righting in the course of early postnatal development. In contrast, neonatal treatment with orexin or its receptor agonist delayed acquisition of negative geotaxis and surface righting. Adult rats pretreated at neonatal

stage with orexin receptor agonist or antagonist were further tested for (i) spatial navigation by dead reckoning test; (ii) motor coordination by rotarod test and balance beam test. Treatment with orexin receptor antagonist enhanced the performance of dead reckoning while treatment with agonist impaired the performance of both dead reckoning and motor coordination. Taken together, our findings demonstrated that orexinergic modulation in the VN impacts developmental refinement of neural circuit for vestibular-related behaviors. [Supported by N_HKU735/14]

Title: Convergence properties of sparse codes adapted to natural head motion

Authors: ***P. HAUSAMANN**[1,2], S. GLASAUER[3,2], M. KLEINSTEUBER[1,2], P. MACNEILAGE[3,2];
[1]Tech. Univ. of Munich, Muenchen, Germany; [2]Bernstein Ctr. for Computat. Neurosci., Muenchen, Germany; [3]German Ctr. for Vertigo, Univ. Hosp. of Munich, Muenchen, Germany

Abstract: Sparse representations of natural stimuli have been shown to be useful models of neuronal population codes in a variety of sensory systems. Here we investigate whether the same principles can be applied to the vestibular system. We learned a sparse code for vestibular stimulation based on 6-degree-of-freedom measurements of angular velocity and linear acceleration of the human head. The resulting set of 6-dimensional time-varying basis functions, or kernels, captures the interdependencies between rotational and translational inputs as well as temporal signal patterns. We compared the convergence properties of this set of kernels to those of neurons in the vestibular nucleus (VN) and the rostral fastigial nucleus (FN), the first points of convergence for one-dimensional linear and angular vestibular afferent motion signals. We found that several properties of the sparse code matched those of central vestibular neurons measured in physiological experiments on mammals.
The sparse code consisting of a set of 6D time-varying kernels was learned in order to efficiently

represent natural head movements using a previously described method, namely a multivariate dictionary learning algorithm. The code was trained using samples of recorded linear acceleration and angular velocity of head motion from 10 different subjects performing 7 different activities each (running, biking, walking on grass, walking on pavement, playing soccer, walking upstairs, walking downstairs) using an inertial measurement unit, the MTx from Xsens.
Similarly to VN neurons, different learned kernels predominantly represent either linear acceleration, angular velocity or both. Furthermore, we observed a distributed encoding of gravitational and inertial components of linear acceleration. This is consistent with the observation that VN and FN neurons tend to encode a linear combination of purely inertial translation and acceleration due to gravity. These findings suggest that the observed convergence properties of our sparse code are indeed a result of adaptation to natural stimulus patterns and support the hypothesis that the otolith/canal convergence of central vestibular neurons is optimized in order to efficiently encode head motion.

Title: Connectivity of the human vestibular cortex revealed by diffusion-based probabilistic fiber tracking

Authors: *M. W. GREENLEE[1], A. WIRTH[2], S. M. FRANK[3], A. L. BEER[1];
[1]Univ. Regensburg, Regensburg, Germany; [2]Dept. of Neurol., Univ. Hosp. Regensburg, Regensburg, Germany; [3]Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: The posterior insula/retroinsular cortex including the lateral sulcus has been associated with self-motion perception, gravity-related processing and the integration of vestibular, optokinetic, proprioceptive and tactile signals. Two areas, referred to as the parieto-insular vestibular cortex (PIVC) and the posterior insular cortex (PIC), represent subareas in this human vestibular system. PIVC and PIC both respond to vestibular stimuli, but PIVC is inhibited whereas PIC is excited by visual motion. The structural connectivity of human PIVC and PIC as

not yet been investigated *in vivo*. Therefore, we investigated the cortical/subcortical connectivity of PIC and PIVC using diffusion-weighted magnetic resonance imaging (MRI) and probabilistic tractography. Anatomical T1-weighted, functional (fMRI), and diffusion-weighted (DWI) images were acquired from 16 healthy participants. A cortical and subcortical reconstruction of the anatomical images was conducted by Freesurfer. Seed regions for the tracking algorithms (PIVC and PIC) were identified in each individual brain by fMRI based on their response to caloric vestibular and visual motion stimulation, respectively. Subcortical target regions were identified in each individual brain by the Freesurfer reconstruction. Additionally, sub-divisions of the thalamus were defined by a Morel-based standard atlas. DWI were acquired along 30 diffusion orientations. Probabilistic tracking with seeds in PIVC and PIC were performed by FSL tools. Track terminations projected to the cortical surface showed that PIVC and PIC shared connections to the insular/lateral sulcus, superior temporal cortex and inferior frontal gyrus. A comparison of the connectivity showed that PIVC was more connected to the anterior insula, Heschl's gyrus and the posterior parietal regions, whereas PIC had more connections to the supramarginal gyrus and superior temporal sulcus. For both seed regions, subcortical connections were observed with vestibular nuclei of the thalamus and the putamen. However, PIVC showed stronger connectivity with the lateral pulvinar than PIC. Our findings suggest that PIVC and PIC have a unique connectivity finger print and should be considered separate areas of the cortical vestibular network.

Title: Visual-vestibular processing in the human sylvian fissure

Authors: *S. M. FRANK[1], A. M. WIRTH[2], P. U. TSE[1], M. W. GREENLEE[2];
[1]Psychological and Brain Sci., Dartmouth Col., Hanover, NH; [2]Inst. of Exptl. Psychology, Univ. of Regensburg, Regensburg, Germany

Abstract: The processing of vestibular cues in humans is well understood on the subcortical level, however, the organization of the cortical vestibular network is less clear. A central role is assumed for the region including and surrounding the posterior part of the Sylvian fissure (also

called lateral sulcus), extending into the posterior insula. Previous functional imaging studies have reported activation in this region during vestibular stimulation and labelled the activation cluster as parieto-insular vestibular cortex (PIVC), following terminology in primates. However, the organization of the Sylvian vestibular network is likely more complex, because another area, labelled posterior insular cortex (PIC), is located in close vicinity posterior to PIVC (Frank et al. 2014). Originally, PIC has been described as a region processing visual object motion cues (e.g., Sunaert et al., 1999; Orban et al., 2003). However, recently, vestibular responses have been reported for PIC as well, suggesting that PIC is part of the vestibular network (Frank et al., 2014). To date, no study has directly compared areas PIVC and PIC in the same participants, rendering the organization of the center of human vestibular cortex unclear. Therefore, in this study (Frank et al., 2016), we defined and compared the areas known as PIVC and PIC in the same participants (n = 15), using caloric vestibular and visual object motion stimuli in functional magnetic resonance imaging (fMRI). An independent vestibular localizer with bithermic caloric stimulation and a visual object motion localizer (dynamic white random dots moved at 15°/s in one of twelve translational directions) were employed to determine locus and size of PIVC and PIC, respectively. We find that both areas respond to caloric vestibular cues, however only the multivariate activity pattern of PIVC in the right hemisphere reliably represented the direction of caloric stimulation. During visual object motion, activation in PIVC was suppressed, whereas PIC was activated. On both, single-subject and group levels, PIC appeared to be split in separate anterior and posterior clusters. Anterior PIC was located in close vicinity to PIVC, whereas posterior PIC was located closer to the posterior ending of the Sylvian fissure. Future studies should therefore consider that the central vestibular network in the Sylvian fissure of humans consists of at least two functionally and anatomically separate areas.

Title: Response characteristics of horizontal semicircular canal afferents to behaviorally-inspired stimuli in late-stage larvae of Xenopus laevis

Authors: K. D. GENSBERGER[1], S. HÄNZI[1], M. G. PAULIN[2], H. STRAKA[1], *L. F. HOFFMAN[3];
[1]Biol. II, Ludwig-Maximillians-Universität München, Munich, Germany; [2]Zoology, Univ. of Otago, Dunedin, New Zealand; [3]UCLA Sch. Med., Los Angeles, CA

Abstract: Though the discharge characteristics of semicircular canal afferent neurons have been investigated in many different animal models, very few studies have endeavored to probe afferent discharge with stimuli resembling self-motion consequences of natural locomotion behaviors. In the present study we measured head kinematics of late stage *Xenopus laevis* larvae during free swimming, which provided the inspiration for the stimuli used to investigate the evoked discharge of individual afferents projecting from the horizontal semicircular canal cristae. Head kinematics during swimming were determined from video capturing short epochs in which animals were free from touching the walls of a small tank. Frame-by-frame analyses were conducted by identifying the eyes in each frame and measuring the angular deviation of the chord connecting their centroids. Stage 51-53 larvae exhibited extremely active swimming in short episodes (2 – 4 sec). Angular head movements in the yaw plane during this locomotion behavior typically ranged between 4 – 6 Hz, with peak angular velocities that reached 400°•s^{-1}. Horizontal semicircular canal afferents in these animals exhibit comparable physiologic heterogeneity as observed in other animal models, including broad diversity in spontaneous discharge rate and interspike interval coefficient of variation (CV), sensitivity, and phase. The analyses of head kinematics during natural swimming compelled our focus on higher stimulus frequencies and a variety of peak velocities during electrophysiological recordings of evoked discharge. Afferents exhibiting higher sensitivities and phase leads, associated with higher values of spontaneous discharge CV, revealed nonlinear response amplitude modulation with increasing peak velocities. Behaviorally-relevant stimulus frequencies of 2 – 4 Hz resulted in a change in response mode to phase locking, whereby further increases in peak head velocities were not accompanied by a comparable increase in peak discharge rate. The response amplitudes of afferents with lower sensitivities and phases, associated with lower spontaneous discharge CV, exhibited stable sensitivities at the stimulus magnitudes tested, indicating more linear characteristics of their response amplitudes. The responses of these afferents were more likely to remain in a frequency modulated mode at behaviorally-relevant frequencies, and more apt to encode increasing head velocity with comparable changes in discharge rate. These findings support the notion that the heterogeneity in afferent discharge characteristics subserve different roles in head movement coding.

Title: Adaptive modifications in vestibular epithelia of Egyptian fruit bats

Authors: K. R. CHOY[1], Y. N. TON[1], *W. METZNER[1], L. F. HOFFMAN[2];
[1]Integrative Biol. and Physiol., UCLA, Los Angeles, CA; [2]Head & Neck Surgery, Geffen Sch. of Med. at UCLA, Los Angeles, CA

Abstract: It is widely acknowledged that bats are among the most agile of mammals by virtue of their aerial behaviors involved in obstacle avoidance and/or prey capture while maneuvering in conditions of low ambient light. While some bat species exhibit adaptations of their cochleae to accommodate the acoustic requirements of echolocation, previous investigations have revealed a notable absence of architectural adaptations of the vestibular labyrinth that would support putative demands for enhanced high frequency head movement coding that are likely associated with greater agility. This motivated the present investigation of cellular modifications within the peripheral vestibular epithelia. Through the present study we tested the general hypothesis that the vestibular periphery exhibit cellular adaptations that are consistent with enhanced capabilities for high-frequency head movement coding. This was achieved by histologic analyses of hair cells and afferent dendrites within the striolae and central zones of utricles and semicircular canal cristae (respectively) harvested from Egyptian fruit bats (*Rousettus aegyptiacus*), which were compared to similar regions in specimens from mice (*Mus musculus*). Utricular striolae and crista central zones were identified as the regions receiving afferent calyces immunolabeled with anti-calretinin (Calb2). We found that total hair cell counts in striolae from *Rousettus* and Mus were similar, though a greater number of hair cells were found in the central zones of *Rousettus* compared to those in *Mus*. Antibodies to β-3-tubulin were used to label all afferent calyces, which enabled unequivocal identification of all type I hair cells. The striolae and central zones in *Rousettus* were found to exhibit greater proportions of type I hair cells (72.5 ± 3.6% and 86.8 ± 1.2%, respectively, relative to all hair cells) compared to these regions in *Mus* (57.2 ± 2.7% and 63.5 ± 1.1%, respectively; $p<10^{-5}$). The expression of oncomodulin, a calcium-binding protein found in striolar and juxtastriolar hair cells, was found to be more extensive in utricles from *Rousettus* compared to *Mus* ($p<10^{-5}$). The expression of Kv7.4 (i.e. KCNQ4) a low-voltage activated potassium channel associated with striolar and central zone calyces, also appeared to be more extensive in neuroepithelia from *Rousettus* compared to *Mus*. These data indicate that vestibular epithelia in *Rousettus* exhibit cellular adaptations supporting enhanced capabilities for

rapid, agile head movements compared to that found in *Mus*. These adaptations are likely driven by requirements of head stabilization during flight and echolocation.

Title: Dynamics of vestibular afferents and their contribution to neck motor-unit activity during electrical vestibular stimulation

Authors: *P. A. FORBES[1,2], A. KWAN[3], B. G. RASMAN[2], D. E. MITCHELL[3], K. E. CULLEN[3], J.-S. BLOUIN[2];
[1]Delft Univ. of Technol., Delft, Netherlands; [2]Sch. of Kinesiology, Univ. of British Columbia, Vancouver, BC, Canada; [3]McGill Univ., Montreal, QC, Canada

Abstract: The nervous system's ability to encode and integrate multiple streams of sensory information affords us with the ability to engage and understand the world around us. The capacity for individual sensory systems to encode natural stimuli can be described by evaluating their dynamic range of performance. For example, the spectrum of light that is visible to the human eye ranges in frequency from 430 - 770 THz, while the human ear can perceive sounds at frequencies from 20 Hz - 20 kHz. The vestibular system, which encodes rotational and translational head motion in space, is described as having a physiologically relevant range of 0-25 Hz. This corresponds with the approximate bandwidth of vestibular input (0-30 Hz) caused by head movement during natural self-motion. Recent studies, however, have demonstrated that neck muscle activity is correlated to electrical vestibular stimuli up to 75 Hz, suggesting that vestibular afferents can evoke muscle responses at higher frequencies. It may seem irrelevant to examine sensory input to muscle activity beyond the physiologically relevant range since the mechanical output of a muscle cannot effectively contribute to postural control. However, exploring the limits of system performance can provide novel insights into the mechanisms underlying neural computations. Therefore in this study, we explore the dynamic range of the vestibular sensorimotor system by recording vestibular canal afferent responses (irregular and regular) in non-human primates, as well as single motor unit activity in a neck muscle

(sternocleidomastoid) in humans (n = 8) during electrical vestibular stimulation up to 300 Hz. Stimuli for both primate and human subjects included single sinusoids from 25-300 Hz and band-limited noise currents from 0-300 Hz. We found that both regular and irregular afferents respond to input stimuli up to 300 Hz. Notably, the cycle-averaged modulation of the afferents' firing rate to electrical stimulation continues to increase beyond the physiologically relevant range of 0-25 Hz. Furthermore, as frequency increased, afferents show increased phase locking with the input current. Human neck muscle motor units similarly respond to inputs up to 300 Hz, although the correlation between motor unit firing and input stimulus is reduced above ~125 Hz. Motor unit response gains peak at 75 Hz and decrease thereafter, while phase lag decreases continually across the bandwidth. Together these results demonstrate that the vestibular system can respond to input and contribute to muscle activity at very high frequencies. This may be relevant during high frequency transient events such as those experienced during direct head impacts.

Title: The ORL-1 receptor activation inhibits the voltage gate calcium current in vestibular afferent of rat

Authors: *E. SESEÑA MENDEZ[1], R. VEGA[2], A. ORTEGA[2], E. LUIS[2], E. SOTO[2];
[1]Fac. De Medicina, Univ. Autonoma De Puebla, Puebla, Mexico; [2]Inst. de Fisiología, BUAP, Puebla, Mexico

Abstract: The vestibular system permanently is modulated by neuromodulators as opioid peptides both at the central and peripheral level. The nociceptin/orphaninFQ peptide (N/OFQ) peptide and its receptor opioid receptor like-1 (ORL-1) has been found to be expressed in the vestibular nuclei complex, and N/OFQ has been shown to modulate the electrical activity of the medial vestibular nucleus neuron. In this work we evaluated in the vestibular afferent neurons

isolated the effect of ORL-1 activation in the voltage-gate calcium current (ICa), in the action potential and in the electric discharge of the vestibular afferent neurons, additionally we evaluated the changes of intracellular calcium through of calcium imaging.The results shown that the perfusion of N/OFQ decreased the high voltage activated ICa (HVA) without significantly modifying the low voltage activated ICa (LVA), the inhibition of the HVA ICa component was dependent on the concentration used. The specific ORL-1 antagonist UFP101 or the preincubation of neurons with pertussis toxin completely occluded the N/OFQ inhibitory action upon the calcium current. Elsemore, the use of ω-ctx-MVIIA (specific N type Calcium channel blocker) alsooccluded the effect of ORL-1 activation. The effect of the N/OFQ on the HVA ICa was also reverted by a prepulse to +80 mV. Ours results showed that ORL-1 activation inhibits the N type ICa in the vestibular afferent neurons in a voltage-dependent manner. We thought that ORL-1 mediates a presynaptic modulation of the neurotransmitter release from the vestibular afferent terminals to the vestibular nuclei neurons, constituting a target to negatively modulate the afferent gain.

