Abstract: Major depressive disorder is an idiopathic syndrome characterized by depressed mood, helplessness, anhedonia, disphoria, altered sleep behavior and appetite, loss of concentration and sometimes is associated with suicide. It has been reported that GABA release in the ventral pallidum (VP) is increased during depressive-like behaviors and the GABAA receptor seems to mediate a tonic instead of a phasic inhibition. However, the function of the GABAB receptor in the VP is not clear. We studied the effect of a specific GABAB agonist baclofen (25, 50 and 100 ng/side) and the antagonist saclofen (100 ng/side), bilaterally microinjected in the VP during the forced swim test (FST) in rats. Intra-VP microinjections of baclofen before FST significantly reduced swimming behaviors (172.1 ± 65.5; n=10, F(4;450), p=0,040) while saclofen did not produce any behavioral change (249.9 ± 161.0, n=10, F(0;001); p=0,970) compared to the control group saline solution (251.1 ± 98.6, n=10) during the day-2 of the FST. On the contrary, saclofen seems to enhance baclofen effect in reducing swimming times (115.83±16.6, n=6, F (16; 238); p=0,001) when both drugs were combined. No significant changes in the swimming behaviors were found between any group (experimental and control)during the day-1 on the FST. Open field test demonstrated that neither baclofen nor saclofen altered locomotor activity so the changes registered during FST could be attributed to modulation of the depression-like behavior. In a separate experiment we measured mRNA expression in the VP of both GABAB receptor subunits (GABAB1 and GABAB2) using semi quantitative RT-PCR comparing rats that showed depressive-like behaviors versus a control group. None changes were found for neither of the subunits GABAB1 and GABAB2. These results suggest that GABAB receptor on the VP might be related to depression-like behaviors and might be acting in a phasic inhibition without any changes in mRNA expression of both of its subunits. Baclofen emulates the increase GABAergic tone reported on the VP during FST and it decreases significantly swimming times as important symptom of behavioral despair.

Title: Induction of CaMKIIβ by HDAC inhibitors might be involved in structural plasticity and behavioral responses to chronic stress

Authors: *T. HOBARA[1], S. UCHIDA[1], H. YAMAGATA[1], F. HIGUCHI[1], N. HIGUCHI[1], T. SHIBATA[1], K. OTSUKI[1], Y. WATANABE[2];

Abstract: Recent reports have suggested that epigenetic gene regulations are closely associated with the development of stress vulnerability, and also contribute to behavioral responses to chronic stress and antidepressants. There is evidence suggesting that histone deacetylase (HDAC) inhibitors have antidepressant-like effects in rodents. However, molecular mechanisms of antidepressant actions induced by HDAC inhibitors remain unclear. The purpose of this study is to clarify molecular mechanisms of antidepressant actions by HDAC inhibitors in vivo and in vitro. First, we confirmed the antidepressant effect of HDAC inhibitor suberoylanilide hydroxamic acid (SAHA) using model mice of depression. We found that subchronic treatment with SAHA reversed the increased depression-related behaviors in mice subjected to chronic stress. In addition, subchronic treatment with SAHA enhanced the expression of calcium/calmodulin-dependent protein kinase (CaMK) IIβ mRNA in the hippocampus of stressed mice. However, subchronic treatment with imipramine, a tricyclic antidepressant , did not affect the expression of CaMKIIβ as well as depression-related behaviors in stressed mice. These data suggest that SAHA has rapid antidepressant actions, and that the induction of CaMKIIβ by SAHA may contribute to the antidepressant actions. We also found that subchronic treatment with SAHA enhanced adult neurogenesis in the dentate gyrus (DG) of the hippocampus. Our results showed that doublecortin positive immature neurons displayed increased dendritic arborization after subchronic treatment with SAHA. In addition, mice with

partially impaired neurogenesis by methylazoxymethanol acetate (MAM) demonstrated depression-related behaviors. Notably, SAHA recovered the increased depression-related behaviors induced by MAM via stimulating maturation of immature neurons. On the other hand, full ablation of neurogenesis by Cytosine β-D-arabinofuranoside hydrochloride (AraC) demonstrated sustained depression-related behaviors in spite of co-treatment with SAHA. Furthermore, cell culture experiments showed the induction of CaMKIIβ mRNA and the increased number of differentiated cells by HDAC inhibitors. Importantly, CaMKIIβ knockdown inhibited the induction of cell differentiation by SAHA. Thus our data suggest that the induction of CaMKIIβ by HDAC inhibitors might be involved in structural plasticity and subsequent behavioral responses to chronic stress.

Title: Individual differences in pre-stress state predict distinct responses to chronic unpredictable stress in rats

Authors: *Y. IGUCHI, S. KOSUGI, Y. MINABE, S. TODA;
Psychiatry & Neurobio., Kanazawa Univ. Sch. of Med., Kanazawa, Japan

Abstract: The individual differences among the patients with major depressive disorder (MDD) are frequently observed in symptoms and responses to antidepressants, suggesting the heterogeneity of this disease.However, the molecular mechanisms and/or genetic backgrounds

underlying them remain elusive. Preclinical models of MDD also have been facing the similar problems. We hypothesized that the pre-existing individual differences in various indexes such as motivation, flexible decision-making or endogenous stress-coping system in naive rats would work as predictive endophenotypes leading to distinct pathophysiological outcomes after the exposure to chronic unpredictable stress (CUS) that is widely used to induce MDD-like phenotypes in animals. To verify this hypothesis, we first tried to classify some distinctive subgroups from naive Sprague-Dawley rats (n = 84) by monitoring the differences in performance of motivation-dependent, goal-directed behaviors in a saccharin-rewarded progressive ratio instrumental training. As a result, the original population was divided into three subgroups as follows; Low Motivation (LM: characterized by consistent low completed ratio, 17% of total animals), Flexible (FL: high completed ratio in the first session followed by a drastic reduction, 57%), and Hyper Motivation (HM: consistent high completed ratio, 26%). The basal level of serum corticosterone was markedly higher in HM than in LM, and the augmentation of serum corticosterone in response to footstock was significantly higher in LM than in other subgroups. Next, we exposed all animals to CUS (randomized one of three stressors once a day; restraint, forced swimming, and social defeat) for 4 weeks, and then examined if these subgroups would differentially perform instrumental behavior after CUS. We found that, on the next day of the last session of CUS, the response rate on a continuous reinforcement schedule was accelerated by CUS in all subgroups. In the progressive ratio performance that was monitored every week, HM showed a significant reduction in the completed ratio immediately after CUS whereas LM showed a significant increase in the ratio 4 weeks after CUS. Meanwhile, the completed ratio was hardly affected in FL during the entire post-CUS period, implying relatively higher resilience to CUS in FL. These results suggested a predictability of distinct MDD-like phenotypes for each individual after CUS based on the individual differences in pre-stress state.

Title: Toward a spontaneous model of depressive symptoms among cynomolgus and rhesus monkeys in farming conditions

Authors: *S. CAMUS[1], C. ROCHAIS[2], C. BLOIS-HEULIN[2], Q. LI[4], M. HAUSBERGER[3], E. BEZARD[1];
[1]CNRS UMR 5293, Inst. of Neurodegenerative Dis., BORDEAUX CEDEX, France; [2]UMR 6552 CNRS Ethologie animale et humaine, Univ. de Rennes 1, Paimpont, France; [3]UMR 6552 CNRS Ethologie animale et humaine, Univ. de Rennes 1, Rennes, France; [4]Motac Neurosci. Ltd, Manchester, United Kingdom

Abstract: Although the pathophysiology of depressive disorders is extensively investigated, their underlying mechanisms remain poorly understood. Such studies have almost exclusively been performed in rodents submitted to environmental, pharmacological, surgical or genetic manipulations, i.e. induced model as opposed to spontaneously occurring disorders, therefore carrying poor construct validity. Adverse early-life experience might lead to the spontaneous expression of abnormal behaviors in animals and the predisposition to psychiatric disorder in Humans. Common breeding processes employ weaning and housing conditions different from what occurs in the wild. Thus, we investigated the existence of spontaneous atypical behaviors displayed by non-human primates (NHP), phylogenetically and behaviorally closer to Humans than rodents, in breeding farms and their possible similarities with human depressive symptoms. Following the identification of atypical behavioral- and their associated physiological-profiles among single-housed monkeys (n=80), we detected such profiles in more naturalistic settings (i.e. social housing) among 115 monkeys. We broached the potential impact of species and early-life experience on the prevalence of depressive-like profiles by analysing data from captive- or wild-born rhesus and cynomolgus macaques. Behaviors, body postures, body orientations, gaze directions, distances between individuals and locations in the cage were collected using an unbiased ethological scan-sampling method followed by multifactorial correspondence and hierarchical clustering analyses. In each species, housing, or origin conditions, we identified distinct profiles, one of them mimicking several depressive symptoms with high level of inactivity, facing the wall, low levels of locomotion, maintenance and investigation behaviors. A greater amount of depressive-like subjects were found in the captive-born and in the rhesus populations, suggesting that unnatural early life events increase the risk of developing pathological symptoms and that rhesus might be more vulnerable to express such symptoms compared to cynomolgus monkeys.
Both birth origin and species should be considered when setting up a preclinical research protocol. The use of unbiased behavioral observations might allow the identification of animal models of human mental/behavioral disorders and their most appropriate control groups.

Title: Characterization of the learned helplessness model and effects of P2X7 blockade

Authors: *N. C. WELTY, M. MORTON, J. SHELTON, B. SAVALL, M. LETAVIC, A. BHATTACHARYA, G. CHEN, J. R. SHOBLOCK;
Janssen, SAN DIEGO, CA

Abstract: The learned helplessness paradigm is a model of depression in which animals are exposed to inescapable shock (IES) and subsequently demonstrate a deficit in evading an escapable shock. Rats that were exposed to inescapable shocks (1.0mA, 15 sec, 120) showed an increase in plasma corticosterone that may have remained chronically elevated compared to animals that were naïve to shock. Altered glucocorticoid receptor expression in the prefrontal cortex and hypothalamus were also observed in animals subjected to shock, which may contribute to some of the behavioral deficits seen in this model. Interestingly, stress resilient animals appeared to have downregulated glucocorticoid receptor in hippocampus. Our preliminary data also suggest that two days after IES, iNOS, capsase-3, and Bax mRNA were all upregulated, suggesting excitotoxicity and apoptosis could be another driving factor of the observed deficits in this model. Since P2X7 is reported to be involved in stress adaptations, glutamate release, and apoptosis, we hypothesized that P2X7 antagonists would be effective in this model. We tested the effects of a P2X7 antagonist (Compound A, 10 mg/kg, s.c.) in the learned helplessness paradigm, dosed 1 h prior to the IES and 1 h prior to testing, for escape deficits and female urine sniffing deficits, a measure of anhedonic-like activity. The P2X7 antagonist had no effect on escape deficits, but appeared to at least partially attenuate the sniffing deficit caused by IES. P2X7 blockade may prevent the development of the anhedonic-like state following IES, perhaps by attenuating IES-induced excitotoxicity or HPA-axis dysregulation. Future experiments to confirm are pending.

Title: Global, early, selective and progressive noradrenergic axonal degeneration in somatostatin 2 receptor but not in somatostain 1 receptor knockout mice

Authors: *C. ADORI[1], L. GLUECK[2], T. YOSHITAKE[3], J. KEHR[3], H. TOMAS[3];
[1]Karolinska Inst. Dept. of Neurosci., Stockholm, Sweden; [2]Friedrich-Schiller-Universität, Jena, Germany; [3]Karolinska Inst., Stockholm, Sweden

Abstract: The somatostatin peptide (SST) has been originally described as a growth hormone release-inhibiting factor but also considered as a neuromodulatory agent in the CNS. SST has an influence on, among others, pain mechanisms, REM sleep and brain ontogenesis. Changes in SST levels and in its receptor expression have been associated with dementia, epilepsy or major affective disorders. SST acts on six types of G-protein-coupled receptors in the brain. Among them, the inhibitory receptor SST2 is the most abundant. In SST2 knockout (KO) mice, increased anxiety-related behavior was described in a number of behavioral paradigms, while locomotor and exploratory activities were decreased in stress-inducing situations. However, no morphological study examined the brains of SST2 KO mice extensively. In our present work we looked for potential alterations in the brain chemical neuroanatomy of SST2 and SST1 KO animals.
E18 - 8 month old SST2 ko /LacZ knockin and SST1 ko /LacZ knockin mice were perfused for fluorescence immunohistochemistry and double-labelings (SST2a receptor plus monoaminergic or cholinergic markers, β-galactosidase, CCK, cortical interneuron- and pyramidal cell markers or glial markers) or were decapitated, and the brains were processed for in situ hybridization (tyrosine hydroxylase, galanin, CCK), HPLC measurements (monoamines and their metabolites) and radioimmunoassay (CCK, somatostatin). The spatial and temporal patterns of noradrenergic alterations, the number of locus coeruleus (LC) cell bodies and their soma area were determined by morphometrical techniques.
We found a widespread and progressive noradrenergic degeneration in SST2 KO, but not in

SST1 KO mice. We showed that this degeneration was selective for the noradrenergic system and apparently did not affect dopaminergic, serotonergic or cholinergic systems. While the LC cell bodies were seemingly intact even in the 8 month old animals, an abnormal noradrenergic fiber pattern could be detected already in the late prenatal period (E18). In addition, we also observed a considerable decrease of CCK immunostainig, decreased CCK mRNA expression and some signs of mild degeneration of CCK immunoreactive fibers in the neocortex, hippocampus and striatum of SST2 but, again, not in SST1 KO animals.
Our results indicate a fundamental role of the SST2 receptor in the global maintenance and integrity of the CNS noradrenergic system. To what extent similar degenerative/expression changes may occur in any neuropsychiatric/neurodegenerative disorder is an interesting question. If so, our studies may provide critical data for therapeutic intervention involving, presumably, SST2 agonists.

Title: Individual differences in peripheral inflammatory signaling controls susceptibility to social defeat stress

Authors: *G. E. HODES[1], M. PFAU[1], S. A. GOLDEN[1], D. J. CHRISTOFFEL[1], M. HESHMATI[1], H. ALEYASIN[1], M. LEBOEUF[2], M. MERAD[2], S. J. RUSSO[1];
[1]Neurosci., [2]Gene and Cell Med. and Oncological Sci., Icahn Sch. of Med. at Mt. Sinai, New York, NY

Abstract: Interleukin-6 (IL-6) is increased in the blood of subjects with depression and may reflect hyperactivity of the peripheral immune system. We utilized repeated social defeat stress (RSDS), an animal model of depression, to examine individual differences in the peripheral

immune response to stress. After exposure to RSDS some animals termed susceptible show a spectrum of depression-like behavior, whereas resilient animals behave more akin to controls. Susceptible mice exhibit heightened IL-6 levels following their first defeat, which remains elevated 48 hours after the last defeat. To examine if IL-6 levels contribute to individual differences in stress sensitivity, peripheral mononuclear cells (PBMCs) were isolated before mice were exposed to RSDS. Cells were stimulated with lipopolysaccharide (LPS) in vitro to examine IL-6 release. PBMCs from animals who later developed a susceptible phenotype had an exaggerated release of IL-6 in response to LPS stimulation. IL-6 release negatively correlated with social interaction ratio scores. Furthermore, mice that became susceptible to RSDS had more circulating PBMCs than mice that displayed a resilient phenotype. The number of isolated PBMCs also negatively correlated with the individual animals social interaction ratio score. To test the functional relevance of what appears to be a heightened peripheral IL-6 response to stress, we blocked susceptibility to RSDS by systemically injecting an antibody that neutralized IL-6 in the periphery. Additionally, IL-6 knockout mice also displayed resilient behavior. We then ablated the peripheral immune system of C57BL/6J mice and replaced it with bone marrow from IL-6 knockout mice. Bone marrow transplantation from an IL-6 knockout mouse promoted resiliency to RSDS. Furthermore, bone marrow transplants from susceptible mice induced social avoidance following a sub-threshold microdefeat. Together these studies indicate that individual differences in the inflammatory response to stress underlie the development of depression-like behavior in the social defeat model.