Title: Vestibular hair cell loss in type 2 diabetic T2DN rats

Authors: S. WANG[1], A. ARTEAGA[1], D. S. SANDLIN[1], R. R. GUYTON[1], Y. YU[1], F. FAN[2], R. J. ROMAN[2], D. E. VETTER[3], K. T. YEE[3], W. ZHOU[1], *H. ZHU[1];
[1]Univ. MS Med. Ctr. Dept ENT, Jackson, MS; [2]Univ. MS Med. Ctr. Dept Pharmacol., Jackson, MS; [3]Univ. MS Med. Ctr. Dept Neurobio. & Anatom. Sci., Jackson, MS

Abstract: Patients with diabetes mellitus are 70% more likely to have dysfunctions of the vestibular system (*Agrawal et al., Disorders of Balance and Vestibular Function in US Adults Data From the National Health and Nutrition Examination Survey, 2001-2004*). The underlying mechanism, however, has not been elucidated. In the present study, we evaluated morphological changes in the vestibular end organs of T2DN rats, a new diabetic animal model that mimics the human type 2 diabetes mellitus with accelerated diabetic nephropathy. Temporal bones were collected from 16-18 month old T2DN rats (n=4) and age-matched Sprague-Dawley control rats (n=3). Cryostat sections of inner ear were prepared and stained with Cresyl Violet. Inner ear morphology was evaluated by light microscopy. Preliminary analysis revealed that there was a substantial hair cell loss in all five vestibular end organs of the T2DN rats compared to the age-matched control rats. These results suggest that type 2 diabetes mellitus causes a loss of vestibular hair cells, which may contribute to the vestibular dysfunctions seen in patients with diabetes. Ongoing studies are to further characterize the structural and functional changes of the vestibular system in the progression of diabetes. Such knowledge is essential for developing effective programs of prevention, assessment and treatment of the diabetes-induced vestibular dysfunction. (Shaoxun Wang and Alberto Arteaga contributed equally to this abstract).

Title: Differential effect of gentamicin on inner ear hair cells and vestibular afferent dynamics in Xenopus laevis tadpoles

Authors: *C. GRAVOT[1,2,3], F. BRANONER[1], A. G. KNORR[4], H. STRAKA[1];

Computat. Neurosci., Planegg, Germany; [4]Dept. of Neurology, Klinikum Großhadern, LMU, Ctr. for Sensorimotor Res., Munich, Germany

Abstract: Vestibulo-ocular reflexes (VOR) assist retinal image stabilization by generating compensatory eye movements in phase opposite to head movements. However, patients with Ménière's disease, suffering from vertigo, are often treated with aminoglycoside antibiotics such as gentamicin that impairs vestibular sensation. This drug causes hair cell damage and apoptosis, however, reliefs most patients from episodes of vertigo attacks. At variance with the well-described effect of gentamicin, several details about the ototoxic mechanism of this antibiotic are still unknown. Due to the experimentally more accessible amphibian compared to the mammalian inner ear and the possibility to employ semi-intact preparations for *in-vitro* morpho-physiological experimentation, we studied the consequences of gentamicin treatment in *Xenopus laevis* tadpoles. Larvae at stages 52-55 were treated with gentamicin (2, 5 and 10 μM) for 1 or 5 days prior to the electrophysiological experiments and eye movement recordings. VOR performance was evaluated by recording extraocular motor nerve discharge during passive motion with a 6-axis hexapod, which allowed separate activation of semicircular canal and otolith organs. Extraocular motor nerve recordings indicated that 1 day of gentamicin treatment reduced the semicircular canal-related activity by ~60%, while utricular-related responses remained relatively unchanged. Longer application of this drug entirely abolished all angular acceleration-induced extraocular motor discharge modulation (semicircular canal) and significantly impaired linear acceleration-induced (utricle) responses. In addition, anatomical stainings with phalloidin (stereocilia), HCS-1 (hair cells) and caspase-3 (apoptosis) revealed a gentamicin-induced disarrangement of cilial bundles and hair cell degeneration. The disruptive effect of hair cell integrity predominated in the center of the semicircular canal cupulae and along the striola of the utricular maculae. Even though *Xenopus laevis* tadpoles, as all anamniotes possess only type II hair cells, the latter differentiate into distinct subtypes with matching morpho-physiological features and regionally specific locations within the sensory epithelia. Our findings suggest that gentamicin treatment causes a partial damage and loss of vestibular hair cells with dynamic response properties and postsynaptic phasic vestibular afferent fibers. The differential influence of gentamicin in *Xenopus* tadpoles suggests a deteriorating impact of this drug of a particular population on hair cells, as in mammals, potentially allowing more insight into gentamicin-induced ototoxicity.

Title: The vestibular calyx ending as an axon initial segment: Na^+ channels and implications for function

Authors: *A. LYSAKOWSKI[1], J. M. GOLDBERG[2];
[1]Dept. of Anat. & Cell Biol., Univ. of Illinois at Chicago, Chicago, IL; [2]Pharmacol. and Physiological Sci., Univ. of Chicago, Chicago, IL

Abstract: Our investigations of Na channel distribution with various Pan-Na_v and Na_v isoform-specific antibodies in vestibular afferents aimed to determine the Nav channel isoforms present in the axon initial segment (AIS) of various vestibular afferent classes. We have also examined their immuno-localization in the various microdomains of the calyx ending (Lysakowski et al., JNS, 2011). Electrophysiological recordings from calyx endings in different species have reported the presence of an A-current and an h-current, so we also searched for candidate molecules for these currents. Afferent class and heminodal location were determined by co-labeling with calretinin (Desai et al., JNP, 2005) and nodal and AIS marker antibodies, such as ezrin, Caspr1, beta-IV spectrin, KCNQ3, and myelin basic protein. An ancillary finding of this study was that about 80% of the time, the heminode of calyx afferents is located at or above the basement membrane in calyx afferents and at or below the same location in dimorphic and bouton afferents, providing a longer AIS for dimorphic and bouton afferents. Whether this affects afferent timing is still undetermined. The inner surface of both calyx-bearing afferent types (Domain 1) contains $Na_v1.5$, while the apical end (Domain 2) contains $Na_v1.9$ in dimorphic afferents and is truncated in calyx afferents. The outer calyx surface (Domain 3) labels with $Na_v1.2$ in dimorphic and $Na_v1.3$ in calyx afferents. $Na_v1.6$ was present at the heminodes (Domain 4) of dimorphic vestibular afferents, but not at pure calyx afferent heminodes, while $Na_v1.1$ is present in all afferents. Using various A-current candidate antibodies ($K_v1.4$, 4.2 and 4.3), we obtained light labeling of dimorphic calyces and intense labeling of dimorphic boutons with $K_v4.3$. Immunolabeling with h-current candidate antibodies (HCN1 and HCN2) produced moderate labeling with HCN2 in all calyx endings, albeit somewhat less in calyx afferents. In conclusion, calyx and dimorphic afferents appear to mostly vary in their ion channel composition and this likely has implications for their separate functions.

Title: Serotonin modulation of ionic currents in the vestibular system primary afferent neurons

Authors: *E. SOTO[1], J. LIMA[2], E. LUIS[2], R. VEGA[2];
[1]Univ. Autonoma De Puebla, Puebla Pue, Mexico; [2]Inst. de Fisiología, Univ. Autónoma de Puebla, Puebla, Mexico

Abstract: The metabotropic 5-HT1B, 5-HT1D and 5-HT1F (Ahn & Balaban, 2010; Vountau & Balaban, 2013) and ionotropic 5-HT3A and 5-HT3B (Takimoto, et al., 2014) serotonin receptors have been identified in vestibular afferent neurons (VANs), suggesting that serotonin may modulate vestibular activity; however, no studies of the action of serotonin in the vestibular afferents has been carried out. The objective of this work was to determine the ionic currents modulated by serotonin in the VANs in primary culture and to determine the action of serotonin in intracellular calcium changes induced by depolarization. To define the peripheral effects of serotonin receptors in the vestibule we study the actions of serotonin on the electrical activity of cultured vestibular afferent neurons of the rat. Using whole-cell patch-clamp recording, we found that serotonin (30 μM) significantly decreased the amplitude of the inward current (attributable to Na^+ current) by 53% measured at +20 mV and the steady-state outward current by 27% measured at +30 mV. Additionally, calcium imaging recordings using the intracellular dye Fluo 4-AM, showed that serotonin (100 μM) significantly reduced the calcium responses generated by depolarization induced by perfusion of high potassium solution (20 mM). Recently, drugs such as serotonin re-uptake inhibitors have been used in the clinics for the treatment of vestibular disorders (e.g. vertigo), their effect has been interpreted in terms of their actions at the central nervous system. However, our results indicate that serotonin receptors may play an important role in vestibular afferent neuron activity modulating the inward currents of these neurons, and intracellular calcium rise caused by depolarization.

Title: Peripheral vestibular damage after exposure to mild, blast wave trauma

Authors: *S. LIEN, Z. MRIDHA, J. D. DICKMAN;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: The increased use of close range explosives has led to a higher incidence of exposure to blast-related head trauma. Exposure to primary blast waves is a significant cause of morbidity and mortality. Active service members who have experienced blast waves report high rates of vestibular dysfunction, such as vertigo, oscillopsia, imbalance, and dizziness. Accumulating evidence suggests that exposure to blast wave trauma produces damage to both the peripheral and central vestibular system; similar to previous findings that blast-results in damage to auditory receptors. Mice were exposed to a 63 kPa peak blast-wave over pressure and underwent behavioral assays to identify balance deficits. Furthermore, we examined the tympanic membrane of each mouse for any signs of perforation. Afterwards, we examined the vestibular receptors, central nuclei, vestibulo-ocular reflex (VOR) behavior, in dark and light, and optokinetic reflex (OKR) in mice after exposure to mild, blast wave trauma. Horizontal vestibular-ocular reflex was tested using sinusoidal motions at 0.5 Hz, 1.0 Hz, and 2.0 Hz over 20 degrees/second over 10 cycles. We also presented the mice with an optokinetic stimulus using a rotating ball containing a light source at a velocity of 20 degrees per second. Vestibular receptors and central nuclei were histologically prepared and the following measures quantified: stereocilia hair bundle counts, density of hair cells (both type I and type II) in the central and peripheral zones. The VOR gain and phase of the eye movement responses were compared for the normal (pre-blast) and the blast exposed animals. To date, we have observed perforations to the tympanic membrane, and a reduction in dark, horizontal VOR gains and alterations of phase at later time points in the animals exposed to a blast-wave over pressure. In addition, the mice had reduced light, horizontal VOR gains; however, the phase of the eye movements showed no significant alterations. We observed loss of stereocillia bundles 1 month in the cristae and otolith organs 1 month after blast-wave exposure. The mice showed decreased performance in a rotarod performance test and righting reflex test indicating some form of motor or balance deficit. Interestingly, the mice showed drastic reductions in the slow phase component of the optokinetic reflex and notable decreases in the number of fast nystagmus beats immediately after blast-wave exposure. These results suggest that blast-wave exposure can lead to peripheral vestibular damage (possibly central deficits as well) and provides some insight into causes of vestibular dysfunction in blast-trauma victims.

Title: Mouse otolith organs in cleared temporal bone

Authors: E. TIGNOR, R. COOK, A. PERACHIO, *T. MAKISHIMA;
Univ. of Texas Med. Br., Galveston, TX

Abstract: Hypothesis: The otolith organs can be visualized within the temporal bone by modification of tissue clearing and be suitable for downstream applications. Background: Histological and anatomical studies of the mouse otolith organs are technically difficult due to small size and location embedded in the temporal bone. Two recently published protocols, SeeDB and Sca/e allow the clearing and 3-D visualization of the whole brain in mice. Our goal was to modify the two protocols to achieve 3-D visualization of inner ear organs encased in the temporal bone and use this method to measure the planar angle of the utricle to the saccule. Methods: Temporal bones were dissected from mice at various ages up to 18 months. The adult temporal bones were decalcified. After fixation in 4% paraformaldehyde in PBS, the cochlear and vestibular hair cells in the temporal bones were labeled with colorimetric dyes. Then the samples were cleared in a series of fructose solutions with increasing concentrations for the SeeDB protocol, or sucrose and urea solutions for the Sca/e protocol. Samples were viewed using light microscopy and the planar angle between the utricle and saccule measured. Results: Successful clearing of the temporal bone was achieved. The planar angle of the saccule to utricle was 80 ± 6 degrees. No difference was found between left and right or male and female temporal bones. Conclusion: Our modified version of the SeeDB and Sca/e protocols were suitable for clearing temporal bones for further downstream applications.

Title: Cilia genes play differing roles in aminoglycoside-induced hair cell death

Authors: T. STAWICKI[1], E. W. RUBEL[2], *D. W. RAIBLE[3];
[1]Biol. Structure, [2]VMBHRC, Univ. of Washington, Seattle, WA; [3]Box 357420, Seattle, WA

Abstract: Hearing loss as a result of hair cell death is a dose limiting side effect of multiple therapeutic drugs, including aminoglycoside antibiotics and chemotherapeutics. We have used genetic screening in the zebrafish lateral line system to identify novel genes involved in hair cell death and survival in response to these medications. Through screening for mutations that confer resistance to aminoglycoside-induced hair cell death we have identified a number of mutations in cilia genes, showing novel roles for these genes in hair cells. Hair cells contain a single primary cilium early in development, known as the kinocilium. This cilium is usually lost in auditory hair cells but maintained in vestibular hair cells. We found that mutations in the intraflagellar transport (IFT) genes *ift88, traf3ip, dync2h1* and *wdr35* all lead to strong resistance to neomycin-induced hair cell death. Mutations in the transition zone genes *cc2d2a, mks1,* and *cep290* lead to more moderate protection. These two classes of genes appear to play different roles in aminoglycoside-induced hair cell death. Mutations in IFT, but not transition zone genes, show a reduction in control hair cell numbers, loss of kinocilia and a reduction of neomycin uptake into hair cells. The individual IFT genes appear to differently affect hair cells as well, as mutations in *ift88, traf3ip* and *dync2h1,* but not *wdr35* show a reduction in hair cell FM1-43 uptake, a process dependent upon mechanotransduction activity. This does not appear to be due to defects in stereocilia morphology. Future work will focus on delineating the mechanisms behind the diverse roles cilia genes play in hair cells.

Title: Quantifying individual behavioral signatures in larval zebrafish

Authors: *E. A. NAUMANN, J. E. FITZGERALD, T. W. DUNN, F. ENGERT;
Harvard Univ., Cambridge, MA

Abstract: How are individual behavioral differences manifested in underlying neural circuits? In order to study such heterogeneity within a basic vertebrate visuomotor system, we performed a detailed kinematic analysis of behavioral signatures across individual zebrafish swimming in response to monocular and binocular optic flow stimuli. Using a closed-loop assay to control the visual environment precisely while monitoring behavior, we quantified kinematic variability across individual fish. While each fish effectively modulates its behavior to eye and direction-specific features of visual motion stimuli, we find that the fine details of the behavioral implementation vary substantially across individuals. Specifically, the absolute and relative frequencies of behavioral events create individual behavioral profile differences that covary across stimuli. We hypothesize that these differences are necessarily embedded within the heterogeneous activity of neurons in the pretectum and hindbrain thought to control the optomotor response. This study of behavior across individuals is crucial for our understanding of functional degeneracy within neural circuits and suggests limitations for standard models fit on average data.

Title: Mismatch receptive-fields in mouse visual cortex

Authors: *P. ZMARZ, G. B. KELLER;
Neurobio., Freidrich Miescher Inst., Basel, Switzerland

Abstract: In primary visual cortex, a subset of neurons responds when a particular stimulus is encountered in a certain location in visual space. This activity can be modeled using a visual receptive field. In addition to visually driven activity, there are neurons in visual cortex that integrate visual and motor-related input to signal a mismatch between actual and predicted visual feedback. Here we show that these mismatch neurons have receptive-fields that signal a local mismatch between actual and predicted visual flow in restricted regions of visual space. These mismatch receptive-fields are aligned to the retinotopic map of visual cortex and are similar in size to visual receptive-fields. Thus, neurons with mismatch receptive fields signal local deviations of actual visual flow from visual flow predicted based on self-motion and could therefore underlie the detection of objects moving relative to the visual flow caused by self-motion.

Title: An optogenetics-based approach to determine functional connectivity in the central brain of *Drosophila*

Authors: *P. T. WEIR, M. H. DICKINSON;
Caltech, Pasadena, CA

Abstract: At peripheral layers of the nervous system, mapping information flow from primary afferents to downstream neurons has been widely successful. Neuroanatomical methods enable tracing topographically organized circuits, and electrophysiology permits tracking the transformation of neuronal responses to external stimuli. In central brain regions, however, these approaches are more difficult to implement and interpret. To examine functional connectivity in a central brain circuit of the fruit fly, *Drosophila melanogaster*, we engineered flies that express the genetically encoded calcium indicator GCaMP6s in all neurons and contain the light-gated

ion channel Chrimson under UAS control. By crossing these flies to flies from various GAL4 driver lines, we can drive expression of Chrimson in genetically defined populations of neurons. In the adult progeny of such crosses, we activated the Chrimson-expressing cells with orange light while imaging activity throughout the brain, and observed light-elicited post-synaptic responses. This activity represents a map of information flow from the cell type of interest to downstream targets. By testing numerous cells types in the central complex, we are beginning to construct a connectivity diagram for circuits far from the periphery.

Title: Action-effect contingency modulates readiness potentials

Authors: *T. VERCILLO[1], S. O'NEIL[2], F. JIANG[1];
[1]Psychology, [2]Ctr. for Integrative Neurosci., Univ. of Nevada, Reno, Reno, NV

Abstract: The temporal window between a voluntary movement and a sensory event is crucial for determining the causal relationship between action and perception. When a delay between a voluntary action and its sensory effect occurs this temporal window is compressed and the two events are bound together to preserve the sense of causality (Eagleman & Holcombe, 2002; Engbert, Wohlschlager & Haggard, 2008; Haggard et al., 2002; Sugano, Keetels & Vroomen, 2010). According to the theory of motor control, the intentional binding effect is linked to internal forward models that are based on the motor efferent copy and predict the outcome of self-produced movements (Wolpert & Ghahramani, 2000; Haggard, 2005; Tsakiris & Haggard, 2003). In support of this idea, it has been shown that the intentional binding only occurs when an action is performed with intent but not when the movement is induced by Transcranial Magnetic Stimulation (TMS). Additionally, the TMS-induced disruption of the pre-supplementary motor area (pre-SMA), a brain region involved in motor preparation and predictive mechanism, was shown to reduce the temporal binding between a voluntary action and a subsequent sensory event

(Moore et al., 2010). However, another alternative explanation for the intentional binding is that the effect might result from retrospective inferences triggered by the sensory event that follows the action (Wegner & Wheatley, 1999). In the current study, we investigated the role of the readiness potentials (Libet et al., 1983) - the pre-motor brain activity registered in SMA and the motor area of the brain - in the intentional binding effect. We recorded EEG data from 128 channels (Biosemi system) and measured the latency and the amplitude of the readiness potentials (RPs) in the Cz channel preceding the onset of the movement in a temporal window of 2 seconds. We compared RPs in an "action-effect" condition where participants performed a motor action that produced a sensory effect 200 ms later, with those measured in an "action only" condition where participants performed the voluntary movement without any sensory feedback. Our results showed different RP patterns between the two experimental conditions. The action-effect contingency significantly modulated RPs near motor areas and these modulatory effects are evident from 500 to 100 ms before the onset of the movements. Our results suggest that predictive motor processes within the motor system contribute to the intentional binding effect.

Title: Functional properties of mirror neurons of the monkey presupplementary motor area f6

Authors: A. LIVI[1], M. LANZILOTTO[1], *M. MARANESI[2], M. GERBELLA[1], L. FOGASSI[1], G. RIZZOLATTI[1], L. BONINI[3];
[1]Dept. of Neurosci., Univ. of Parma, Parma, Italy; [2]Dept. di Neuroscienze, Parma, Italy; [3]Inst. Italiano di Tecnologia (IIT), Parma, Italy

Abstract: Mirror neurons (MNs) are a class of cells originally discovered in the ventral premotor cortex of the macaque that discharge both during the execution and the observation of goal-directed motor acts, such as grasping. Recently, neurons with mirror-like properties have been described in a wide network of anatomically connected areas, including the pre-supplementary

motor area F6, where they seem to play a role in the distinction between self- and other's action. However, an extensive description of F6 MNs functional properties is still lacking.
Here we recorded single neurons activity from area F6 in three hemispheres of two monkeys during two main experimental conditions: the execution of a visuomotor task (ET) and the observation of the same task performed by an experimenter (OT). The OT was carried out in two different modes: 1) within the monkey peripersonal space, in which the monkey observed the experimenter's action presented in a subjective view (OTp); 2) in the monkey extrapersonal space, in which the monkey observed the experimenter's action from a side view (OTe). An additional control condition with a non-biological moving stimulus (NBM) was employed in order to verify the specificity of possible action observation responses in the OTe.
We recorded 359 neurons. Among them, 67 responded during action observation in the OTe, and the great majority of this subset of neurons (75%) also showed a motor response during the ET. Moreover, 46 of the 67 neurons discharging during OTe showed a marked specificity for grasping observation relative to the NBM: interestingly, 36 of them were not at all activated by the NBM. During the OTp 113 neurons showed a significant response to action observation and 39 of them discharged also during action observation in the OTe. This finding evidences a certain degree of view- and space-invariant coding of the observed action in area F6.
The results of this study support the idea that area F6 plays an important role in the action execution-observation network, and provides an additional source of information to the "core" MN areas in the parieto-frontal cortex.

Title: MEG shows a progressive sensory-to-motor transformation for reaching in cortical space and time

Authors: *G. BLOHM[1], H. ALIKHANIAN[2], W. C. GAETZ[3], H. C. GOLTZ[4], J. F. X. DESOUZA[5], D. O. CHEYNE[6], J. D. CRAWFORD[5];
[1]Ctr. for Neurosci. Studies, [2]Queen's Univ., Kingston, ON, Canada; [3]Children's Hosp. of Philadelphia, Philadelphia, PA; [4]Univ. of Toronto, Toronto, ON, Canada; [5]York Univ., Toronto, ON, Canada; [6]Hosp. for Sick Children, Toronto, ON, Canada

Abstract: Planning an accurate reaching or pointing movement towards a visual target requires a complex sensory-to-motor transformation. This includes converting an early sensory code of the target into a shoulder-centered motor plan. Despite much recent progress, it still remains unclear where, how and when this transformation is carried out in the human brain. In particular, it is unclear whether these transformations occur in a feed-forward fashion between brain areas, predicting a gradual sensory-to-motor transformation across different brain areas in the processing hierarchy; or if these transformations occur dynamically in localized regions, predicting a dynamic change from sensory to motor coding within the same brain area(s) during the task. We use high spatio-temporal resolution magnetoencephalography (MEG) in an attempt to uncover (1) which brain areas are involved in transforming visual signals into appropriate motor commands for the arm, and (2) how this transformation occurs on a millisecond time scale. Ten human subjects sat upright in the MEG apparatus and were asked to perform delayed (1500ms delay) visually-guided pointing movements towards (pro) or away from (anti) visual targets on a fronto-parallel screen. Pro- and anti-trials required opposite motor output following identical visual stimulation, which allowed distinction between the sensory goal and motor plan. A beamformer-based spatial filtering algorithm (event-related Synthetic Aperture Magnetometry) was employed to reconstruct brain activity from the MEG recordings. Using adaptive hierarchical clustering (Alikhanian, et al., 2013), we identified 16 bilateral brain regions consistently active across all 10 participants during the task. Time-frequency response analysis was employed to find significant sensory or motor coding in different frequency bands. We also computed a sensory-motor index based on alpha and beta band powers of sensory and motor coding. Together, both analyses showed brain areas purely coding sensory information in alpha and beta bands (V1/2, V3/3a and SPL). On the other end of the spectrum, PMv only showed motor coding. Interestingly, most areas displayed a progressive transition between sensory and motor coding (SPOC, AG, POJ, mIPS, VIP, IPL, STS, S1, M1, SMA, PMd and FEF) during the delay period. This demonstrates that sensory-to-motor transformations are neither carried out in a purely feed-forward fashion, nor with a single isolated brain area. Rather, our results point towards a gradual transformation in cortical space and time.

Title: Merging visible and invisible light in rat V1 using a cortical prosthetic system

Authors: *E. E. THOMSON, I. ZEA, Y. THENAISIE, F. WENDY, W. WINDHAM, M. NICOLELIS;
Duke Univ., Durham, NC

Abstract: Rats equipped with a sensory prosthetic system that projects information from the infrared (IR) environment to somatosensory cortex (S1) readily learn to discriminate among IR sources, typically invisible to the rat. It takes approximately 4 days for them to learn to perform a simple IR discrimination task. In the present study, we investigate the consequences of projecting IR information directly to primary visual cortex (V1), a sensory area already devoted to processing electromagnetic radiation. Remarkably, when IR information is projected to V1 instead of S1, rats typically learn to discriminate IR sources on their first day of training, normally in fewer than 50 trials. We then examined the brain's ability to integrate the new IR information into its ongoing visual processing in V1. Namely, in a visual-IR integration task we presented multiple visual and IR lights simultaneously, and the animal was rewarded only for selecting those target stimuli that combined both visible and IR lights, and had to learn to ignore distractor stimuli in which only IR or only visible cues were present. Their ability to successfully perform this multimodal integration task suggests that the information from the IR prosthesis is integrated into ongoing V1 operation, rather than simply displacing or hijacking normal visual system function. This is also supported by separate experiments in which the IR prosthesis was implanted in S1, and the animals' ability to perform whisker-based tactile discriminate tasks was unimpaired.

Title: Don't look: Cerebellar and cortical activity during an antisaccade task in adolescents with FASD

Authors: *A. D. BOLANOS[1], B. A. COFFMAN[3], P. KODITUWAKKU[2], J. M. STEPHEN[3]; [1]Neurosci., [2]Pediatrics Ctr. for Develop., Univ. of New Mexico, Albuquerque, NM; [3]Neurosci., The Mind Res. Network, Albuquerque, NM

Abstract: Individuals prenatally exposed to alcohol may develop fetal alcohol spectrum disorder (FASD), which is characterized by a broad range of cognitive and behavioral deficits along with functional and structural neural anomalies. Previous studies suggest that basic sensory deficits in individuals with FASD may contribute to deficits in sensorimotor integration. Results also show atypical development of parietal and frontal cortical networks in individuals with FASD. Both cerebellar and cortical areas comprise the eye gaze network. Animal studies have demonstrated that prenatal alcohol exposure leads to cerebellar hypoplasia and human studies of children with FASD show reduced brain volume, particularly in cerebellar regions. The current study investigated the neurophysiology of the eye gaze network during an antisaccade task in adolescents with FASD compared to age-matched healthy controls (HC) using the Elekta Neuromag 306 channel magnetoencephalography (MEG). We hypothesized a difference in cerebellar, parietal, or frontal evoked response amplitude between the FASD group and HC group during antisaccades. The antisaccade task requires a saccade to the opposite visual hemifield relative to a suddenly appearing target stimulus. Eye movement was recorded and synchronized to the MEG data using an SR Research MEG-compatible eye tracker. MEG data were filtered and head movement compensation was implemented using Maxfilter. The MEG data were analyzed relative to the onset of the target. Source modeling through spatio-temporal multidipole analysis was performed on the averaged evoked response to target stimuli for correct trials. Individuals with FASD showed a significant increase in peak amplitude 104ms after target stimulus presentation in the cerebellum compared to HC. Individuals with FASD also showed a

significant increase in peak amplitude 116ms after stimulus presentation in the inferior parietal lobule compared to HC. However, behavioral performance did not differ by group. These findings suggest that individuals with FASD exhibit greater activity within the cerebellum and parietal cortex during performance of antisaccades, which may suggest increased effort. Further investigation is needed to understand the role of cerebellum in the eye gaze network to elucidate sensorimotor integration deficits in children with FASD. Title: Natural saccadic eye movements of the awake, running mouse

Authors: *J. M. SAMONDS, N. J. PRIEBE;
Univ. of Texas At Austin, Austin, TX

Abstract: Few studies have characterized the saccadic eye movements of mice despite the increasing use of the mouse as a model to study the visual system. Most eye movements for afoveate animals stabilize gaze during head movements and the lack of a fovea raises the question as to why mice make saccades. We measured saccadic eye movements in head-fixed mice running on a track ball while they were free-viewing natural images presented in front of them. Saccades were highly correlated between the eyes ($r > 0.9$). This correlation was reduced partly because the eyes tended to diverge slightly during fixations. We found that mice tend to make saccades an order of magnitude less frequently compared to primates (0.1-0.4 saccades/s). During periods of running, however, the saccade rate increased and was more comparable between mice and primates (1-2 saccades/s). Most saccades occur along the horizontal axis, as they do in other mammals (Otero-Millan et al., 2013). Saccade sizes were an order of magnitude larger in the mouse compared to primates, ranging from 5 to 30 degrees of visual angle. Both the rate and size of saccades increased as we increased the size of natural images. This range of saccade sizes largely overlaps with the known range of receptive field sizes in the primary visual cortex (V1) of mice (Niell and Stryker, 2008; Bonin et al., 2011). Such large saccadic eye

movements could act to introduce novel and independent visual information to V1 receptive fields. When we silenced the binocular visual fields in V1 by activating parvalbumin-expressing inhibitory neurons optically, we found that mice both ran and made saccades significantly less frequently. Overall, we propose that mice use horizontal saccades to scan across scenes that are correlated along the axis of running direction (e.g., along a wall) to decorrelate incoming visual information to maximize cortical information processing. Title: Eye movements affect the coupling between visual information and body sway of young adults

Authors: *P. F. POLASTRI ZAGO[1], M. B. BRITO[1], F. A. BARBIERI[1], R. L. MORAES[1], D. N. LIMA[1], B. C. CAVALIERI[1], J. A. BARELA[2], S. T. RODRIGUES[1];
[1]Dept. of Physical Educ., Univ. Estadual Paulista - UNESP/Campus Bauru, Bauru, Brazil; [2]Dept. of Physical Educ., Cruzeiro do Sul Univ., São Paulo, Brazil

Abstract: Gaze behavior appears to be associated with changes in stability. However, little is known about the effects of visual mechanisms in the postural control. The aim of the study was to investigate the effect of eye movements on the coupling between visual information and body sway in young adults. Thirteen young adults (20.3 ± 1.8 years) stood in a quiet upright stance on a force platform, inside of a “moving room”, using an eye tracker device for sixteen trials of 60 seconds. The room was stationary in the first eight trials. In the following eight trials the room

was oscillated backward and forward at 0.2 Hz with amplitude of 0.65 cm. The participants remained looking forward and performed four visual tasks: free-gaze with absent target (AT); gaze directed to stationary target (ST); and moving target with certain (CT) and uncertain (UT) locations. The target was a filled circle with 3 cm of diameter displayed in the room's frontal wall. In the latter two conditions, the task required horizontal saccadic eye movements towards the target moved to right or left at 1.1 Hz. Target eccentricity was 11.5 degrees of visual angle. Dependent variables were: mean latency between horizontal saccades and visual target, number and duration of fixations, mean sway amplitude at anterior posterior (AP) direction, gain and phase between room's movement and body sway. Results showed lower number of fixations and higher fixation duration at ST task and higher number of fixations and lower fixation duration at CT compared with UT task. Only for the stationary moving room, negative mean latency revealed saccadic anticipation to the target at CT compared to UT task. Mean sway amplitude (AP) was higher during the room's movement compared with stationary room. Phase values were similar and close to zero across conditions; gain values were higher at AT task compared with UT one. These novel results suggest that gaze control changes the coupling between visual information and body sway of young adults and this effect seems dependent on the visual task challenge.