Title: The Role of 5-HT4 receptor in hippocampal neurogenesis increased by chronic SSRI treatment

Authors: *E. SEGI-NISHIDA[1], Y. IMOTO[1], T. KIRA[1], K. KOBAYASHI[2];
[1]Systems Biosci., Kyoto Uni. Phamacutical Sci., Kyoto, Japan; [2]Nippon Med. Sch., Tokyo, Japan

Abstract: Hippocampal neurogenesis is increased by chronic treatment of selective serotonin (5-hydroxytryptamine, 5-HT) reuptake inhibitors (SSRIs). SSRIs increase proliferation and differentiation of neural progenitors in the dentate gyrus (DG). Among 14 subtypes of 5-HT receptors, Gs-coupled receptors, such as 5-HT type 4, 5, 6, 7 receptors, in the postsynaptic cells have been postulated to be involved in the promotion of neurogenesis. Since 5-HT type 4 (5-HT4) receptor is expressed at a high level in the DG and the treatment of 5-HT4 receptor agonist increases cell proliferation in the DG, we investigated whether 5-HT4 receptor is involved in the promotion of hippocampal neurogenesis by SSRI treatment by using 5-HT4 receptor deficient (5-HT4R KO) mice. 5-HT4R KO mice and wild-type (WT) mice were treated with fluoxetine as a SSRI at a dose of 22 mg/kg/day for 21 days. While the fluoxetine treatment significantly increased cell proliferation in the DG of WT mice, no significant change was observed between saline and the fluoxetine treatment in 5-HT4R KO mice. Doublecortin-immunoreactivities (DCX-IRs), as one of the markers for neurogenesis, in the DG were also increased in fluoxetine-treated WT mice compared with saline-treated WT mice. On the other hand, no changes were observed in DCX-IRs between saline and the fluoxetine treatment in 5-HT4R KO mice. We then examined whether 5-HT4 receptor regulates expression change of genes by the fluoxetine treatment in the DG. The expression of several genes, such as NPY, in the DG of WT mice was significantly increased by the fluoxetine treatment, but not in that of 5-HT4R KO mice. These results suggest the involvement of 5-HT4 receptors in the increase of the hippocampal neurogenesis by the chronic SSRI treatment.

Title: Epigenetic modulation of hippocampal mGluR5 regulates coping strategies to repetitive stress

Authors: *Y. YEONG SHIN, G.-T. KIM, C. KIM, D. KIM;
Yonsei univ. col. of medicine, Seoul, Korea, Republic of

Abstract: After repetitive exposure to the same stressor, varied behavioral responses can occur and are often maintained long time. We investigated the role of mGluR5 in individual differences in coping strategies established in response to stressful stimuli in rats and discovered that, repeated exposure to restraint stress caused variably altered mGluR5 protein expression levels in the hippocampus. SD rats were subjected to the restraint stress for 1 hour/day for 6 consecutive days, and the effect of restraint stress on mGluR5 expression was examined. During each stress episode, electroencephalogram (EEG) was measured in order to observe the real-time brain activity. The low mGluR5 protein expression group showed increased methylation sites on the CpG island of the mGluR5 gene, decreased mGluR5 mRNA expression, and unaltered basal theta electroencephalogram power and corticosterone blood concentrations, suggesting positive behavioral adaptation. In contrast, the high mGluR5 protein expression group showed the opposite results, suggesting negative adaptation. These individual differences were abolished by injection with the mGluR5 antagonist MPEP. Thus, this study suggests that memories on previous experiences of stress determines levels of individual's stress controllability, which then constructs certain skills for behavioral adaptation needed to cope with stress when given repetitively. Moreover, this study also found that mGluR5, one of the candidate molecules that may have potential connections to behavior adaptation patterns, played a critical role in the development of these stress coping strategies.

Title: Next generation sequence analysis of mRNA expression in the prefrontal cortex of mice subjected to chronic unpredictable stress

Authors: *J. A. AZEVEDO[1], C. L. COOKE[2], J. M. MCKLVEEN[4], J. P. HERMAN[4], R. C. THOMPSON[3];
[1]PiBS Neurosci., [3]Psychiatry, [2]Univ. of Michigan, Ann Arbor, MI; [4]Psychiatry and Behavioral Neurosci., Univ. of Cincinnati, Cincinnati, OH

Abstract: Chronic stress is recognized as a major precipitating event for a host of psychiatric illnesses including affective and mood disorders. Here we report the use of unbiased next-

generation sequencing methods to examine mRNA expression profiles in the infralimbic/prelimbic cortex (IL/PL) of mice subjected to chronic variable stress (CVS), an animal model of depression, as well as control mice.
For mRNA expression profiling, RNA libraries were constructed using Illumina adapters and methods. Sequences were generated by the University of Michigan DNA sequencing core facility with an average of 57.7 million reads per sample. After sequences were confirmed to contain inserts, adapter sequences were trimmed and the resulting 50 base pair reads mapped to UCSC genome annotations. Final mRNA counts were derived through an Oracle-based pipeline and subjected to RPKM normalization to derive the final results.
Analysis revealed roughly 5,000 differentially expressed transcripts ($p<0.05$). We selected 64 mRNAs for qPCR validation (60 transcripts identified by RNA-seq as differentially expressed, 2 endogenous controls and 2 “housekeeping” genes) based primarily on prior association with psychiatric illness. The expression of these transcripts were then measured using Taqman Low-Density Array cards (ABI); from these, 31 transcripts achieved significant differential expression compared to controls ($p<0.05$).
Comparative in situhybridization studies currently underway focus on a subset of these mRNA transcripts to identify the neuroanatomical component of stress-induced mRNA alterations. In addition, as prior studies have linked microRNA (miRNA) disruption to both anxiety and affective disorders (Perkins et al, 2007; Kim et al, 2011) we are currently performing additional miRNA profiling studies to identify stress-induced alterations in the miRNA regulatory network. By examining widespread genomic disruptions, as well as their neuroanatomy and epigenomic regulatory effects, we will be in a position to better understand the contribution of dysregulated gene expression in the pathophysiology of psychiatric illness.

Title: Comparing chronic exposure to light and agomelatine in the reversal of depressive-like behaviour in a rat model of depression

Authors: *J. J. DIMATELIS[1,2], D. J. STEIN[3], V. A. RUSSELL[2];
[2]Human Biol., [3]Psychiatry and Mental Hlth., [1]Univ. of Cape Town, Cape Town, South Africa

Abstract: Exposure to stressors during the early stages of development has been shown to have a negative impact on psychopathology in later life. Rat pups subjected to repeated separation from the dam (for 3h per day during the first 2 weeks of life) display behavioral, endocrine and molecular changes that reflect changes found in patients with depression and hence provides a useful model to study the molecular basis of behavioral alterations induced by early adversity. Light treatment has previously been shown to have antidepressant effects in a rodent model of maternal separation (MS) and hence this study aimed to compare the effects of chronic constant light exposure (3 weeks, from postnatal day (P) 42 - 63 during adolescence with an anti-depressant (agomelatine, treated from P42 - 99) in MS rats. As agomelatine acts on similar molecular targets as light exposure, the comparison between treatments would provide valuable information with regard to their mechanism of antidepressant action. Behavioral assessments included ultrasonic vocalizations (22 kHz) and forced swim test (FST) which were conducted at two time points (P65-67 and P97-99) to determine short and long term effects of treatment. At P98, MS resulted in an overall increase in the duration of 22 kHz vocalization, which is in line with increased anxiety-like behavior in depressed animals. At P65 and P98, treatment with agomelatine resulted in increased duration of 22 kHz calls in MS animals compared to vehicle treated rats. Similarly, agomelatine increased the number of 22 kHz calls at P65 of MS rats. Light treatment did not have an effect on 22 kHz vocalizations at any time point. No differences were found in locomotor activity in the open field. In the FST, MS resulted in decreased swimming and hence were less mobile, while agomelatine increased swimming in MS rats, which is in line with the molecular actions of the antidepressant acting to increase serotonergic neurotransmission and that increased swimming in the FST is driven by a greater serotonergic drive. Conversely, MS increased climbing in the FST, while agomelatine decreased climbing behavior in MS rats. The results suggest that agomelatine has an anxiolytic/antidepressant effect on MS rats. Agomelatine also appeared to increase social anxiety and exploratory activity in the MS rats by increasing 22 kHz calls when removed from the home cage and increasing time spent in the center zone of the open field. Constant light exposure during adolescence did not have any effect in this study.

Title: Involvement of homer1a in resilience to chronic mild stress

Authors: *Y. SHUI[1,2], R. YAMAMOTO[2], N. KATO[2];
[1]China-Japan Friendship Hosp., Beijing, China; [2]Physiol. Dept., Kanazawa Med. Univ., Uchinada, Japan

Abstract: Chronic stress is a risk factor for psychiatric diseases. Homer1a is an activity-dependently induced member of the scaffold protein family Homer1, which is implicated in stress-induced emotional changes. To clarify the role of Homer1a protein during chronic mild stress, we investigated the effects of chronic restraint stress (CRS) on wild-type and Homer1a knockout (Homer1a(-/-)) mice. Both types of mice were under restraint for 2 hrs daily for 7 consecutive days, and compared with respective no-restraint controls in behavioral tests. In either group of mice, the restraint induced no change in anxiety-like behavior or pain responses. However, the open field test revealed hypoactive locomotion in the Homer1a (-/-) group without restraint, whereas those with restraint showed a significantly elevated locomotive activity. In brain slices prepared from the mice used for behavior, we examined neuronal excitability in cingulate cortex pyramidal neurons and synaptic efficacy in the hippocampal CA1. In wild-type mice after restraint, the excitability or synaptic efficacywas not significantly different than in non-restraint controls. By contrast, in slices from Homer1a (-/-) mice after restraint, the excitability was elevated as assessed with the frequency of spikes evoked by current injection. Also, the restraint broadened the spike width, which was caused byBK channel blockade. Furthermore, the synaptic efficiency was significantly increased, as revealed by calculating the fEPSP slope vs. the size of fiber volley. These results suggest that the locomotive activity increased by chronic mild stress in Homer1a (-/-) mice may be attributed to cortical hyper-excitability and synaptic up-regulation, and that Homer1a may be required for resilience to chronic mild stress.

Title: Nogo-Receptor-1 limits behavioral and anatomical plasticity associated with fear learning and extinction

Authors: *S. M. BHAGAT[1], S. M. STRITTMATTER[2];
[1]Cell. Neuroscience, Neurodegeneration and Repair, [2]Neurol., Yale Univ., New Haven, CT

Abstract: During early development behavioral and cortical plasticity are more labile compared to adulthood. Previous studies have shown that extinction training can erase fear memories in rodent pups (prior to P16). However, in adulthood, after the formation of myelin and perineuronal nets, fear memories become resistant to erasure. Our lab has recently shown that Nogo Receptor 1 (NgR1), a neuronal receptor for myelin associated inhibitors, limits cortical plasticity, decreasing turnover of dendritic spines and axonal varicosities in the adult CNS. We found that NgR1 knockout (KO) mice maintain juvenile levels of cortical plasticity throughout adulthood. Therefore, we are currently investigating whether adult NgR1 KO mice show similar behavioral plasticity in fear conditioning and extinction similar to that seen in juvenile mice. We found that adult male NgR1 KO mice show enhanced fear learning in a weak fear-conditioning paradigm compared to WT mice. In this paradigm mice are presented with three pairs of a tone followed by a low amplitude foot shock. However, with a stronger conditioning paradigm, including a higher amplitude foot shock, the NgR1 KO and WT mice showed equal freezing rates. On the second day of extinction, 48 hours after acquisition using the stronger fear conditioning paradigm, NgR1 KO showed enhanced extinction compared to controls. A week later we found that, unlike WT mice, NgR1 KO mice exhibit no spontaneous fear recovery during recall. This suggests that NgR1 KO adult mice undergo fear erasure following extinction. In addition, tamoxifen-inducible conditional NgR1 KO mice show similar rates of extinction and extinction recall as do constitutive NgR1 KO mice, indicating that these effects do not require NgR1 deletion during development. We are using two-photon in vivo imaging to explore the correlation of spine turnover in the frontal association cortex with the behavioral findings. These studies elucidate NgR1 as a potential novel target for treating Post Traumatic Stress Disorder.

Title: Fluoxetine reverses disrupted maternal care but not depressive-like behavior after chronic corticosterone exposure

Authors: *J. L. WORKMAN[1], A. R. GOBINATH[1], N. F. KITAY[1], C. CHOW[1], S. BRUMMELTE[2], L. A. M. GALEA[1];
[1]Univ. of British Columbia, Vancouver, BC, Canada; [2]Wayne State Univ., Detroit, MI

Abstract: Women are twice as likely as men to suffer from depression and the postpartum period confers considerable risk for developing depression. Stress and glucocorticoids are consistently associated with depressive disorders and individuals with depression generally have higher cortisol concentrations and impaired HPA axis negative feedback. In many rodent studies, chronic variable stressors or exogenous corticosterone (CORT; the primary glucocorticoid in most rodents) induce a depressive-like phenotype. However, most models of depression have primarily used males. Our prior research indicates that high CORT given to postpartum females reduces maternal care, increases depression-like behavior, and alters hippocampal plasticity, consistent with a depressive-like phenotype. The goals of the present study were to investigate how chronic CORT alters behavior and the brain in females at different reproductive stages and to determine whether a CORT-induced behavioral phenotype can be reversed using a common antidepressant, fluoxetine (FLX). Female Sprague Dawley rats were either mated or remained reproductively inexperienced (nulliparous) and then received either CORT or oil and FLX or saline (yielding 8 groups) every day for 22 days (for postpartum rats, this coincided with postpartum days 2-24). Maternal care was observed postpartum days 2-8 and depressive-like behaviors were assessed in the forced swim test (FST) on days 23-24. As previously established, postpartum CORT disrupted maternal care and increased immobility in the FST. Notably, FLX reversed CORT-induced changes in maternal care. However, FLX did not significantly decrease immobility in the FST in either nulliparous or postpartum females. Furthermore, contrary to our expectations, nulliparous females spent more time immobile compared with postpartum females in response to CORT. Nulliparous females also had a shorter latency to first immobility. We are currently investigating how CORT and FLX regulate hippocampal plasticity in this study. These data contribute to our understanding of how reproductive states may alter the susceptibility to depression and antidepressant efficacy in CORT-induced depression-like behavior in females. Title: The role of spontaneous neurotransmission in fast-acting antidepressant response

Authors: *E. S. GIDEONS, E. T. KAVALALI, L. M. MONTEGGIA;
Neurosci., UT-Southwestern Med. Ctr., Dallas, TX

Abstract: Recent work has shown that spontaneous release of glutamate activates a subset of *N*-methyl-*D*-aspartate receptors (NMDARs), which are distinct from NMDARs that are activated by action-potential mediated release of glutamate. Spontaneous release of glutamate and activation of NMDARs generates relatively small influxes of calcium (Ca^{2+}) that has been shown to mediate tonic levels of eukaryotic elongation factor 2 (eEF2)-kinase activity in phosphorylating eEF2, thereby suppressing protein translation in the dendrite. In contrast, acute blockade of NMDARs at rest inhibits eEF2-kinase phosphorylation of eEF2; leading to desupression of local translation in the dendrite of many proteins. Ketamine, a non-competitive NMDAR antagonist, causes a fast-acting anti-depressant effect in depressed patients and preclinical models. Additionally, it causes decreased phosphorylation of eEF2 and increased BDNF translation in the hippocampus within 30 min following administration. While the clinical data of ketamine's fast-acting antidepressant effect is exciting, it is known that ketamine has a high abuse potential so memantine, a NMDAR open channel blocker that is FDA approved for other indications, is under investigation for fast-acting antidepressant efficacy. A single dose of memantine has not been shown to cause a fast-acting antidepressant effect in depressed patients leading to the natural question, why not? This study will address three main questions: 1) does a single dose of memantine cause a fast-acting antidepressant response in a preclinical mouse model? 2) does ketamine or memantine block the NMDAR at rest with physiological Mg^{2+} present? 3) what effects will memantine have on the phosphorylation of eEF2?