Title: Characterizing the dynamic neural transition from sensory input to motor output - an EEG/fMRI study

Authors: ***T. T. NGUYEN**[1], T. POTTER[1], R. G. GROSSMAN[2], C. KARMONIK[2], Y. ZHANG[1];
[1]Biomed. Engin., Univ. of Houston, Houston, TX; [2]Houston Methodist Hosp. Neurolog. Inst., Houston, TX

Abstract: Brain regions associated with visual perception and motor execution have been extensively studied. However, dynamic interactions of the regions associated with the perception and processing of stimuli and the generation of willed motor responses remain poorly known. We present a multimodal neuroimaging approach to characterize neural dynamics during the transition from sensory input to willed motor output using electroencephalography (EEG) and concurrent functional magnetic resonance imaging (fMRI) recording. EEG and fMRI data were collected from three right-handed healthy participants while viewing the serial presentation of unpleasant and pleasant faces presented in random order. The subjects were instructed to squeeze their right hand if a face was perceived as emotionally unpleasant. Structural MRI was acquired for constructing subject-specific head models and defining the source spaces to perform EEG source imaging. FMRI BOLD signal activation maps revealed multiple brain regions activated by unpleasant face stimuli and willed movement of the right hand, including the bilateral visual cortices and fusiform face areas, left motor cortex and supplementary motor area, bilateral insula and posterior cingulate cortex. Activated regions of interest (ROI) were used as fMRI spatial priors to guide EEG source imaging, yielding a time-course of current density for each ROI. The sequence of time courses of current density of ROIs following the presentation of a face perceived as unpleasant was of early activation of the bilateral visual cortices followed by activation of the cingulate cortex and insula followed by left supplementary motor area and of brief left motor cortex activation followed by prolonged activation of the left motor cortex that was concurrent with the willed movement of the right hand. The findings provide information on the neural dynamics during the transition between sensory input and motor output during the generation of willed movement evoked by stimuli that evoke emotion and demonstrate the capability of EEG/fMRI multimodal imaging to examine neural activity with high spatiotemporal resolution.

Title: Beta frequency coherence between PPC and PFC local field potentials in monkeys performing a memory guided saccade task

Authors: *R. J. GERTH[1,3], N. HALL[2,3], C. OLSON[3], C. COLBY[2,3];
[1]Bioengineering, [2]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [3]Ctr. for Neural Basis of Cognition, Pittsburgh, PA

Abstract: The dorsolateral prefrontal cortex (PFC) and the posterior parietal cortex (PPC) of the macaque monkey are linked to each other by dense reciprocal axonal projections. Both areas contain neurons that exhibit spatially selective cue-period, delay-period and saccade-period activity during performance of a memory guided saccade task. How interconnections between the two areas contribute to their function is not yet well understood. To explore this issue, we have analyzed the coherence of local field potential (LFP) signals monitored simultaneously in PFC and PPC during performance of a memory guided saccade task. During each experimental session, we recorded with an eight-channel linear electrode array in each area. This approach permitted comparing signals recorded from multiple pairs of sites within a single session. However, it prevented systematic placement of the saccade target relative to the response field, because neurons at different sites had different patterns of spatial selectivity. We presented targets at two widely separated contralateral sites during each session and characterized spatial selectivity at each site post hoc on the basis of differential neuronal responses on trials involving the two targets.
We analyzed coherence of LFPs recorded at pairs of sites, one in PFC and the other in PPC. We focused on oscillations in the beta range (12-25 Hz). The degree of coherence depended on time during the trial and also on whether the target was at the preferred or non-preferred location. During the visual epoch, there was a decrease in coherence. In the delay epoch there was an increase in coherence. In the peri-saccadic epoch, coherence again decreased. Each effect was most pronounced during trials in which the target was at the preferred location.

Title: Descending control of landing in *Drosophila* is gated by behavioral state

Authors: *J. M. ACHE, S. NAMIKI, A. LEE, K. BRANSON, G. M. CARD;
HHMI/Janelia Res. Campus, Ashburn, VA

Abstract: *Drosophila* have a numerically small nervous system but are nonetheless able to perform a plethora of sophisticated behaviors in different contexts. For example, they eat, mate, escape, fly, and land when appropriate. In many cases, two completely different actions can be elicited by the same stimulus, depending on context. For example, a dark looming object on the fly's retina can elicit an escape takeoff in a walking fly, or a landing response in a flying fly. Furthermore, most behaviors are driven by a population of only about 300 descending interneurons (DNs), which connect the brain to motor areas of the ventral nerve cord. Controlling a large number of behaviors with such a small number of DNs is a challenging task, which vertebrates face as well. Using electrophysiology, optogenetics, and computer vision strategies, we show how a small population of descending neurons controls one of the most important behaviors in a fly's life - landing.

Through an extensive optogenetic activation screen, we discovered only two bilateral pairs of DNs whose activation drives simultaneous extension of all six legs. These leg extensions mimic those observed during the 'landing response', which flying flies perform when confronted with an approaching object. We recorded the activity of all four landing DNs via whole-cell patch-clamp in awake, behaving flies, while tracking leg movements using computer vision algorithms. We found that both DN types were multimodal, responding to visual and mechanosensory stimuli. Activity in landing DNs preceded leg movements, and the firing rate of the neurons was positively correlated with leg displacement magnitude. This indicates that landing DNs are not simple command neurons, which elicit a pre-programmed movement sequence in an all-or-none manner, but instead control leg motion using a rate code. Surprisingly, visual responses were sharply reduced in one landing DN type and completely eliminated in the other when the fly was not flying. Further investigation revealed that this flight-dependence of the visual response is mediated by the known flight-related neuromodulator, octopamine, in only one of the DN types, but by a different, likely internal circuit mechanism in the other.

These results suggest that the *Drosophila* nervous system ensures the landing motor pattern does not interfere with other behaviors, like walking or takeoff, by switching off the landing DNs when the fly is not flying. Such behavioral gating of DNs, in which individual neurons are switched on or off depending on the animal's behavioral state, may be a simple, general mechanism for action-selection and descending motor control.

Title: Altered balance between top-down and bottom-up saccadic control across exploration and exploitation

Authors: *B. A. EBITZ[1], T. MOORE[3], T. BUSCHMAN[2];
[2]Princeton Neurosci. Inst., [1]Princeton Univ., Princeton, NJ; [3]Neurobio. Dept. & HHMI, Stanford Univ., Stanford, CA

Abstract: We are constantly bombarded by numerous visual stimuli, any of which could be targeted by saccadic eye movements. Some stimuli will be targeted because of top-down information (e.g. it matches a searched-for-template or is known to be rewarding). Other stimuli attract gaze in a bottom-up manner: they are visually salient due to contrast or brightness. Critically, little is known about how we combine top-down and bottom-up influences into unified eye movement decisions, much less about how we adjust the balance between these influences in different environments or to achieve different goals. In order to begin to understand these questions, we characterized how the balance between top-down and bottom-up attentional priorities changes across different decision-making regimes. In variable and uncertain environments, periods of sampling options known to be rewarding ("exploit" states) are interspersed with periods of sampling alternative, uncertain options in order to learn about the environment ("explore" states). Emerging electrophysiological and psychophysical work suggests that exploration is an indeterminate state in which choices are random. However, we find that saccadic selection is not truly random during exploration. Instead, it is influenced by bottom-up factors: task-irrelevant, visually salient stimulus features have a greater impact on gaze during periods of exploration. This shift from top-down to bottom-up control may be a computationally efficient way to allow for the discovery of novel rewards, overcoming the strong pull of reward history on gaze. It remains unclear whether exploration is associated with enhanced bottom-up control or, instead, if bottom-up control is permitted through reduced top-down influences. We anticipate that the pattern of saccadic choice and reaction time will disambiguate these possibilities. Ultimately, this work provides a model for future investigations into how top-down and bottom-up attentional priorities are balanced and adjusted, with application to work in both humans and rhesus macaques.

Title: Using the optocollic response to determine visual perception in the homing pigeon (Columba livia).

Authors: ***J. T. ERICHSEN**[1], C. M. DILLINGHAM[2], J. A. BARNES[1], T. MEYDAN[1]; [1]Cardiff Univ., Cardiff, United Kingdom; [2]Inst. of Neurosci., Trinity Col. Dublin, Dublin, Ireland

Abstract: As their eye movements are limited, many birds respond to continuous movement of their visual world by a reflexive oscillation of their heads, analogous to OKN eye movement in primates. To elicit this optocollic response (OCR), we have placed homing pigeons in the centre of a circular arena of high-resolution monitors and then presented drifting vertical gratings while recording their head movements. If the combination of the spatial frequency and contrast of the grating is beyond their visual capabilities, the reflexive movements cease, allowing us to establish what the animals can and cannot see. The results thus far have successfully replicated a previously published spatial contrast sensitivity curve obtained by more invasive electrophysiological methods. However, our initial study of 3 males and 3 female birds suggests that the males have a much higher sensitivity to contrast at low spatial frequencies. Such a sex difference has not been found in humans, and the reason for such a dimorphism is not clear.
In addition to defining the limits of spatial vision, this psychophysical approach can permit an investigation of the effect of stimulus velocity on the OCR. We employed two paradigms in this experiment: (1) presentation of a continuously moving drifting pattern whose velocity is increased by a constant step, and (2) presenting the same velocities in a randomized order with a static pattern in between. The results from experiment 1 show that, if the step is 10^{o}/s, the OCR continues up to very high velocities (e.g. 70^{o}/s), whereas in experiment 2, OCR only became evident quickly for velocities lower than 20^{o}/s. The presentation of a higher velocity drifting pattern only elicited OCR after a prolonged “warm up” period, which became longer the higher the step change in velocity. In humans, such a delay in the development of OKN is normally only observed in young infants. These data suggest that the pigeons are only able to stabilise their view quickly when the movement of the visual world produces a retinal image shift that is

relatively slow.
This approach is clearly applicable to exploring the visual performance of any animal in which gaze stabilization is achieved by head rather than eye movements.

Title: Marmoset viewing preferences for social stimuli

Authors: J. HYMAN[1], *R. LANDMAN[2], J. SHARMA[1], R. DESIMONE[1], G. FENG[2];
[1]MIT, Cambridge, MA; [2]MIT, Broad Inst., Cambridge, MA

Abstract: Eye tracking has been used for many years in humans to investigate looking patterns, especially with respect to socially salient stimuli. Eye tracking is especially advantageous because it can be used with individuals who cannot follow verbal instructions, such as infants, and is non-invasive. More recently, eye tracking has been used to investigate reliable differences between autistic and typically developing children. Differences are found in preferential looking at faces vs bodies, eyes vs mouth, biological vs non-biological motion and gaze following in response to another individual's cues. For future development of a transgenic primate model of genetic variations associated with autism, it is important to know the extent to which wild-type primate behavior is comparable to human behavior. In non-human primates, eye tracking is typically done in head-fixed animals implanted with a head holder. Here we demonstrate preferential looking patterns using head-free eye tracking in a common marmoset (*Callithrix jacchus*). Marmosets were habituated to a small transport cage with a view port for looking at a computer screen. A small video shown at various locations on the screen was used for calibration. After calibration, a variety of stimuli were shown to investigate animals' preference for images of humans, marmosets and other animals in various forms and over multiple sessions. In support of previous studies, we find marmosets prefer to look at animals rather than objects and faces rather than the rest of the body. In addition, there is preference for upright faces over inverted faces. Within faces, we find a preference for looking at eyes, followed by mouth and other features. These results suggest that looking preferences in marmosets are similar to humans

in certain respects that are relevant to autism. The absence of lengthy animal training requirements and the head-free preparation make it relatively easy to test a larger number of animals, which is useful for comparing between groups.

Title: Internal models hold the key to prey fixation in dragonflies: evidence from a perturbative study

Authors: *M. MISCHIATI, A. LEONARDO;
Howard Hughes Med. Inst. Janelia Farm Res. Campus, Ashburn, VA

Abstract: While maneuvering to intercept prey, dragonflies continuously rotate their head to hold the prey at a fixed position on the eye. These head rotations counteract movement of the prey-image from both self-motion and prey-motion, and do so with zero delay when the prey moves at constant velocity. Such predictive control cannot result from visual reflexes, but requires forward and inverse models of the body and internal estimates or memory of prey motion.
A crucial implication of these observations is that much of head steering during interception flights is internally driven and non-visual in nature. To investigate this, we induced interception flights to computer-controlled artificial prey that were temporarily hidden from view. We used a suspended tunnel to occlude part of the prey trajectory, and positioned the dragonflies in specific perching conditions that reproduced the period of prey occlusion across flights.
When the tunnel was placed so to hide ~20% of the prey trajectory after takeoff, the dragonflies continued chasing their prey without hesitation. The accuracy of prey fixation on the eye when the prey was occluded was comparable to when it was visible. In both conditions, head rotations counteracted the body rotations that would have caused prey-image drift on the eye. Continuous visual feedback from prey motion is thus not necessary for target fixation during pursuit of constant speed prey, and internal models alone can drive the behavior.
During flight, prey-image drift from self-motion is substantially larger than that from prey-

motion, making it hard to evaluate if both are counteracted by the head during prey occlusion. We thus also analyzed prey fixation during the preparatory head movements the dragonfly makes before takeoff. In this regime there is no self-motion and we could unequivocally assess whether head rotations counteracted expected prey movement during periods of occlusion. We found no qualitative difference in prey fixation during periods of prey occlusion versus visibility, demonstrating that head movements are driven by an internal representation of the prey's speed that persists without vision for at least 70 ms.
These results highlight the salience of internal models in the prey fixation behavior of dragonflies, and establish a novel paradigm for investigating the neural implementation of these computations in an insect.

Title: Unimanual versus bimanual arm cycling movements - muscle activity variances.

Authors: M. MRAVCSIK[1], N. ZENTAI[1], L. BOTZHEIM[2], *J. LACZKO[1,3,2];
[1]Univ. of Pecs, Pecs, Hungary; [2]Information Technol. and Bionics, Pazmany Peter Catholic Univ., Budapest, Hungary; [3]Laboaratory of Rehabil. Technol., MTA Wigner Res. Ctr. for Physics, Budapest, Hungary

Abstract: Arm cycling movements were performed on a cycle ergometer (MEYRA, Kalletal Germany) by 19 right handed, able bodied individuals. They cycled in various crank resistance conditions (RCs) unimanually and bimanually. In our earlier study, it was found that crank resistance didn't have a significant effect on joint angle variances. Considering variances at muscle level, when cycling was performed unimanually by the right arm for a short time (10 cycles), the crank resistance didn't have a significant effect on variances (across participants and cycles) of muscle activity patterns. This study has now been extended for longer movement time (30 cycles per participants and cycling conditions). Fatigue was not a factor as the movement time was still short. It was hypothesized that 1. The crank resistance doesn't have a significant effect on variances of arm muscle activities when cycling either bimanually or unimanually. 2. There is no significant difference in variances of muscle activity patterns comparing unimanual and bimanual cycling regarding either the left or the right arm. Methods: Participants cycled with a cadence of 60 revolutions per minute. Surface EMGs were recorded from the right and left

arm's biceps, triceps, delta anterior, delta posterior. Variances (across cycles) of muscle activities (mean EMG amplitudes) were computed for each participant. Mean muscle activity variances were compared for cycling with low RC (1.16Nm) versus high RC (3.09Nm). Cycling was performed bimanually and also unimanually with the left and with the right arm. Variances obtained in low and high RCs were compared for each arm, for unimanual and bimanual cycling separately and variances obtained in unimanual versus bimanual cycling were compared for the two arms and for both RCs separately by student's t test ($p=0.05$). Results: 1.There was significant effect ($p<0.01$) of RCs on muscle activity variances both in uni- and in bimanual cycling. The variance was significantly higher during cycling against larger resistance.This was found for the right and left arm too. 2. There were significant differences in the variances comparing uni- and bimanual cycling. The variance was significantly higher when cycling was performed unimanually compared to the bimanual case ($p<0.01$). This holds in each RC, for the left and the right arm. Conclusion: These results present quantitatively that motor control of arm cycling, at muscle level, is more stable when cycling is performed against lower resistance and when cycling is executed by two arms instead of one. Opposing our expectations, the central control may not be so stable when crank resistance is increased or when arm cycling is performed by one arm.