Title: Anxiety- and depressive-like behavior in an experimental model of perimenopause

Authors: *K. V. WEISSHEIMER[1], D. E. RIBEIRO[2], S. R. L. JOCA[3], J. A. ANSELMO-FRANCI[1];
[1]Dept. of Morphology, Physiol. and Basic Pathology, Univ. of Sao Paulo - Dent. Sch., Ribeirao Preto, Brazil; [2]Dept. of Pharmacol., Univ. of Sao Paulo - Sch. of Med., Ribeirao Preto, Brazil; [3]Dept. of Physics and Chem., Univ. of Sao Paulo - Sch. of Pharmaceut. Sci., Ribeirao Preto, Brazil

Abstract: Perimenopause is a stage of fluctuations in plasma levels of sex steroids, when the woman experiences regular and irregular cycles, or prolonged amenorrhea of less than 12 months. This transition period to menopause may cause an increase in vulnerability in some women to mood disturbances like depression and anxiety, resulting in a decreased quality of life. However there is some degree of controversy in the etiopathogeny of mood disorders in perimenopause. Hormonal, neurochemical and genetic factors have been suggested, but these explanations remain to be clarified. Ovariectomy has been the primary rodent model to examine effects of ovarian hormone loss on mood disorders. This model limits evaluations to abrupt and complete ovarian hormone loss, and it does not reproduce the transitional hormone fluctuation via ovarian follicular depletion that occurs in woman. An ovotoxic chemical, 4-Vinylcyclohexene-diepoxide (VCD), produces accelerated ovarian follicular depletion in rats, with reproductive hormone profiles similar to naturally menopausal transition in women. We have evidenced that VCD injected intraperitoneally (160 mg/kg/day) in rat for 15 days causes follicular depletion, decrease in progesterone levels and corporal temperature, 80 days after VCD treatment has begun, indicating a perimenopausal period. In this study, we investigated whether VCD administration would promote behavioral effects on mood of female rats and how they would respond to treatment with saline (S) or imipramine (Im), a tricyclic antidepressant. Rats (28 days) received vehicle (V) or VCD for 15 days. From the 45º day after this treatment, estrous cycles were verified during 2 weeks and animals were selected to the behavioral tests on diestrus II day within the regular cycle. Rats were submitted to open field and forced swimming test (FST) around the 80º day after the beginning VCD treatment. Open field was performed one day before FST. Animals received 3 injections of saline or imipramine (1 mg/kg) 24, 13 and 1 hour before FST. They were divided into V+S, VCD+S, V+Im and VCD+Im groups (n= 6-9/group). Open field and FST data were analyzed by t-test and two-way ANOVA respectively. Exploration of the periphery and rearing frequency of the open field were significantly reduced in VCD+S vs V+S. Immobility time in FST was significantly increased in VCD+S when compared to other

groups. Imipramine significantly decreased immobility time in FST in vehicle and VCD animals. Our results indicate that the VCD rat-model of perimenopause promoted mood disorders, similar to women during the menopause transition, and imipramine treatment prevented depressive behavior.

Title: Effects of testosterone on depressive-like behavior and hippocampal gene expression in male rats

Authors: *S. K. SALAND[1,2], N. M. CARRIER[3], F. DUCLOT[1,2], M. KABBAJ[1,2];
[1]Dept. of Biomed. Sci. & Program in Neurosci., [2]Ctr. for Brain Repair, Florida State Univ., Tallahassee, FL; [3]Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX

Abstract: Gonadal hormones have been implicated in the pronounced sex differences in depression, where the prevalence is at least twice as high in women as it is in men. In particular, low levels of circulating testosterone in hypogonadal men are associated with an increased incidence of depression, which can be effectively reversed with testosterone replacement. Moreover, testosterone supplementation reverses and protects against depressive-like behaviors in gonadectomized (GNX) and aged male rats, respectively. Previous work from our lab demonstrated a role for the hippocampus, an area highly implicated in the etiology of depression, in mediating these effects in male rats. In this brain region, testosterone may exert its antidepressant effects through androgen receptor mediated mechanisms, or via local aromatization to estrogen. Therefore, we examined the roles of testosterone and estrogen on depressive-like behaviors and gene expression in the hippocampus of adult male rats. Supplementation with both testosterone and estradiol in GNX male rats attenuated depressive-like behavior in the forced swim test and sucrose preference test. Blocking the conversion of testosterone to estrogen in the hippocampus with the aromatase inhibitor fadrozole produced variable effects on behavior, suggesting a complex functional role of these hormones in the hippocampus on anxiety- and depressive-like behaviors in male rats. Genome-wide cDNA microarray analysis was used to examine potential mechanisms in the hippocampus by which

testosterone and estrogen influence depressive-like behavior, revealing substantial and overlapping transcriptional regulation of depression-relevant genes by both hormones in GNX male rats.

Title: Comparison of antidepressive effects following cortical versus auricular electroconvulsive stimulation in rats

Authors: W. THEILMANN[1,2], C. BRANDT[1,2], M. RHEIN[3], H. FRIELING[3,2], S. BLEICH[3,2], *W. LOSCHER[1,2];
[1]Dept. of Pharmacology, Toxicology, and Pharm., Univ. of Vet. Med. Hannover, Hannover, Germany; [2]Ctr. for Systems Neurosci., Hannover, Germany; [3]Dept. of Psychiatry, Social Psychiatry and Psychotherapy, Hannover Med. Sch., Hannover, Germany

Abstract: Major depressive disorders are one of the most common psychiatric illnesses in industrial nations. A very effective treatment of severe depression is the induction of controlled therapeutic seizures, which are known as electroconvulsive therapy (ECT). There are several experimental studies in which electroconvulsive shocks (ECS) are delivered to rodents via earclip (auricular) electrodes. This is not in line with the clinical procedure where seizures are induced via stimulation of cortical areas, using electrodes attached to the scalp. It is known from epilepsy research that the location as well as the type of stimulation has a crucial impact on the seizure event.
Aim: The aims of this study were to establish a model of ECS that is closer to clinical conditions and to compare the regulation of brain-derived neurotrophic factor (BDNF) after auricular and cortical stimulation.
Methods: Male Wistar (Janvier) rats were implanted with screw electrodes over the primary motor cortex. The animals received five ECS on consecutive days either via cortical or auricular stimulation. Stimulation strength was 7-10 mA for 1 sec with cortical and 70-85 mA for 0.5 sec with auricular stimulation, using a 100-Hz stimulus. A simultaneous EEG-recording allowed the evaluation of seizure severity and length according to the clinical procedure. A further group of animals was treated with citalopram (15 mg/kg) for 21 days. The forced swim test, sucrose

preference test, hyponeophagia test and the recording of ultrasonic vocalization were performed to reach conclusions about the antidepressant effect of ECS. Subsequently, changes in DNA methylation and protein expression of BDNF in the prefrontal cortex and hippocampus were analyzed.
Results: Both types of stimulation induced similar convulsive seizures of 18-21 sec duration as well as similar effects in the forced swim test. Furthermore, auricular stimulation was associated with adverse effects such as significant weight loss and increased occurrence of aversive 22 kHz calls, which was not observed with cortical ECS. Preliminary experiments on Bdnf DNA methylation in the prefrontal cortex BDNF expression did not indicate any differences between control and ECS-treated rats.
Outlook: This new established model for ECT is the basis for further studies in chronic models of depression in which it is planned to investigate mechanism of resistance to ECS.

Title: Adaptive fitness; early life adversity improves adult stress coping in heterozygous serotonin transporter knockout rats

Authors: *R. VAN DER DOELEN[1], T. KOZICZ[2], J. HOMBERG[3];
[1]Cell. Animal Physiol., Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]Anat., [3]Cognitive Neurosci., Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands

Abstract: Early life adversity in the form of childhood abuse has been associated with increased risk for the development of psychiatric disorders like major depression. Recent reviews, however, have postulated the possibility that instead of a necessary pathological role of early life adversity rather the match or mismatch between the early and later (e.g. adolescent, adult) life environment could determine vulnerability to stress-related psychiatric disorders. Using the maternal separation paradigm as a model of early life stress, we tested serotonin transporter heterozygous and homozygous knockout and wild-type rats for their shock escape behavior, after previously being exposed to inescapable shock stress. The maternal separation group showed

decreased escape latencies, which was found to be most significant in heterozygous serotonin transporter knockout rats (doi: 10.1038/mp.2012.186). Our study therefore shows that a putative match between early life adversity and later life adversity leads to an adaptive stress escape response, particularly in subjects that are stress sensitive by genotype. Our results nuance the prevailing theory that 5-HTTLPR s-allele carriers have an increased risk to develop depression when exposed to ELS, and suggest that carrying the s-allele does not inevitably have negative consequences. Rather, the increased sensitivity of s-allele carriers to a respective match or mismatch between the early and adult life environment may govern their adaptive or maladaptive responses to stress.
Within our animal model we have found that early life stress and serotonin transporter gene variation interact to program basal activity of the adult hypothalamo-pituitary-adrenal axis. We furthermore found that this gene x environment programming is most profound at the level of the adrenal gland. At the meeting, we would like to propose a working hypothesis which is a synthesis of our behavioural and physiological findings.

Title: Clinical doses of citalopram reduce immobility time in the forced swimming test in Wistar rats with low immobility, while reboxetine or amitriptyline modulates all female rats. Citalopram (10 mg/kg) lacks of effect in all female rats

Authors: *J. PINEDA, A.-G. FLORES-SERRANO, F. J. HEREDIA-LOPEZ, F. J. ALVAREZ-CERVERA, J. L. GONGORA-ALFARO;
Univ. Autonoma de Yucatán, Merida, Mexico

Abstract: The sensitivity of the immobility time (IT) in the forced swimming test to antidepressant-drugs such as Amitrityline differs in rats expressing motor activity with high or low level during the first five minutes at the onset of the conditioning session of the forced swimming test (FST). However, it is not known whether this heterogeneity is also expressed in female rats after the administration of the most selective reuptake inhibitors for 5-HT (SSRI) citalopram, or for noradrenaline (SNRI) reboxetine. Since it is known that the effective dose of

the SSRIs and SNRIs to modulate the behavior during the forced swim in rodents is about ten times larger than the dose used in clinical, in this work we compared the influence of clinical doses of either the SSRI citalopram or the SNRI reboxetine, with the action of the tricyclic antidepressant amitriptyline on two subgroups of female Wistar rats which expressed high IT (HI; at or above the mean) or low IT (LI; below the mean) during the initial 5 minutes of the first session of the FST. When vehicle was applied to any of HI or LI rats, the IT increased in the second session of the test ($p < 0.001$). This increment concurred with a climbing time (CT) decrement ($p < 0.001$) without any change in the swimming time (ST; $p > 0.05$). When amitriptyline (15 mg/kg) was tested, the CT increased for both HI and LI rats ($p < 0.0001$). This increment was accompanied by an IT decrement in HI rats ($p < 0.003$), while for LI rats there was no change in the ST ($p > 0.05$) or in the IT ($p > 0.05$). Reboxetine (0.16 or 1 mg/kg) precluded the IT and CT changes in both HI and LI rats ($p > 0.05$) and reduced the ST in LI rats ($p < 0.05$). Citalopram (0.4 to 3 mg/kg) differentially mimicked the influence of reboxetine on the IT and CT in LI rats ($p > 0.05$), and in HI rats only at 3 mg/kg ($p > 0.05$). The effect persisted when the IT and the CT of LI rats were evaluated with citalopram (3 mg/kg) during metaoestrus/diestrus, and during proestrus/estrus. Yet, at the dose of 10 mg/kg citalopram completely lacked of effect in HI or LI rats. None of the tested drugs increased motor activity in the open field test. These results show that clinical doses of citalopram selectively preclude to the behavioral changes only in female Wistar rats showing high level of motor activity at the onset of the first session (first five minutes) of the FST. Alternatively, the amitriptyline or reboxetine preclude the behavioral changes during the FST in all the female Wistar rats.

Title: The change of astrocytic proteins in the depressive-like mouse brain

Authors: *H. KIM, H. G. S. S. HYUN JOON KIM;
Dept. of Anat. and Neurobio., Gyeongsang Natl. Univ. Sch. of Med., Jinju, Korea, Republic of

Abstract: Many evidences from postmortem and rodent studies indicate that astrocyte pathology and glutamate metabolism abnormalities are associacted with the aetiology of depression. Astrocyte is known to play an important role in the glutamate metabolism through forming tripartite synapse and glutamate/glutamine (Glu/Gln) cycle. The glutamine synthetase (GS), an enzyme that forms glutamine by an ATP-dependent amination of glutamate, is related to metabolism of neurotransmitter and the glial fibrillary acidic protein (GFAP) is relevant to structural change of astrocyte. Therefore, this study investigated the changes of GS and GFAP in the mouse brain after chronic immobilization stress (CIS), a rodent model of depression. Moreover, we measured Glu/Gln contents in the brain and blood using high-performance liquid chromatography. To measure the GS activity more directly, we established new GS activity assay method. Animals exposed to CIS exhibited a significant reduction in body weight and behavioral symptoms of depression in the sucrose preference test and forced swim test. The GS activity was increased in the prefrontal cortex (PFC) of CIS-induced depression animals, but not GS expression. Unlike the GS, GFAP was decreases in the PFC in stress group compared with the control. The Glu and Gln levels were decreased after CIS treatment in the PFC and blood. These results suggest the involvement of astrocytic glutamate regulation and structural alteration in the aetiology of depressive disorder.

Title: Female H/Rouen mice selectively bred for depressive-like behavior display enhanced vulnerability for cocaine reinforcing effects

Authors: *V. RAPPENEAU[1], A.-L. MOREL[1], P.-H. LUPPI[1], J.-M. VAUGEOIS[2], M. EL YACOUBI[1], A. BEROD[1];
[1]UMR5292/INSERMU1028 Physiopathologie des réseaux neuronaux du cycle veille-somme, Ctr. De Recherche En Neurosciences De Lyon, LYON, France; [2]Univ. de Rouen, EA 4651-ABTE /ToxEMAC, U.F.R. Médecine & Pharmacie, Rouen, France

Abstract: Cocaine addiction is often associated with psychiatric disorders, in particular with depression. To shed light on the neurobiological mechanisms by which depression-like states may enhance addictive behaviors, we used Helpless mouse line (H/Rouen) that exhibit depression-like behavior in validated tests compared to Non Helpless mouse line (NH/Rouen) derived from the same colony.
To test the sensitivity to cocaine of these two lines, dose-response curves for cocaine-induced motor activity (0-30 mg/kg doses) were performed. Interestingly, a right shift of the dose-response curves and higher ED50 values were observed in both male and female H/Rouen mice, in comparison with NH/Rouen mice, indicating that H/Rouen mice were less sensitive than NH/Rouen mice to the acute psychomotor effects of cocaine. Interestingly, despite differences observed after acute injection, H/Rouen and NH/Rouen mice displayed similar sensitivity to chronic cocaine psychomotor stimulant effects assessed in the behavioral sensitization paradigm. Conditioned place preference (CPP) tests were then conducted to establish the relative potency of cocaine reinforcing effects in the different mouse lines. Preferences scores were evaluated 1 and 5 days after 4 cocaine pairings (10 mg/kg). In male mice, equivalent CPP responses were observed in the two lines. In contrast, female H/Rouen mice exhibited a stronger cocaine-induced CPP compared to NH/Rouen mice at 1 and 5 days after conditioning, indicating a higher sensitivity to cocaine reinforcing properties.
Our results show that psychostimulant properties of cocaine would not predict the strength of its reinforcing or addictive effects, suggesting that distinct neurobiological mechanisms underlie the motor and reinforcing effects of cocaine. Moreover, they offer the possibility to explore the neural substrates that mediate the increased sensitivity to cocaine reinforcing effects observed in female H/Rouen mice. Preliminary results, using Fos immunohistochemistry, highlight a lower activation of subregions of the prefrontal cortex in female H/Rouen mice compared to female NH/Rouen mice, suggesting a reduced executive control over motivation triggered by the cocaine-paired environment. Moreover, they underline a higher activation of the nucleus accumbens core and the amygdala in female H/Rouen mice compared to female NH/Rouen mice, that may reflect their higher propensity to conditioned drug-seeking. Further analyses are currently performed to fully characterize the neurobiological mechanisms underlying the enhanced vulnerability of H/Rouen females for rewarding effects of cocaine.