Abstract: How is bimanually coordinated behavior represented in the central nervous system? Rodents have been used to understand the neural mechanism of motor control by fully taking advantage of the combination of electrophysiology and genetic tools such as optogenetics and DREADDs (Designer Receptors Exclusively Activated by Designer Drugs). Although there are the potential advantages of use of rodents, the animal has not been employed to study bimanual coordination because of limited behavioral measures of bimanual coordination. Here, we

demonstrate a novel behavioral measurement of rats' bimanual coordination under a head-fixed behavioral system. In the task, rats were trained to be head-fixed and allowed to retrieve donut-shaped sausages. Rats' bimanual eating behavior was recorded with two high-speed cameras at 200 fps. Three dimensional coordinates of their paws were reconstructed with Matlab thereby detailed kinematic analysis of paw movements became possible. Rats showed a variety of bimanual movements such as rotations, adjustments and strokes of the food. We demonstrate a cross-correlation based analysis to classify those bimanual behaviors into asymmetric and symmetric bimanual movements. We propose potential usage of the behavioral framework in the future.

Title: Characterizing de novo learning of a feedback control policy using a novel bimanual reaching task

Authors: *J. PAKPOOR[1], A. M. HAITH[2];
[1]Neurol., Johns Hopkins Univ., Baltimore, MD; [2]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: A central question in motor skill learning is how we acquire the ability to continuously control novel tools, such as riding a bike or playing a video game. Such skills require learning of a new feedback control policy relating sensory states to actions. Determining how new feedback control policies are acquired is complicated by the relationship between the new controller to be learned, and pre-existing controllers. In some cases, the new control policy to be learned might be similar enough to existing controllers that these can simply be recalibrated and repurposed (e.g. reaching with a 30° rotated cursor), with no need to create a brand new policy (Telgen et al., 2014, J Neurosci 34(41):13768-79). In other cases, existing controllers might directly conflict with the new controller to be learned (e.g. reaching with a mirror-reversed cursor), in which case existing control policies may interfere with learning and/or the expression of the new one. In the presence of such conflicts, it is impossible to determine whether the difficulty in performing a new task is due to an inability to learn a new feedback control policy,

or an inability to suppress a prepotent existing one.
We devised a novel bimanual cursor-control task which avoids these confounds, allowing us to unambiguously track de novo learning of a feedback control policy. In a planar bimanual reaching task, we mapped arm locations to cursor locations in such a way as to ensure that the new actions required would be orthogonal to those required at baseline; the x-location of the cursor was determined by the y-location of the left hand, and the y-location of the cursor was determined by the x-location of the right hand. Consequently, the new control policy to be learned was orthogonal to that used at baseline.
Participants found this task extremely challenging at first, but were able to gain fluid control over the cursor after practicing for four consecutive days. Path length and reaction time reduced steadily with practice, while peak velocity increased. To specifically examine feedback control, we occasionally displaced the target during movement. Early in learning, participants showed little or no systematic response to this perturbation, but with practice developed a rapid and robust feedback response. After ~4 hours of practice, participants' performance was similar to that for veridical, unimanual control, with the exception that latency of responses for the newly learned skill was 50-100 ms longer than in the unimanual condition. Thus, in the absence of interference from existing controllers, a few hours of practice is sufficient to establish a new feedback control policy.

Title: The role of handedness in a multi frequency bimanual coordination task

Authors: *S. PANZER[1], M. MASSING[1], D. KENNEDY[2], C. H. SHEA[2];
[1]Saarland Univ., Saarbrücken, Germany; [2]Texas A&M Univ., College Station, TX

Abstract: Handedness is related to asymmetries in the functions of the neural structure and appears on the behavioral level on asymmetries in the manual performance. But until now the role of handedness in bimanual coordination tasks is not completely understood. Kennedy and colleagues (2015) were interested if limb dominance is associated with interference that occurred in the contralateral limb in a bimanual isometric coordination task. They showed that in dominant right handers interference in a 1:2 or 2:1 bimanual task occurred in the limb which had to produce half of the force compared to the contralateral limb, independent of the dominant

limb. The present experiment had three aims: 1st to replicate these findings in a dynamic 1:2 or 2:1 multi frequency task where performers had to move their wrists; 2nd to determine the impact of hand preference in performing the dynamic bimanual task; 3rd to determine the impact when the start position was changed from 0° to 180° or from 180° to 0°. Changing the start position required performers to start each cycle of the movement pattern with homologous muscle activation (0°) or non-homologous pattern (180°). By starting from a non-homologous pattern, the amount of possible distortions (both wrists were in the opposite direction or both limbs moving in the opposite direction) in a cycle increased. Dominant left handers (N=13; LQ = -78.94) and dominant right handers (N=16; LQ = 91.25) (determined by the Oldfield (1971) test) were required to perform a 2:1-0°, a 2:1-180°, an 1:2-0°, or an 1:2-180° (order counterbalanced) coordination pattern using Lissajous feedback (10 practice trials and 3 test trials in each condition; 30 s each). The harmonicity value was calculated to quantify the distortions in the trial-time series. The analysis demonstrated that regardless of handedness, or the different start positions, and regardless of whether the left or right wrist was moving faster, harmonicity was always lower in the slower moving wrist than in the faster moving wrist. As in the Kennedy et al. (2015) experiment, the muscle activation pattern of the faster moving wrist appeared to influence the movements of the slower moving wrist, independent if the performers were dominant left or right handed. The present results extend the previous findings to a dynamical bimanual coordination task. However, it appears that the Lissajous display minimized the effect of the different start positions, and allowed participants to produce relatively stable coordination patterns in each of the conditions. More interesting is the finding that handedness did not result in different performance patterns.

Title: Competing demands of individual movements modulate visual control in bimanual activities

Authors: ***S. D. SARDAR**, S.-H. YEO, R. F. REYNOLDS, J. ALLSOP, T. D. PUNT;
Univ. of Birmingham, Birmingham, United Kingdom

Abstract: The control of bimanual activities is characterised by strong inter-limb coupling, even when the demands of the individual movements involved vary considerably. Such behaviour

creates a clear challenge for how attention is 'divided' based on these 'competing' demands. We measured limb and eye movements in 10 right-handed participants while they made visually-guided pointing movements to small and large targets presented on a touchscreen monitor. Movements were either, 1. unimanual; 2. bimanual congruent (same sized targets); or 3. bimanual incongruent (different sized targets). Target size and hand dominance were expected to contribute to the relative difficulty of the individual movements. While kinematic data of limb movements confirmed strong elements of coupling, asymmetries also emerged. For congruent bimanual movements, while target acquisition was synchronous and there was no directional bias in eye movements, accuracy was reduced for the non-dominant limb. For incongruent bimanual movements, further asymmetries became evident. Movements towards the small target were associated with enhanced accuracy regardless of limb dominance. However, where the small target was acquired by the non-dominant limb, eye movements were biased in this direction and the target was acquired earlier. Data highlight the complex challenges involved in the visual control of bimanual activities. Our task elicited directional biases in eye movements and asynchrony in the terminal phase of movement to optimise control. Hand dominance was critical in modulating these findings.

Title: Bimanual corrective responses are driven by the biomechanics of the upper limbs

Authors: *D. CORDOVA BULENS, F. CREVECOEUR, J.-L. THONNARD, P. LEFÈVRE; Univ. catholique de Louvain, Louvain La Neuve, Belgium

Abstract: Most daily tasks involve bimanual coordination, which in many cases offers redundancy in the way the two limbs can achieve task success. Although previous work highlighted the importance of biomechanics in a broad range of contexts, its impact on bimanual

control has received comparatively little attention. Here, we show that the nervous system considers biomechanical factors to optimally distribute control across limbs during a bimanual force production task as well as when correcting for external disturbances.
The task consisted in producing a 20 N force using both arms towards visual targets representing the resultant force in the horizontal plane. Visual feedback was provided by mapping the sum of forces applied on the fixed robotic interface onto cursor motion in a virtual reality display (KINARM, BKIN Tech.). The force distribution between arms was unconstrained. Eight different directions of force production were tested. In 80% of the trials, the cursor jumped perpendicularly to the target direction after crossing the midline between the start and goal targets (jumps were ±3cm or ±5cm), requiring participants to adjust the resultant force online. We extracted the baseline forces produced by each arm after stabilization at the target force during unperturbed trials. We observed that control was distributed across limbs in a way that was compatible with a bio-inspired optimal control model. In the tested joint configuration, the relative contribution of each arm to the total force was direction dependent. Indeed, the left arm contributed more for targets placed in the 2^{nd} and 4^{th} quadrants and the right arm for targets in the 1^{st} and 3^{rd} quadrants of the horizontal plane.
The results from the perturbed trials showed that the motor correction produced by each arm was dependent on the direction of the perturbation. In particular, the motor corrections were dynamically adjusted in a way that was predicted by the direction-dependent weighting of each arm extracted during stationary holding. The initial adjustments appeared as early as 140ms following the perturbation, and displayed a clear modulation accounted for by the biomechanical constraints. For instance, for a target placed in the midline towards the body of the participant and for a rightward corrective cursor movement, the relative contribution of the left arm increased and that of the right arm decreased compared to the baseline trials. For a leftward corrective movement, we observed the opposite modulation of correcting forces.
These results show that the mechanism that optimally distributes mechanical efforts across limbs takes biomechanics into account in the online compensation of a perturbation.

Title: Bilateral reflexes in shared bimanual task are asymmetric

Authors: *J. SCHAFFER[1], R. L. SAINBURG[1,2];
[1]Kinesiology, The Pennsylvania State Univ., University Park, PA; [2]Neurol., Penn State Col. of Med., Hershey, PA

Abstract: Previous research from our lab has shown that during a bilateral task, in which a single virtual object is carried by both arms, perturbation to the dominant arm produces reflexive responses in the non-dominant arm (Mutha and Sainburg, 2009). However, when the same bilateral motions are performed without a common object, bilateral reflexes responses are absent. In that study, we did not assess dominant arm responses to non-dominant arm perturbations. Given the substantial movement asymmetries between the dominant and non-dominant arms, we now ask whether such bilateral responses are symmetric.
We tested this question using a virtual object (bar) manipulation task in which both arms are required to work together while moving a shared object into a target. At the onset of occasional and unpredictable trials, a solenoid acted as a clutch preventing motion along the medial-lateral axis, which produced errors in motion of the bar. Our preliminary results suggest that reflex responses (EMG responses that occurred < 100 milliseconds following the perturbation) were elicited in the arm that did not receive the perturbation, whether the perturbation occurred on the dominant or non-dominant arm. However, contralateral responses of the non-dominant arm were substantially larger than those of the dominant arm. These findings are consistent with previous research on unimanual movements, suggesting that the non-dominant hemisphere/arm is specialized for feedback responses to unexpected changes in environmental conditions.

Title: A virtual-reality based circle drawing task to assess spatial and temporal characteristics between mirror- and non-mirror-symmetrical upper limb movements

Authors: *P.-C. SHIH[1], C. J. STEELE[1,2], A. VILLRINGER[1,3], B. SEHM[1];

Abstract: Coordinating limbs in a meaningful way is essential for most daily tasks. Previous studies found behavioral differences between two fundamental bimanual movement patterns: moving the limbs in a mirror-symmetrical (MS) pattern was less demanding than a non-mirror-symmetrical (non-MS) pattern (Keslo et al., 1989). A better understanding of the underlying processes might help in the development of bimanual training in patients with motor impairments. Here, we developed a virtual reality(VR) based circle drawing task to assess and compare the kinematic characteristics of MS and non-MS movements. A circle drawing task, involving shoulder and elbow joints, was developed on an upper limb robotic exoskeleton device (KINARM, BKIN Technologies). Ten young right-handed adults performed a total of four bimanual conditions: two non-MS (clockwise and counterclockwise) and two MS (inward and outward) conditions. Participants were instructed to draw consistent circles in synchrony with a 0.85Hz auditory metronome. During performance, the ideal circle (radius=7cm) was displayed. Position data was collected at a rate of 1000 Hz and the spatial and temporal features of movement were compared. First, participants exhibited decreased circularity during non-MS movements compared to MS movements. Furthermore, non-MS movements showed larger deviation distances from the ideal circle, compared to MS movements (Fig1). Second, during the bilateral counterclockwise condition (non-MS), we observed a time lag between hands, with the right hand in the leading position. Taken together, our VR-based circle drawing task is sensitive for differentiating behavioral performance during different bilateral movement patterns. The observed spatial and temporal variations between MS and non-MS conditions might reflect different neural processes involved in interlimb coordination during fundamental bilateral movement patterns. In the future, studies on stroke patients will be conducted to provide knowledge on how stroke changes movement behavior, in order to benefit rehabilitation goal setting.

Title: Inter-limb reaction times depend strongly on the certainty of perturbation direction and modestly on the coordination pattern

Authors: *I. KURTZER, T. FITZGERALD, A. YASIN;
Biomed. Sci., New York Inst. of Technol. Col. of Osteo. Med., Old Westbury, NY

Abstract: Fast bimanual actions are more stable when subjects voluntarily co-activate the same muscles of the two arms versus co-activate different muscles of the two arms. This difference in motor performance partially reflects greater neural connectivity between the same muscles of the two arms versus different muscles. We predicted that differences in motor performance would also be evident for bimanual reactions to a load perturbation, faster co-activation of the same arm muscles compared to co-activation of different arm muscles. 10 healthy individuals (mean age = 25yro, 7M/3F) interacted with a programmable robot (KINARM, BKIN Technologies) which supported both arms in the horizontal plane and allowed flexion and extension of their shoulder and elbow joints. Direct vision of their arms was obscured by a metal partition and no targets or hand feedback was provided. Surface emg (Bortec AMT-8) was obtained from an elbow flexor (EF) and elbow extensor (EE) of each arm. In each trial (240 total) subjects experienced a sudden mechanical load (elbow torque = 2Nm) which could flex or extend their right elbow. Subjects were instructed to resist the perturbation of the right arm and also react with their left arm in a "mirror" or "opposite" manner. Accordingly, bimanual responses could either involve co-activation of the same arm muscles (flex both arms; extend both arms) or co-activation of different arm muscles (flex right arm/extend left arm; extend right arm/flex left). Subjects were encouraged to react as quickly as possible. Lastly, the instruction was always fixed in a block of trials - "mirror" or "opposite" - however, the perturbation direction could either be predictable or randomly alternating. When the perturbation direction was predictable, muscle onset times of the unperturbed left arm were similar for parallel activation (EF = 133 ± 6 ms; EE = 136 ± 7 ms) as reciprocal activation (EF = 127 ± 7 ms; EE = 137 ± 5 ms), $p > 0.5$. Onset times for parallel activation were significantly delayed when the perturbation direction was uncertain (EF = 194 ± 14 ms; EE = 181 ms ± 7 ms), $p < 0.001$. Moreover, the delay induced by directional uncertainty was even greater for reciprocal activation (EF = 215 ms ± 16 ms; EE = 197 ms ± 12 ms), $p < .05$. In sum, inter-limb reactions are equally fast for parallel and reciprocal activation when the perturbation direction is certain, are substantially delayed by uncertainty in perturbation direction, and are more severely delayed for reciprocal than parallel activation.