Abstract: Mehamphetamine (METH) abuse leads to cognitive and mood abnormalities including depressive symptoms. A single METH-injection to rodents recapitulates the dopaminergic/serotonergic dysfunction seen in METH addicts. However, the behavioral correlate of these neurochemical deficits has been overlooked. Herein, we aimed to characterize the neurobehavioural changes at early and long-term stages following a single-high dose of METH. Adult C57BL/6 mice (3-4 month-old) were injected with 30 mg/kg METH,i.p and evaluated up to 49 days post-injection. Pole-test (PT), Morris water maze-(MWM, cued platform) and tail-suspension test (TST) were conducted to evaluate movement, procedural memory and depressive-like behaviors parameters. Frontal cortical and striatal changes in monoamine homeostasis as well as GFAP levels were also evaluated by HPLC-ED and western-blotting. All values were expressed as means ± SEM and statistical significance was evaluated by Student's two-tailed t test or by ANOVA followed by Newman-Keul´s (GraphPad Prism 5.00.288). The significance level was set at a p value less than 0.05. METH increased the immobility time at 3 and 49 days post-treatment in the TST ($p<0.05$). On the contrary, METH did not disrupt basal ganglia-related movement as seen in the PT at 3 days post-treatment. Additionally, METH did not impair procedural learning and memory over the four testing days in the cued version of the MWM (1-4 days post-treatment). Moreover, swimming velocity was not changed in METH treated mice. This further stresses that intoxicated mice had normal motor activity. As per neurochemistry parameters, DA and TH depletion (30 - 40%; $p<0.05$) that were observed in frontal cortex and striatum at 3 days remained at 49 days post-treatment. METH evoked a 5-HT depletion in frontal cortex at 3 days post-treatment (*circa* 25%; $p<0.05$) that was maintained for 7 weeks. A robust yet transient astrogliosis was observed in striatum at 3 days ($p<0.01$). This further confirms the neurotoxic profile of this single dose. Our results show for the first time that a bolus injection of methamphetamine imposes a prolonged depressive-like behavior underlined by a long-term serotoninergic/dopaminergic frontostriatal disruption. This experimental model of long-term depression-like behavior is of relevance to unravel the neurobiological substrate underlying depressive symptoms seen in METH addicts.

Title: Clomipramine relieves chronic social defeat induced depression-like symptoms in male tree shrews

Authors: *Y. X. YANG, SR, W. JING;
Kunming Inst. of Zoology, Yunnan, China

Abstract: In this paper, we use chronic social defeat model in male tree shrews (*Tupaia belangeri chinensis*) as a new depression animal model. Because activity-dependent persistent changes in synaptic strength can be mediated by stress processes in brain areas such as the hippocampus, we examined whether social defeat affected synaptic plasticity in the CA1 region of the hippocampus of stress-exposed tree shrews. We also tested the effects of a classical tricyclic antidepressant (TCA) clomipramine in this model to evaluate the face validity, the predictive validity, and the construct validity.
The modeling includes four phases: adapting phase (the 1^{st} week), stress phase (the $2^{nd}$to the 6^{th} week), drug administration with social defeat phase (the 3^{rd} to the 6^{th} week) and recovery phase (the 7^{th} week). Each two male tree shrews were housed in a pair-cage consisting of two independent cages separated by a wire mesh partition with a door connecting the two cages. After one week adaptation, the connecting door was opened and a brief fighting occurs between the two male tree shrews and this social conflict session consisted of 1 h direct conflict (fighting) and 23 h indirect influence (e.g. smell, visual cues) per day. The defeated tree shrew was considered the subordinate.After establishing the social defeat model successfully, we gave the drug intervention, and tested the symptoms correlated with the depressed patients (including anhedonia, urine cortisol level and negative memories) and the symptoms uncorrelated with the depressed patients (including body weight, jumping, self-grooming and avoid behavior) in each

weekend. Clomipramine was given 50 mg/kg intragastriclly (i.g.) every morning during the drug administration phase. It is important to note that the psychosocial stress situation was continued during the drug treatment. After 35 days chronic social defeat, depression-like symptoms as decrease of 5% sucrose preference, loss of body weight, reduction of locomotors and self-grooming, increase of avoidance behavior, disrupted urinary cortisol rhythm and strengthened of one-trial captive conditioning memory (that is negative memory) were all emerged on subordinate tree shrews (Sub + saline group) compared with naïve animals (Ctrl group).

Title: The effect of maternal care on depressive-like behaviors in female offspring

Authors: *A. BORROW, M. STOLOW, N. M. CAMERON;
Psychology, Binghamton Univ., Binghamton, NY

Abstract: Natural variations in maternal care have demonstrated effects on progesterone levels in female rat offspring. Females exposed to low levels of maternal licking/grooming during the first week of life (Low LG) exhibit higher plasma progesterone levels at proestrus relative to recipients of high levels of maternal care (High LG). Progesterone has been shown to decrease depressive-like behaviors on the forced swim test. Attenuation of depressive-like behavior may occur through progesterone's upregulation of brain derived neurotrophic factor (BDNF), a neurotrophin that has been negatively correlated with depression symptomatology. We sought to assess whether natural variations in maternal care could induce differences in depressive-like behaviors, and to determine if this effect was mediated by differences in progesterone activity. To obtain High and Low LG offspring for testing, maternal behavior of Long Evans dams was scored on postnatal days 1-6 during five daily observations that occurred every three minutes during 72-min periods. Licking/grooming (LG) behavior 1SD above the cohort mean was characterized as High LG behavior, whereas behavior 1SD below the mean was considered Low LG. Adult female offspring were subjected across the estrous cycle to either a saccharin preference task or a forced swim test. For the saccharin preference task, animals were deprived of water for two hours, then administered a two-bottle choice test for one hour across a 10-day period. For the forced swim test, animals were tested over two days across proestrus and estrus

or estrus and metestrus. Our data show that Low LG offspring preferred saccharin more than Highs, with significant differences at both estrus and diestrus. Low LG females tested on the forced swim task during proestrus and estrus spent the least amount of time floating and had a longer latency to float on the second day of testing. Given the established differences in progesterone levels between Low and High LG female offspring, it is possible that these group differences in behaviors are mediated by this sex hormone. Plasma progesterone levels will be assessed and BDNF protein levels will be quantified in brain regions associated with rodent models of depression.

Title: Sex differences in topographically-specific effects of social stress on ventral tegmental area dopaminergic neurons

Authors: *G. GREENBERG[1], M. Q. STEINMAN[2], K. R. SCROGGINS[2], I. E. DOIG[2], D. G. ESQUIVEL[2], B. C. TRAINOR[1];
[1]Neurosci. Grad. Group, [2]UC Davis Dept. of Psychology, Davis, CA

Abstract: Activity of mesolimibic dopaminergic neurons in the ventral tegmental area (VTA) has generally been associated with hedonic experiences, but VTA activity has also been linked to aversive stimuli. Indeed, there is increasing evidence for topographical organization of dopaminergic neurons in the VTA, with distinct projections responding to hedonic or aversive stimuli. Social defeat stress is an ethologically valid paradigm for modeling stress in rodents, and it consistently produces a distinct suite of depressive-like symptoms, including social withdrawal. Previous studies in male mice suggest differences in susceptibility to social defeat stress stem from changes in VTA dopaminergic neuron excitability. Whether this system influences differences in female responses to social stress is not known. This is in part because the majority of studies using social defeat in animal models have focused on male rodents. We previously reported sex differences in the effects of social defeat on social withdrawal behavior in California mice (Peromyscus californicus). Here, we randomly assigned male and female California mice to three episodes of social defeat or control conditions. We characterized

neuronal activity within the dorsal-ventral extent of the VTA, employing cFos and tyrosine hydroxylase (TH) double-label immunohistochemistry to indirectly measure dopaminergic neuron activity. Stressed female mice had a significantly greater percent of TH cells in ventral VTA coexpressing cFos when compared to control females, suggesting increased dopaminergic activity in this region. Additionally, stressed female mice had significantly more TH-positive cells in ventral VTA compared to control females. These increases were not observed in stressed male mice. Interestingly, both control male and female mice had significantly increased percent colocalizations in the middle VTA when compared to stressed mice. No effects of stress on percent colocalization were observed in dorsal VTA. These data support the hypothesis that responses of VTA dopamine neurons to aversive contexts are topographically organized.