Title: The consistent nature of interference associated with the activation of homologous and non-homologous muscles

Authors: *D. M. KENNEDY, C. H. SHEA;
Dept. of Hlth. & Kinesiology, Texas A&M Univ., College Station, TX

Abstract: Recent research has indicated the neural crosstalk manifests differently during the coordination of the limbs depending on several factors including the activation of homologous or non-homologous muscles (Kennedy et al. 2014). More specifically, the results indicated a distinct pattern of interference in the forces produced by the left limb that could be associated with the activation of homologous and non-homologous muscle in the right limb during a 1:2 coordination task. The purpose of the current investigation was to determine if the pattern of interference observed in a 1:2 coordination task could be used to predict how and when interference occurred during a 1:3 coordination task and to develop an index to characterize the interference between the limbs. Participants rhythmically produced a pattern of isometric forces in a 1:2 and 1:3 multi-frequency coordination pattern using either homologous (triceps muscles of the left and right limb) or non-homologous (biceps left limb and triceps right limb) muscles. Lissajous displays were provided with a goal template and a cursor indicating the forces produced with both limbs. The template illustrated the specific pattern of force requirements needed to produce the goal coordination pattern (1:2, 1:3). Consistent with the previous investigation, the results for the 1:2 task indicated consistent and identifiable distortions in the left limb forces that could be associated with the forces produced by the right limb with a distinct pattern of interference observed with the activation of homologous and non-homologous muscles. In the homologous muscle conditions, as the right limb increased or decreased force production there were similar unintended increases or decreases in the force produced by the left limb. In the non-homologous conditions, it appears that interference occurs at the point when the right limb was initiating force production, but only while the left limb was releasing force. This interference continued from the point of muscle activation to peak force velocity. A similar pattern of results were observed for the 1:3 task. More importantly, the results indicated that interference between the limbs could be predicted based upon the activation and/or release of force in the right limb and whether homologous or non-homologous muscles were activated. The results were supported by the creation of an index that demonstrated the interference between the limbs.

Title: A single session of acute intermittent hypoxia increases corticospinal excitability in humans

Authors: *L. CHRISTIANSEN[1], M. A. URBIN[1], G. S. MITCHELL[2], M. A. PEREZ[1];
[1]Dept. of Neurolog. Surgery, The Miami Project to Cure Paralysis, Univ. of Miami, Miami, FL;

Abstract: An increasing number of studies support the view that exposure to brief episodes of hypoxic air (acute intermittent hypoxia, AIH) enhances voluntary motor output in humans with and without motor disorders (for review see Gonzalez-Rothi et al., 2015; Verges et al., 2015). The neuronal mechanisms contributing to the AIH aftereffects in humans remain largely unknown. Using non-invasive transcranial magnetic stimulation we examined motor evoked potentials (MEPs, an index of corticospinal excitability) in an intrinsic finger muscle before, immediately after, and up to 75 min after 30 min of exposure to AIH or AIH_{sham} in randomized sessions separated by at least 5 days in control subjects. In the AIH protocol, participants received 15 episodes of 60-second hypoxic air (F_iO_2 =0.09) interspaced with 60-second of normoxic air (F_iO_2 =0.21). In the AIH_{sham} protocol, normoxic air (F_iO_2 =0.21) was applied during all 15 episodes. We found that MEPs size increased by 33.3±4.2% above the baseline immediately after and for up to 75 min in the AIH group ($p<0.001$). Note that oxygen saturation values decreased to 76.5±1.3% during the hypoxic episodes. In contrast, MEP size remained unchanged when subjects received AIH_{sham} at any of the times tested ($p>0.05$), and oxygen saturation remained stable at baseline levels (98.1±0.1%).We provide the first evidence that a

single session of AIH increases transmission in corticospinal projections to finger muscles in humans. AIH effects on the excitability of cortical and subcortical pathways remain to be tested.

Title: Acute intermittent hypoxia enhances synaptic-like plasticity after human spinal cord injury

Authors: *M. URBIN[1], L. CHRISTIANSEN[1], G. S. MITCHELL[2], M. A. PEREZ[1]; [1]Univ. of Miami Sch. of Med., Miami, FL; [2]Ctr. for Resp. Res. and Rehabilitation, Dept. of Physical Therapy and McKnight Brai, Univ. of Florida, Gainesville, FL

Abstract: Exposure to episodes of acute intermittent hypoxia (AIH) enhance voluntary motor output in humans with spinal cord injury (SCI; Trumbower et al., 2012; Hayes et al., 2014). It has been proposed that the beneficial effects of AIH are related to strengthening mechanisms involved in synaptic plasticity (Dale et al., 2014). To test this hypothesis in humans, we combined spike timing-dependent plasticity (STDP), a protocol that likely reflects changes in corticospinal-motoneuron synaptic efficacy, with AIH and AIH_{sham} in a crossover design in individuals with chronic incomplete cervical SCI. During STDP, transcranial magnetic stimulation over the primary motor cortex was used to elicit descending corticospinal volleys, and electrical stimulation of the ulnar nerve was used to elicit antidromic action potentials to depolarize spinal motoneurones. During AIH, participants received 15 episodes of 60-second hypoxic air (F_iO_2 =0.09) interspaced with 60 seconds of normoxic air (F_iO_2 =0.21). In the

AIH_{sham} protocol, normoxic air (F_iO_2 =0.21) was applied during all 15 episodes. Consistent with our previous results (Bunday and Perez, 2012), we found that the size of motor evoked potentials (MEPs) in an intrinsic hand muscle increased by ~20% above baseline for up to 30 min when the STDP protocol was combined with AIH_{sham}. Notably, when the STDP protocol was combined with AIH the size of MEPs increased by ~60% above baseline for up to 30 min. Our findings are the first demonstration that plasticity at corticomotoneuronal synapses is a possible mechanism contributing to AIH aftereffects following human SCI.

Title: Classification of neurons in the motor reticular formation and their changes after a unilateral pyramidal tract lesion in primate

Authors: *B. ZAAIMI, D. S. SOTEROPOULOS, K. M. FISHER, S. N. BAKER; Newcastle Univ., Newcastle Upon Tyne, United Kingdom

Abstract: The reticular formation is the source of the reticulospinal tract, an important descending pathway in primates. We previously reported reticulospinal plasticity after a unilateral pyramidal tract lesion, when reticulospinal input to forearm flexors and intrinsic hand muscles shows a dramatic increase. Here we investigated whether sub-classes could be discerned amongst reticular neurons, and how these changed after corticospinal lesion. We recorded reticular formation neurons in five control and two lesioned monkeys. Two animals were trained to move a cursor to follow a target on screen by performing index finger flexion/extension movements. Four monkeys (including one lesioned) performed a food retrieval task requiring dexterous right hand and finger movements; one lesioned animal did not perform a dexterous hand task. 197 and 110 cells were recorded from five control and two lesioned monkeys respectively. We performed a principal component analysis of the spike width along with other measures derived from the inter-spike intervals (ISI): the mode ISI, the irregularity index (IR),

the peak of the after-hyperpolarization trajectory (AHP) assessed by an interval death-rate analysis, and the burst index. This allowed the identification of three classes of cells in the control monkeys. Cells in cluster 1 were characterized by their slow firing rate (mean mode ISI =38 ± 26 ms, cluster 2: 19 ± 7 ms, cluster 3: 22 ± 17 ms) and a strong modulation with the task. Cluster 2 contained rhythmic cells: 58% had a significant peak in their AHP trajectory. Cluster 3 had narrow spike waveforms (mean width cluster 1= 2.1 ± 1.1 ms; cluster 2= 2.4 ± 1.1 ms; cluster 3= 1.6 ± 0.8 ms), the largest burst index (mean cluster 1= 24 ± 28%; cluster 2= 20 ± 18%; cluster 3= 65 ± 23%), and the most irregular firing pattern (mean IR cluster 1= 0.73 ± 0.34; cluster 2= 0.47 ± 0.15; cluster 3= 1.09 ± 0.25). In the animal one year after a corticospinal lesion, changes in the spiking patterns of the three clusters could be observed relative to the unlesioned controls. Both the baseline firing rate and the bursting index of cluster 1 doubled. The proportion of rhythmic cells in cluster 2 reduced by 34%. Cells in cluster 3 increased their burst index and their baseline firing rate. These changes could reflect altered cortical input to the reticular formation and the increased importance of reticulospinal output for hand control after recovery, which may have produced modifications in the intrinsic properties of the cells.

Title: Rapid plasticity in human motor cortex following temporary digit fusion

Authors: *M. GARDNER, M. M. GANNON, S. M. LONG, N. A. PARKS;
Psychological Sci., Univ. of Arkansas, Fayetteville, AR

Abstract: Extensive literature has delineated remarkable effects of long-term neuroplasticity (weeks, months, or years) and topographical reorganization in sensorimotor cortex following amputation, stroke, and practice. However, very little is understood about the occurrence of early rapid functional adaptations in motor cortex representations that may mediate long-term reorganization. We investigated such short-term motor plasticity (minutes to hours) in human motor cortex by using cortical motor event-related potentials (ERPs) in a temporary “digit

fusion" paradigm. The index and middle fingers of the dominant hand were temporarily fused together with an over-the-counter topical skin adhesive. Such artificial syndactyly caused the two fused digits to move together as a single unit with use of the dominant hand. Immediately following digit fusion, we recorded motor ERPs in a simple bimanual motor response task and again approximately 45 minutes later, following a period of motor dexterity practice during which a set of fine motor tasks (Purdue peg board and marble parceling task) were repeatedly performed with the dominant and non-dominant hand. Motor potentials were also recorded in an additional control session in which subjects performed an identical set of tasks but without temporary digit fusion. Preliminary results indicate that, following practice with the fused digits, motor potentials increase in amplitude relative to the control session (or motor potentials evoked by responses given with the non-fused hand). These findings demonstrate the occurrence of rapid early functional adaptations in motor cortex following constrained motor output and are consistent with the occurrence of a mechanism of disinhibition within sensorimotor digit representations in driving such short-term motor plasticity.

Title: Cortical reorganization following peripheral nerve change: a functional connectivity analysis

Authors: ***F. P. FISCHMEISTER**[1], E. MATT[1], A. AMINI[1], R. SCHMIDHAMMER[2], R. BEISTEINER[1];
[1]Med. Univ. of Vienna, Vienna, Austria; [2]Ludwig Boltzmann Inst. for Exptl. and Clin. Traumatology, Vienna, Austria

Abstract: *Introduction:*
Although the flexibility of the cortex to adapt to central nervous system damage is well documented, only few studies report on the cortical reorganization in response to peripheral nerve damage and no data exist concerning functional connectivity changes in primary motor cortex. Following brachial plexus avulsion, connecting the ending of the denervated

musculocutaneous to the phrenic nerve allows regaining elbow flexion. Therefore, the diaphragm motor area has to accomplish a new double function; the independent control of breathing and elbow flexion. However, although associated cortical changes are evident from activation within the diaphragm area (occuring simultaneously with arm area activations), possible network mechanisms accompanying this acquisition are unresolved (Beisteiner et al. 2011).

Methods:

Six right-handed patients (one female, aged 26-47y) with brachial plexus avulsion participated in this study. All were operated within one year before the investigation and only minor biceps innvervations of the injured arm were evident. Functional images were acquired on a 7 Tesla MAGNETOM system (Siemens, Erlangen, Germany) while performing the following tasks: (1) elbow flexion of the injured and (2) healthy arm; (3) forced abdominal respiration. For the estimation of task-based connectivity individual seed regions were derived from single-subject data and use for an ROI-to-ROI analysis. Based on our primary hypothesis individual functional connectivity estimates while performing the different tasks were calculated, specifically connectivity between primary motor arm and diaphragm areas during injured and healthy movements. The resulting estimates were Fisher z-transformed and used for further analysis.

Results:

Task-based functional connectivity exhibited higher connectivity of primary motor arm and diaphragm areas for the injured arm. In all patients movement related connectivity was found to be increased between the injured arm area and the ipsilateral diaphragm area as compared to the corresponding regions in the healthy hemisphere during healthy arm movements.

Conclusion:

Here we provide first evidence of a functional connectivity change in primary motor cortex of a healthy brain in response to a peripheral change. Results indicate the early establishment of intracortical functional connectivity between the denervated and a take-over region which may provide the decisive mechanism to regain arm movement.

Title: Motor imagery of muscle contraction is available to induce long-lasting potentiation in indirect cortico-motoneuronal excitation in a relaxed muscle.

Authors: *S. IRIE[1], T. NAKAJIMA[1], S. SUZUKI[1], R. ARIYASU[1], T. KOMIYAMA[2], Y. OHKI[1];
[1]Dept. Integrative Physiol., Kyorin Univ. Sch. of Medicine,, Tokyo, Japan; [2]Fac. of Educ., Chiba Univ., Chiba, Japan

Abstract: Repetitive combined stimulation (RCS) of pyramidal tract and peripheral nerve can induce long-lasting potentiation (LLP) in indirect cortico-motoneuronal (C-M) excitation, which could be mediated by cervical interneurons (INs) in humans. However, this procedure has a limitation for clinical application, since the LLP could be induced only when the target muscle is voluntarily contracted. Therefore, we investigated if motor imagery (MI), which is known to enhance C-M excitation, can be substituted for voluntary contraction to induce LLP in the indirect C-M pathways.
Healthy volunteers (n=10), who all gave informed consent, were seated with surface electoromyogrphic recording from right biceps brachii (BB). RCS intervention (0.2 Hz, 10 min) was the same as in the previous study (Nakajima et al., Society for Neuroscience 2014). Transcranial magnetic stimulation (TMS) to the arm area of the left motor cortex was delivered with the right ulnar nerve stimulation at wrist level as a combined stimulation (CS). Interstimulus interval was set at 10 ms (TMS behind), which gave converging inputs in cervical IN systems. Stimulus strengths were determined to observe the maximum spatial facilitation in BB by the CS. As for the MI during RCS, participants were instructed to imagine performing maximal elbow flexion with sound cue signals, which was kept from 2 seconds before to 0.5 second after CS. Three types of interventions were conducted in separate experiments; (1) RCS alone, (2) RCS with MI, and (3) RCS during weak voluntary contraction of BB.
After RCS alone, motor evoked potential (MEP) in BB induced by single TMS was significantly depressed, and this depression lasted for ~60 min. Interestingly, RCS with MI induced LLP of BB MEP, which was similar to that after RCS during voluntary contraction. Furthermore, amount of spatial facilitation by CS was similarly enhanced after RCS with MI and RCS during voluntary contraction (Nakajima et al., Society for Neuroscience 2012). These findings suggest that RCS with MI could enhance indirect C-M excitation via cervical IN systems even without voluntary activation of target muscle.

Title: Mirror visual feedback induced changes in resting state functional connectivity in a complex ball-rotation task

Authors: *V. RJOSK[1], J. LEPSIEN[1], E. KAMINSKI[1], M. HOFF[1], B. SEHM[1], C. J. STEELE[1,2], A. VILLRINGER[1,3], P. RAGERT[1,4];

Institute, McGill Univ., Montreal, QC, Canada; [3]Mind and Brain Inst., Charité and Humboldt Univ., Berlin, Germany; [4]Inst. for Gen. Kinesiology and Exercise Sci., Univ. of Leipzig, Leipzig, Germany

Abstract: Motor recovery after stroke depends on neural plasticity, which is impaired in the lesioned hemisphere and therefore needs to be facilitated by repetitive, intensive and task-relevant movement training in rehabilitation. Mirror visual feedback (MVF) is an encouraging approach to enhance motor performance without training in healthy adults as well as in patients with focal brain lesions. While the underlying neural mechanisms remain elusive, there is preliminary evidence that a functional modulation within and between primary motor cortices (M1) as assessed with transcranial magnetic stimulation (TMS) might be one candidate mechanism mediating the observed behavioral effects. Recently, studies using task-based functional magnetic resonance imaging (fMRI) indicated that MVF-induced functional changes might not be restricted to M1 but also include higher order regions responsible for perceptual-motor coordination and visual attention. Resting-state functional connectivity (rs-FC) represents intrinsically generated neuronal activity patterns acquired by resting-state fMRI (rs-fMRI). These patterns are temporally correlated as well as behaviorally relevant and can be used to describe plasticity-induced changes and learning-engaged cerebral regions. In the present study, we asked whether MVF induces functional network plasticity as assessed with rs-fMRI. Here, we compared the rs-FC of 17 young, healthy right-handed subjects (MG) before and after performing a complex ball-rotation task of the right hand (RH) with MVF and 18 age-matched control subjects (CG) without MVF. The primary outcome measure was the performance improvement of the untrained left hand (LH) before and after RH training. On a behavioral level, MG showed superior performance improvements of the untrained LH as compared to CG. Rs-fMRI revealed MVF-induced functional alterations in bilateral sensorimotor cortex (SM1), left anterior intraparietal sulcus (aIP) and left visual cortex (V4). A TIME (rs-fMRI pre vs. post) x GROUP (MG vs. CG) analysis revealed a significant interaction in left visual cortex (V1, V2). Furthermore, a correlation analysis revealed a linear positive relationship between MVF-induced

improvements of the untrained LH and functional alterations in left sensorimotor cortex (SM1). Our results suggest that MVF-induced performance improvements are associated with functional brain plasticity in widespread brain regions, a finding of potential interest for neurorehabilitation to depict potential target regions for non-invasive brain stimulation techniques.

Title: Characterisation of glutamatergic and $GABA_A$ mediated neurotransmission in motor and dorsolateral prefrontal cortex using paired-pulse TMS-EEG

Authors: *R. CASH[1,2,3], Y. NODA[2], R. ZOMORRODI[2], N. RADHU[2,3], F. FARZAN[2], T. RAJJI[2], R. CHEN[3], Z. DASKALAKIS[2], P. FITZGERALD[1], D. BLUMBERGER[2];

Hlth. Network, Toronto, ON, Canada

Abstract: Short interval intracortical inhibition (SICI) and intracortical facilitation (ICF) are non-invasive transcranial magnetic stimulation (TMS) measures of $GABA_A$ receptor mediated inhibition and glutamatergic excitatory transmission respectively. Conventionally these measures have been restricted to the motor cortex. We investigated whether SICI and ICF could be recorded from dorsolateral prefrontal cortex (DLPFC) using combined TMS and electroencephalography (TMS-EEG). We first characterized the neural signature of SICI and ICF in M1 in terms of TMS evoked potentials (TEPs) and spectral power modulation. Subsequently these paradigms were applied in DLPFC to determine whether similar neural signatures were evident. With TMS at M1, SICI and ICF led to bidirectional modulation (inhibition and facilitation respectively) of P30 and P60 TEP amplitude which correlated with MEP amplitude changes. With DLPFC stimulation, P60 was bidirectionally modulated by SICI and ICF in the same manner as for M1 stimulation, while P30 was absent. The sole modulation of early TEP components is in contradistinction to other measures such as long interval intracortical inhibition and may reflect modulation of short latency EPSPs and IPSPs. Overall the data suggest that SICI and ICF can be recorded using TMS-EEG in DLPFC providing non-invasive measures of

glutamatergic and $GABA_A$ receptor mediated neurotransmission. This may facilitate future research attempting to ascertain the role of these neurotransmitters in the pathophysiology and treatment of neurological and psychiatric disorders. *RC & YN contributed equally.

Title: The involvement of different motor cortical interneurons in the plasticity induction with paired associative stimulation

Authors: ***Z. NI**, C. GUNRAJ, R. CHEN;
Div. of Neurol., Krembil Neurosci Ctr. and Toronto Western Resch Inst., Toronto, ON, Canada

Abstract: Paired associative stimulation (PAS) involves pairing sensory afferent inputs induced by median nerve stimulation (MNS) with direct activation of primary motor cortex (M1) by transcranial magnetic stimulation (TMS) at specific times. TMS in posterior-anterior (PA) current direction predominantly produces early indirect (I)-waves while that in anterior-posterior (AP) current direction predominantly produces later I-waves. PAS at stimulus intervals of both 21.5 and 25 ms between MNS and TMS in the PA direction produces spike timing dependent long term potentiation (LTP) like effect in M1. Short interval intracortical inhibition (SICI) refers to the cortical inhibition where a subthreshold conditioning stimulus (CS) inhibits the motor evoked potential (MEP) generated by a superthreshold test stimulus (TS). SICI inhibits later I-wave but has little effect on early I-wave. Engagement of SICI during PAS at 25 ms interval in PA current blocks LTP induction. We hypothesize that both early and later I-waves are involved in PAS induced LTP-like effect. We tested PAS at 21.5 ms interval conditioned by SICI and PAS alone in 9 healthy subjects. In the SICI conditioned PAS, the triple-pulse (MNS-CS-TS) intervention was repeated 180 times. This was compared to a traditional PAS intervention (180 pairs of MNS-TS). Both PA and AP current directions were tested. Cortical excitability measures were repeated before intervention (baseline) and up to 60 minutes after the intervention. The measures were MEP amplitude, SICI, intracortical facilitation (ICF), long

interval intracortical inhibition (LICI) and short latency afferent inhibition (SAI). The measures were tested both in PA and AP current directions. We found that PAS alone in both PA and AP current directions produced MEP facilitation. PAS induced by AP current decreased SICI and SAI while that by PA current did not change intracortical circuits. Conditioning SICI did not alter the effects of PAS in PA direction but reduced MEP facilitation by PAS in the AP direction. The reduction in MEP facilitation was accompanied by restoration of SICI and SAI. LICI and ICF did not change with any interventional protocols. The results indicated that PAS at stimulus interval of 21.5 ms with PA directed current was mediated by early I-wave and was not affected by SICI, whereas same protocol with AP current was due to later I-waves and was blocked by SICI. We conclude that LTP-like effects induced by PAS at different current directions of TMS are mediated by separate subgroups of cortical facilitatory interneurons responsible for the generations of early and later I-waves. They have different susceptibility to cortical inhibitory circuits.

Title: The influence of an acute bout of lower-limb cycling on sensorimotor integration.

Authors: *K. E. BROWN[1], J. L. NEVA[2], C. S. MANG[3], W. R. STAINES[4], L. A. BOYD[1]; [1]Physical Therapy, [3]Rehabil. Sci., [2]Univ. of British Columbia, Vancouver, BC, Canada; [4]Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada

Abstract: A growing body of literature suggests that an acute bout of exercise influences the excitability of multiple cortical areas, including the prefrontal and primary motor cortices. Understanding the influence of exercise on neurophysiology is essential for developing potential interventions to optimize neural plasticity and behavioural outcomes. Moreover, sensorimotor integration is an integral part of motor learning and motor control, as incorporation of relevant somatosensory feedback to inform movement enables successful interactions with our environment. Therefore, we aimed to determine if an acute bout of aerobic exercise would alter upper-limb sensorimotor integration in young, healthy individuals. We hypothesized that an acute bout of exercise would release short-latency afferent inhibition (SAI), increase afferent facilitation (AF) and increase long-latency afferent inhibition (LAI).
Young, healthy individuals completed two sessions examining the influence of an acute bout of

lower-limb, moderate intensity cycling on primary corticospinal and primary somatosensory cortical excitability (session 1) and sensorimotor integration (session 2). In session 1, somatosensory-evoked potentials (SEPs) and motor evoked potential (MEP) recruitment curves were assessed at two time-points prior (30 minutes pre- and immediately pre-exercise) to an exercise bout and two time-points following an exercise bout (immediately post and 30 minutes post-exercise). The exercise bout consisted of a 5-minute warm up, followed by 20 minutes of cycling at an intensity set to maintain individuals within a range of 65-70% of their age-predicted maximum heart rate. In session 2, measures of sensorimotor integration (SAI, AF and LAI) were assessed twice prior to and following exercise, as in session 1.
There was no significant difference between baseline time-points, and thus the two pre-exercise time-points were collapsed to provide an average baseline value for all measures. A repeated-measures ANOVA with percent inhibition as the dependent variable for LAI revealed that there was a significant effect of time ($F_{(2,12)}$=3.941, p=0.048). Tukey's HSD tests revealed that the immediately post-exercise time-point had significantly greater inhibition than at baseline (p=0.047). There was no effect of exercise on any of the other measures.
The current dataset is the first to suggest that the neurophysiology of upper-limb sensorimotor integration may be influenced by a single bout of acute lower-limb cycling. This may have implications for neurorehabilitation approaches designed to improve sensorimotor integration as a mechanism for optimizing motor output.

Title: Anodal transcranial direct current stimulation (tDCS) over motor cortex enhances split-belt treadmill adaptation in stroke

Authors: *X. LI[1,2], S. M. MORTON[1,2];
[1]Physical Therapy, [2]Grad. Program of Biomechanics and Movement Sci., Univ. of Delaware, Newark, DE

Abstract: Motor adaptation is a form of motor learning critical for locomotion, enabling relatively fast adjustments of walking patterns to unexpected changes in the environment. Whereas the cerebellum is known to play a major role in the initial adaptation process, recent

evidence suggests that motor cortical brain areas may be more important for consolidation and retention of motor memories. People with stroke affecting the corticospinal tract have intact locomotor adaptation but their learning is slowed and retention is poor. Transcranial direct current stimulation (tDCS) has successfully been used to induce changes in motor neuronal excitability and to induce positive behavioral changes in motor tasks in both healthy and stroke-affected individuals. However, the capability of tDCS to improve motor adaptation post-stroke has not been studied. The goal of this study was to test whether anodal tDCS could improve locomotor adaptation or its retention in people with stroke. Subjects with chronic unilateral stroke affecting the corticospinal tract participated in 2 study sessions 24 hours apart. They were assigned to receive either real or sham anodal tDCS applied over the leg representation of the lesioned hemisphere primary motor cortex (M1). During the first session, participants received tDCS while adapting their walking symmetry on a split-belt treadmill with belts set to a 2-to-1 speed ratio. Twenty-four hours later, retention was tested. Kinematic data were collected on both days using a 3D motion capture system. Preliminary results so far show that the magnitude of learning on both days is greater in the real group compared to sham, with a greater difference between groups on day 2. In addition there may be somewhat greater retention in the real group compared to sham and the rate of learning is greater in the real group on day 1, but not day 2. Overall, our results suggest that anodal tDCS over the lesioned hemisphere M1 in stroke subjects during split-belt adaptation may increase both the rate and magnitude of locomotor learning and improve its retention. We postulate that lower limb M1 activity is beneficial for locomotor adaptation and retention processes.

Title: Rats gone wild: How seminatural rearing of laboratory animals shapes behavioral development and alters somatosensory and motor cortex organization

Authors: *D. F. COOKE[1,2], M. K. L. BALDWIN[1], M. S. DONALDSON[1], J. HELTON[2], D. S. STOLZENBERG[2], L. KRUBITZER[1,2];
[1]Ctr. Neurosci, [2]Psychology, UC Davis, Davis, CA

Abstract: The mammalian neocortex and the behavior it generates are highly adaptable. Few species exemplify this better than rats, which for thousands of years have thrived everywhere that humans have settled; traveling in our ships, living in our houses and cities, and eating our food despite an unending campaign of cats, traps, and poisons. Such adaptability to various climates, habitats, food sources, and predators is due, in part, to well-established sensitivity of the mammalian cortex to environmental conditions during development. This early experience can shape sensory and motor cortical maps, leading to behavior adapted to the local environment. Most studies of this process are necessarily restricted to laboratory animal models reared in a relatively deprived environment. Here we take a different approach and investigate how early natural environmental experiences shape neocortical development. We compare control rats reared in standard laboratory cages with genetically identical rats reared in an outdoor, seminatural environment: large wire mesh enclosures (9.75 X 2.5 X 2.5 m) roughly 3000 times the size of a standard rat cage. These field pens, located in a nature reserve, expose rats to weather (e.g. 12.8-43.3 °C, 4-100% humidity), day/night length and sun/moon light level conditions, as well as the sights, sounds, and smells of wild animals, including predators. A dirt floor populated by wild plants and invertebrates permits burrowing and hunting, while the mesh walls and introduced branches promote climbing. These are atavistic behaviors typical of wild rats and require sensorimotor processing entirely absent in standard laboratory cages. 24-h video recordings were made with overhead infrared cameras in the enclosure and the burrow box from which social behaviors were scored across the lifetime. Electrophysiological sensory mapping and intracortical microstimulation in adult anesthetized animals were used to examine the organization of somatosensory and motor cortex. Our preliminary data indicate that seminatural rearing shifts the timing of neurobehavioral development as well as adult exploratory, social, and cognitive behaviors. These behavioral alterations are associated with changes in the representation of movements in motor cortex, with relatively more cortical area devoted to the representation of trunk and tail movements at the expense of neighboring movement domains. Such data are critical for understanding how distinct phenotypes emerge from a single genotype based on differential early experience.

Title: Participation of medial prefrontal cortex in plasticity induced by acrobatic exercise training

Authors: ***S. R. MOTA-ORTIZ**, P. N. DIAS, C. R. PIRES, W. F. DE OLIVEIRA, R. S. PIRES;
Univ. Cidade De São Paulo, São Paulo, Brazil

Abstract: Acrobatic training in animals promotes synaptogenesis in regions of the cerebellum and motor cortex, as well as behavioural changes, such as increasing the task performance, indicating an increase in the acquisition of motor skills. Several studies showed that many areas of the cerebral cortex are primarily involved in the processing of sensory information or the planning and execution of motor commands. During the learning process, there are changes in the structure and function of neural cells and their connections, namely learning promotes plastic changes, such as growth of new endings and synaptic buttons, growth of dendritic spines and increased functional synaptic areas. Our aim was to analyze the participation of the prefrontal cortex in plastic mechanisms promoted by acquisition of a new complex motor skill after bilateral neurochemical lesions in the mPFC of rats submitted to different time of acrobatic training. Eighteen animals were divided into 2 groups, namely Control (C) and mPFC lesion (L), and each one was subdivided into short acrobatic training (AC1, n=10) and long acrobatic training (AC4, n=8). The AC moved through a circuit of obstacles 5 times/day, 3 days/week for 1 and 4 weeks. At the end of the training, their brains were removed for immunohistochemistry assays to analyze the expression of a marker of recent neuronal activity (Egr-1) in the primary and secondary motor cortex, dorsolateral and dorsomedial striatum. Statistical analyses were performed using one-way ANOVA with the Bonferroni *post hoc* test. Our data revealed that mPFC lesion induced distinct neural mobilization in the brain areas analyzed after short and long-term of acrobatic training. In the control groups, our data revealed that AC4 (C+AC4) induced Egr-1 decreases in the secondary motor cortex (ca. 26%, $p<0.05$), dorsomedial and dorsolateral striatum (ca. 68% and ca. 69%, $p<0.0001$; respectively) compared to (C+AC1), and didn't change in the primary motor cortex. In addition, our results showed that short-term AC in the mPFC lesion group (L+AC1) induced Egr-1 decreases (ca. 38%, $p<0.05$) in the secondary motor cortex and Egr-1 increases in dorsomedial and dorsolateral striatum (ca. 32%, $p<0,05$; ca. 29%, $p<0,05$; respectively) compared to control group (C+AC1). Long-term acrobatic in the mPFC lesion group (L+AC4) induced Egr-1 decreases (ca. 38%, $p<0.05$) in the secondary motor cortex and Egr-1 increases in dorsomedial and dorsolateral striatum (ca. 32%, $p<0,05$; ca. 29%, $p<0,05$; respectively) compared to control group (C+AC4). In conclusion, our data suggest that mPFC cortex modulated motor cortex and striatum differentially within the learning of complex motor skill.

Title: Targeted cortical reorganization using optogenetics in non-human primates

Authors: D. B. SILVERSMITH[1], *A. YAZDAN-SHAHMORAD[2], P. SABES[2];
[1]Bioengineering Grad. Program, UCB-UCSF, San Francisco, CA; [2]Physiol., Univ. of California San Francisco, San Francisco, CA

Abstract: Brain stimulation has shown promise for neural rehabilitation after injury. However, current stimulation based therapies are non-specific. A proposed mechanism for targeted reorganization is spike timing dependent plasticity (STDP): the relative timing of pre- and post-synaptic activity determines synaptic plasticity. We used optogenetic stimulation with STDP-based protocols to investigate the feasibility of inducing specific cortical reorganization.
We used a large-scale optogenetic interface that enables surface stimulation of excitatory neurons (AAV5-CamKIIa-C1V1-EYFP) and simultaneous electrocorticographical (ECoG) recording from primary somatosensory (S1) and motor (M1) cortices in two macaques. Stimulation in S1 and M1 evokes a direct response in the stimulated area followed by a delayed, indirect response in the other cortical area. To probe functional connectivity between S1 and M1 we measured the relative amplitude of the direct and indirect responses. We determined connectivity changes following two simple stimulation protocols: 1) single-site pulse trains in one cortical area and 2) paired pulse trains separated by a brief time delay across two cortical areas.
These stimulation patterns induced measureable cortical plasticity within 50 minutes. Single-site stimulation significantly increased connectivity between cortical areas; this result is consistent with STDP since indirect responses occur within 3-5ms, well within the potentiation window of STDP. Furthermore, using paired stimulation across cortical areas we were able to manipulate

the relative timing of light-evoked responses. We chose stimulation sites so that the direct response from the leading site overlapped with the indirect response from the lagging site. For large time delays (100ms) the sites acted independently, and increased connectivity was seen for both sites. When the delay was short (10ms), consistent with single-site stimulation, we saw a significant increase in connectivity for the leading site. However, there was a significant decrease in connectivity for the lagging site because the post-synaptic activity from this site occurred 13-15ms before the pre-synaptic activity, which is within the depression window of STDP.
Using optogenetic stimulation and ECoG recordings, we selectively strengthened and weakened existing connections across sensorimotor cortex in a manner consistent with STDP. This demonstrates the feasibility of driving targeted, bi-directional cortical plasticity with optogenetic stimulation and without spike-based recording; an ability that would likely find many applications for neural rehabilitation.

Title: An acute bout of exercise modulates interhemispheric inhibition in primary and non-primary motor-related areas.

Authors: *J. L. NEVA, K. E. BROWN, L. A. BOYD;
Dept. of Physical Therapy, Univ. of British Columbia, Vancouver, BC, Canada

Abstract: The potential for aerobic exercise to modulate cognition, behaviour and cortical excitability is becoming of great interest to researchers and clinicians. Recently, work from our lab and others have shown that the excitability of the primary motor cortex (M1) is modulated by a single session of exercise. Specifically, a single session of lower-limb cycling exercise modulates M1 intracortical inhibitory [1] and facilitatory circuitry [1], cerebellar inhibition [2] and transcallosal inhibition within M1 in non-exercised upper-limb representations. This suggests that exercise may alter multiple networks of intrahemispheric and interhemispheric cortical circuits. Interhemispheric inhibition (IH) can be elicited from M1 and non-M1 areas such as primary somatosensory cortex (S1), dorsal premotor cortex (PMd) and the dorsolateral prefrontal cortex (DLPFC) to the contralateral M1 using dual-coil paired pulse transcranial magnetic stimulation (TMS) [3]. However, it is not known how IHI elicited from non-M1 areas

may be modulated after an acute bout of cycling exercise. The purpose of this study was to investigate the effects of a single bout of moderate exercise on IHI between M1 and non-M1 cortical regions. Dual-coil paired pulse TMS was used to measure IHI between M1 and non-M1 regions to the contralateral M1 of the non-exercised first dorsal interosseous (FDI) muscle representation. IHI was measured between right (non-dominant) hemisphere M1, S1, PMd and DLPFC to the contralateral (dominant) M1. For M1 and PMd, IHI was measured with a 10 ms (IHI-10) interstimulus interval (ISI) and a 50 ms (IHI-50) ISI to determine the potential distinct phase of IHI modulation, whereas S1 and DLPFC was only measured with a 50 ms ISI [3]. IHI was measured two time points before (baseline and pre-exercise) and one time point immediately after exercise (post-exercise). Healthy young participants performed moderate intensity cycling exercise was performed for 20 min at 65-70% of age-predicated maximum heart rate on a stationary ergometer. Preliminary results suggest that M1 IHI-50 was decreased and DLPFC IHI was enhanced post-exercise. These results suggest a decreased inhibition between M1, confirming previous work from our lab, and an increased inhibition from DLPFC after exercise. This potentially indicates that cycling exercise can concurrently modulate multiple interhemispheric circuits connected to M1. Recruitment for this study is ongoing.

Title: Changes in cortical activity induced by an intervention using electromyography-driven functional electrical stimulation in individuals with moderate to severe chronic stroke

Authors: ***K. B. WILKINS**[1], C. CARMONA[2], J. DROGOS[2], J. SULLIVAN[2], J. P. A. DEWALD[2], J. YAO[2];
[2]Physical Therapy and Human Movement Sci., [1]Northwestern Univ., Chicago, IL

Abstract: Introduction: Individuals with moderate to severe chronic stroke usually lack control of their paretic hand, which may be partially due to damage to the ipsilesional corticospinal tract.

Previous evidence shows that cortical activity related to the paretic arm movements commonly shifts to the contralesional hemisphere as a function of shoulder abduction in individuals with moderate to severe stroke. This suggests that with increasing task demands, subjects no longer can rely on residual ipsilesional corticospinal tract resources, and instead increasingly rely on the contralesional hemisphere. In this study, we investigated the changes in cortical activity related to hand control induced by an intervention using a newly developed electromyography-triggered neuromuscular electrical stimulation system - ReIn-Hand that allows our targeted population to use their paretic hand in a task-specific intervention. Methods: Six individuals with moderate to severe chronic stroke participated in a 7-week intervention, 3 sessions per week. In each session, subjects used the paretic arm to perform 20-30 trials of reaching, grasping, and releasing a jar with the assistance of the ReIn-Hand device. Pre- and post-intervention, 160 channel electroencephalography (EEG) was measured when participants performed paretic hand opening with the arm resting on a haptic table or lifting up against 50% of maximum voluntary shoulder abduction force (MVF). Cortical activity was reconstructed based on subject-specific head models, and then used to quantify a Laterality Index (LI = (ipsilesional-contralesional)/(ipsilesional+contralesional)) with -1 to +1 indicating complete contra- or ipsilesional activity in the sensorimotor cortices. Results: Following the intervention, subjects showed improved range of motion, sensation, and grip strength at the hand. A 2-way (intervention and loading) repeated measure ANOVA showed that the intervention had a significant effect on LI ($F=11.8$, $p=0.018$). The post-hoc paired t-test showed that cortical activity related to paretic hand opening significantly shifted from the contralesional hemisphere to a more ipsilesional pattern for both the table condition and the 50% MVF condition. These results demonstrate that a ReIn-Hand assisted intervention could increase the use of remaining corticospinal resources from the ipsilesional hemisphere, resulting in a more typical activation pattern commonly seen in healthy individuals and well-recovered stroke subjects. This shift may serve as an indicator for improved functional gains of the paretic upper limb.

Title: Contribution of BDNF to spontaneous and modified recovery after stroke in a rat model

Authors: *B. FRITSCH, L. TOMETTEN, M. R. CURADO, J. REIS;
Univ. of Freiburg/ Neurocenter, Freiburg, Germany

Abstract: Neuroplastic changes apparent during motor training and after brain injury have been shown to critically depend on neurotrophins, e.g. BDNF. Moreover, noninvasive electrical brain stimulation, specifically anodal tDCS, is capable of enhancing learning processes (Reis et al. 2009) and effects are also dependent on BDNF (Fritsch et al. 2010). Here, we hypothesized that an immediate increase of BDNF expression after stroke will be beneficial for motor recovery and a later decrease may hamper the possibility to undergo neuroplastic changes after stroke. Furthermore, we hypothesized that anodal tDCS applied to the lesioned motor cortex can beneficially influence BDNF levels. We planned to clarify in rats whether body fluids (blood plasma, cerebrospinal fluid) are indicative of BDNF protein content in cerebral tissue. First, we investigated BDNF protein concentration in cerebral tissue, CSF and plasma of rats 2, 4, 8, and 24 hours as well as 7 and 14 days after photothrombotic stroke or sham surgery. Second, we extended the experiments to include the investigation of anodal tDCS-effects on stroke lesion size and BDNF levels. The ELISA was optimized by a fluorometric technique with a detection limit of 1 pg BDNF protein/mg total protein. BDNF protein concentration was increased in the stroke and peri-stroke cerebral tissue as early as 2 hours post stroke and further increased over the time course reaching a maximum at 24 hours post stroke. This increase was not seen in the contralesional hemisphere. BDNF levels returned to close to normal levels by day 14 post stroke. This time course paralleled the time course of recovery measured by the mNSS stroke severity scale and the adhesive removal test. BDNF protein tissue concentration in the peri-stroke area did not correlate with BDNF protein concentration in CSF or plasma. Anodal tDCS applied to the primary motor cortex (M1) at a current density clearly below lesion thresholds (8A/m2) enhanced cerebral BDNF protein concentration under the stimulated area (M1 and striatum) but not in the neighboring cortex (S1) or distant brain regions, when applied 2 hours post stroke. tDCS applied 24 hrs post stroke, where BDNF levels were maximally increased, did not further enhance protein content. tDCS applied at day 7 post stroke only slightly elevated BDNF protein. Whether this intervention also changes the time course of recovery is currently under investigation. Our preliminary conclusion is that BDNF protein tissue levels are indicative of the course of motor recovery after stroke. Interventions affecting this relation, such as noninvasive brain stimulation using tDCS, may hold the potential to positively modify the recovery phase.

Title: Anodal transcranial direct current stimulation enhances intra-limb motor transfer

Authors: F. A. ROTTMANN, M. R. CURADO, B. FRITSCH, *J. REIS;
Univ. of Freiburg, Freiburg, Germany

Abstract: Stroke is a major cause of impaired upper limb motor function. Many patients suffer from severe paralysis of both forearm and hand while to some degree motor function of the proximal upper limb remains intact. In this proof-of-concept study we asked whether proximal isometric motor training with the triceps muscle improves distal fine motor function of the ipsilateral hand (motor transfer) and vice versa and if such a transfer effect can be enhanced by applying transcranial direct current stimulation (tDCS) to the motor cortex contralateral to the trained limb. We modified the sequential isometric Pinch Force Task (SVIPT, Reis er al 2009), a visuomotor task, for execution with either triceps or hand. Skill of the training body part (triceps or hand) and skill of the transfer body part (hand or triceps) was determined by an adjusted mathematical Model based on the change of the speed accuracy tradeoff.
Adult, healthy participants were randomized into two groups to investigate a transfer from proximal (triceps) to distal (hand) OR distal (hand) to proximal (triceps) upper limb. Before training each participant's baseline skill of the transfer effector was measured. Training with either triceps or hand lasted for approximately one hour. During training participants received either anodal tDCS or sham tDCS over the contralateral motor cortex (M1). A separate group did not undergo any training to measure the repetition effect on transfer effector performance only.
We found a significant improvement of hand motor skill after triceps training, i. e. transfer from proximal to distal. No such transfer was detected from distal to proximal (i.e. triceps). However, anodal tDCS enhanced transferred skill in both groups.
From this study in healthy subjects it is tempting to speculate that patients with upper limb paralysis may benefit from combining tDCS with rehabilitation exercises of the arm. Further studies with patients are planned.

Title: Learning specific VTA activation in a skilled reaching task

Authors: *S. LEEMBURG, T. CANONICA, A. LUFT;
Univ. of Zurich, Zurich, Switzerland

Abstract: Dopaminergic terminals in the primary motor cortex (M1) mainly originate in the ventral tegmental area (VTA). Dopamine release from these terminals is essential for the acquisition of motor skills. While motor skill learning requires multiple brain functions, it is unclear which behavioral element triggers VTA activation. Here, we used immunofluorescence for tyrosine hydroxylase (TH) and c-fos in combination with the retrograde tracer FastBlue to investigate learning- and reward-related activation of VTA neurons projecting to M1. After tracer injection, one group of rats was trained to perform a single pellet reaching (SPR) task for 3 days. Reward control rats (RC) received food rewards whenever SPR rats successfully retrieved a pellet. Cage control animals (CC) were kept in training cages for equal amounts of time as the other groups, but did not receive any pellets. While c-fos expression in dopaminergic neurons was increased in both SPR and RC rats, only SPR specifically activated M1-projecting dopaminergic neurons in the trained hemisphere of the caudal VTA. Moreover, animals that were showed extremely poor performance on the reaching task did not show increased dopaminergic activation. Non-dopaminergic VTA neurons are unaffected by both SPR and reward. These results indicate that the dopaminergic VTA-M1 projection is involved in successful motor skill learning and is functionally distinct from projections mediating food rewards.

Title: Enhanced motor recovery by vagus nerve stimulation requires cholinergic innervation in a rat model of ischemic stroke.

Authors: *A. D. RUIZ[1], S. HAYS, 75080[2], A. BERRY[2], S. VALLEJO[2], L. BARRON[2], X. CARRIER[2];

Abstract: Stroke is a debilitating neurological insult that affects approximately 795,000 people in the U.S. each year. Following a stroke, many patients are left with impairment in upper extremity function, even after intensive rehabilitation therapy. Recent studies indicate that vagus nerve stimulation (VNS) paired with rehabilitative training significantly enhances recovery of forelimb function in models of ischemic stroke, intracerebral hemorrhage, and traumatic brain injury. Nevertheless, the mechanisms that underlie VNS-dependent enhancement recovery are largely unknown. The cholinergic nucleus basalis (NB) is a critical substrate in cortical plasticity, and several studies suggest that VNS activates cholinergic circuitry. Previous studies demonstrated that cholinergic innervation of the motor cortex is required for VNS-dependent enhancement of cortical plasticity. In this study we examine whether cholinergic innervation is required for VNS-dependent enhanced recovery in a rat model of ischemic stroke. A cohort of rats was trained to proficiency on the isometric force task, an automated and qualitative measure of forelimb function and then received a cortical ischemic lesion to impair the trained forelimb. Rats then received injections of the highly selective immunotoxin IgG-192-saporin into the nucleus basalis to deplete cortical cholinergic innervation (NB-) or control injections (NB+). Two weeks after stroke and immunolesion, rats underwent rehabilitative training for 6 weeks with or without VNS paired with forelimb movement. At the conclusion of behavioral testing, pseudorabies virus labelling was performed to assay anatomical plasticity in motor circuits controlling the forelimb. Preliminary findings indicate that VNS-dependent enhancement of stroke recovery requires cholinergic innervation.

Title: Interhemispheric pathway modulation between homotopic sites in rat primary motor cortex (MI) leads to expression of new motor output in the ipsilateral forelimb

Authors: *A. L. CURRY[1,2], V. PELLICER-MORATA[4], B. MORSHED[3], S. NARAYANA[5], R. S. WATERS[4];
[2]Biomed. Engin., [3]Electrical & Computer Engin., [1]Univ. of Memphis, Memphis, TN; [4]Anat. and Neurobio., [5]Pediatrics, Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Introduction: Intracortical microstimulation (ICMS) of forelimb representation in rat primary motor cortex (MI) evokes muscle contractions and/or movements only in the contralateral forelimb. An interhemispheric connection exists between homotopic forelimb representations in MI, but ICMS fails to evoke motor responses in the ipsilateral forelimb. We reported that chronic stimulation of the interhemispheric pathway between forelimb homotopic regions in somatosensory cortex (SI) enhanced the pathway, and led to new input in ipsilateral SI from the ipsilateral forelimb. Here, we examined the generality of interhemispheric pathway enhancement to assess whether chronic stimulation of the pathway between homotopic sites in MI evokes new motor responses in the ipsilateral forelimb. Methods: A carbon fiber electrode was inserted into MI and ICMS, consisting of a train of 13 pulses, was delivered to layer V to identify a site evoking movement in the contralateral forelimb. A second electrode was inserted in the opposite MI and used to find a site yielding a similar motor response in the contralateral forelimb. One of the electrodes (stimulating electrode) delivered single pulse stimulation and the second electrode (recording electrode) in opposite MI was used to record evoked response to establish a connection between homotopic motor sites. Once confirmed, single pulse stimulation was continually delivered to the stimulating electrode to evoke responses and enhance the pathway in the contralateral MI. At 15 min intervals, ICMS was delivered through the stimulating electrode and motor responses were reexamined in the periphery. If ICMS led to bilateral motor responses, inactivation of the interhemispheric pathway was carried out by applying a cooling probe to the cortical surface in the enhanced hemisphere. Lesions were made following recording to mark locations of stimulation and recording sites. Results: 1. ICMS delivered to homotopic MI initially evoked motor responses only in the contralateral forelimb. 2. Chronic single pulse stimulation enhanced the interhemispheric pathway between homotopic MI sites. 3. After 30-60 min of chronic stimulation, ICMS evoked motor responses in both contralateral and ipsilateral forelimbs. 4. Ipsilateral movement was abolished by inactivation of the enhanced MI, while the motor response in the contralateral forelimb was unaffected.

Conclusion: Interhemispheric enhancement modulates neuronal activity in SI and MI and results in expression of new functional responses. These stimulation parameters can be translated to transcranial magnetic stimulation (TMS) to improve efficacy in stroke treatment in humans.