Title: Angiotensin-(1-7) central administration induces anxiolytic-like effects in elevated plus maze and decreased oxidative stress in the amygdala

Authors: *C. ALIN STELIAN[1], W. BILD[2];
[1]Alexandru Ioan Cuza Univ. Iasi, Iasi, Romania; [2]UMF Iasi, Iasi, Romania

Abstract: There is increasing evidence that besides the well-known angiotensin (Ang) II, other renin-angiotensin system (RAS) peptides, including Ang-(1-7), could have important effects at the central level.
However, very few things are known about the central actions of Ang-(1-7), while the effects of its administration alone on anxiety were not tested to this date, according to our knowledge. In this way, we were interested in studying the effects of Ang-(1-7) intracerebroventricular administration on anxiety levels, as studied through some main behavioral parameters in the elevated plus maze, as well as the importance of Ang-(1-7) in the oxidative stress status from the amygdala, which is one of the key brain regions involved in mediating anxiety.
We report here a possible anxiolytic-like effect of Ang-(1-7) administration, as demonstrated by the increased percentage of time spent and frequency of entries in the open arms of the elevated plus maze, as well as increased head-dipping behavior in the open arms and decreased stretching

in closed arms. Also some antioxidant effects of Ang-(1-7) are suggested since a significant increase of GPX specific activity and a decrease of the main peroxidation marker MDA were observed in the amygdala. Moreover, we found a significant correlation between most of the behavioral parameters in the elevated plus maze and the levels of the oxidative stress markers. However, further studies are necessary in order to elucidate the effects of Ang-(1-7) administration on anxiety and oxidative stress status and also on the possible correlation that might exists between these aspects.

Title: Single prolonged stress: Validity of translating PTSD model into mice

Authors: *A. L. EAGLE[1], K. MULO[1], R. J. KOHLER[1], A. CONTI[2,3], S. A. PERRINE[1]; [1]Psychiatry & Behavioral Neurosci., [2]Neurosurg., Wayne State Univ. Sch. of Med., Detroit, MI; [3]John D. Dingell VA Med. Ctr., Detroit, MI

Abstract: The single prolonged stress (SPS) rat model of posttraumatic stress disorder (PTSD) has shown great potential in understanding the behavioral phenotypes, such as re-experiencing memories triggered by cues associated with the trauma, as well as their underlying neurobiological bases, such as enhanced dexamethasone suppression of the HPA-axis stress response. The current project aimed to translate the SPS model for use in mice and investigate its validity as a rodent model of PTSD. Male C57 mice were exposed to a modified “mouse SPS” (mSPS) paradigm or control treatment and were tested 7 days post stressors. Separate groups of mice were tested for trauma cue-induced freezing, locomotor activity, and anxiety-like (thigmotaxis) behavior in a novel open field or dexamethasone suppression of plasma corticosterone (CORT) levels. For trauma cue-induced freezing a pulsed tone sequence was

paired with the mSPS stressors. Seven days later the mice were placed into a novel open field and reintroduced to the tone. Another group of mice were treated with daily oral paroxetine (10 mg/kg/day), a selective serotonin reuptake inhibitor (SSRI), in their drinking water during the 7 day period after mSPS and then tested for trauma cue-induced freezing behavior. The mSPS treatment increased trauma cue-induced freezing, but when the tone was not present did not produce freezing. The increase in trauma cue-induced freezing was blocked by paroxetine. mSPS also enhanced dexamethasone-induced suppression of plasma CORT. Hippocampal glucocorticoid receptor expression, linked to the enhancement of dexamethasone suppression, is currently being investigated in this model. mSPS did not produce significant changes in either locomotor activity or anxiety-like behavior, mirroring previous findings with SPS in rats. The enhanced trauma cue-induced freezing and increased suppression of plasma CORT reflect clinical symptoms. Blockade of trauma cue-induced freezing by paroxetine, an SSRI and primary treatment of clinical PTSD, models current drug therapy to reduce the symptoms of PTSD. These findings provide strong construct and predictive validity for mSPS as a model of PTSD in mice.

Title: The rewarding effects of exercise do not depend on wheel running controllability

Authors: *J. J. HERRERA[1], P. J. CLARK[2], S. M. ENGEL[2], B. N. GREENWOOD[2], M. FLESHNER[2];
[2]Integrative Physiol., [1]Univ. of Colorado, Boulder, CO

Abstract: The mesolimbic reward pathway is implicated in the development and treatment of stress-related psychiatric disorders such as anxiety and depression. Exercise can reduce the incidence of stress-related disorders, but the contribution of exercise reward to exercise-induced stress resistance is unknown. We have reported that the anxiolytic and antidepressant-like effects of exercise are independent of exercise controllability; whereby both voluntary and forced wheel running protect rats against behavioral consequences of stress. Voluntary exercise is a natural reward, but whether rats can find forced wheel running rewarding is unknown. The goal of the

current studies was to determine whether the rewarding effects of wheel running depend on its controllability. Following 1 week of voluntary running, male F344 rats (8 / group) were divided into voluntary and forced groups. The wheels belonging to rats in the forced group were rotated by motors following a predetermined schedule designed to closely resemble the typical pattern of voluntary running behavior. For 5 weeks, rats were placed into their assigned voluntary or forced wheels or, on alternating nights, into an empty cage. Two hours after wheel or empty cage exposure, rats were placed on one distinct side of a conditioned place preference (CPP) chamber. One side was always paired with running (paired) and the opposite side was paired with the empty cage (unpaired). Probe tests to determine CPP were conducted 1, 3, and 5 weeks after the start of CPP training. After the final probe trial, and 24 hours after the last running exposure, rats were placed on either the paired or unpaired side and sacrificed 30 minutes later. Double in situ hybridization (FISH) was used to assess potential conditioned activation of reward circuitry elicited by acute exposure to the side paired with exercise. Finally, pCREB expression in the medial and lateral VTA, subregions of the VTA implicated in the signaling of reward and aversion respectively, were quantified in a separate cohort of rats given access to voluntary or forced wheels for 6 weeks. Results suggest that both voluntary and forced wheel running are rewarding. Rats spent more time on the side of the CPP chamber paired with exercise during each probe trail, regardless of wheel running controllability. Moreover, both voluntary and forced wheel running increased pCREB in DA neurons in the medial, but not lateral, VTA. Analyses of the double FISH are currently underway. Together, these data suggest that both voluntary and forced wheel running can be rewarding. The rewarding effects of exercise could contribute to the mechanisms by which exercise increases stress resistance.

Title: The impact of voluntary exercise on stress-induced disruptions in diurnal rhythms of sleep and physiology

Authors: *R. S. THOMPSON[1,2], B. N. GREENWOOD[1,2], M. FLESHNER[1,2];
[1]Univ. Colorado Boul, BOULDER, CO; [2]Ctr. for Neurosci., Univ. of Colorado at Boulder, Boulder, CO

Abstract: Exercise can increase resistance to stress-related psychiatric disorders such as anxiety and depression. One way exercise may confer stress resistance is by reducing the impact of stress on sleep and diurnal physiological rhythms; disruptions of which are thought to contribute to stress-related disorders. Indeed, exercise is a powerful non-photic entrainment cue to the biological clock and thus could help prevent or reverse stress-induced disruptions in diurnal rhythms. Adult male F344 rats (8 per group) remained sedentary or had voluntary access to wheels for 6 weeks. After 4 weeks of exercise, rats were implanted with F40-EET biotelemetry devices (DSI) and real-time continuous diurnal/circadian rhythms were recorded. Following a 1-week recovery period, rats were again allowed access to running wheels for an additional 2 weeks. Diurnal rhythms of locomotor activity, heart rate, body temperature, and sleep (i.e. REM, NREM, and WAKE) were continually recorded in the presence of a 12hr light/dark cycle in running and sedentary rats. After a total of 6 weeks of exercise, both the sedentary and running rats were exposed to a single acute stressor (100, 5-s, 60-s ITI inescapable tail shock) previously reported to disrupt physiological diurnal rhythms and produce behaviors resembling symptoms of affective dysregulation. Physiological parameters were measured prior to, during, and following stressor exposure. Compared to sedentary rats, exercise rats had larger diurnal amplitudes of locomotor activity rhythms, core body temperatures and %REM during the light (inactive) cycle prior to stressor exposure. The increase in REM persisted following stress in the exercise rats. During stress, both groups reached maximal heart rate, but physically active rats reached a higher maximum body temperature. Stressor exposure impacted diurnal rhythms of activity, heart rate, body temperature, and sleep in both sedentary and exercise rats; and these changes persisted for 48-96 hours. These data suggest that protection against stress-induced disruptions in diurnal rhythms and increases in REM sleep could contribute to the cognitive and affective benefits of exercise.

Title: Plasma testosterone levels and the development of posttraumatic stress symptoms after military deployment: A prospective cohort study

Authors: A. REIJNEN, *E. GEUZE, E. VERMETTEN;
Military Mental Hlth/UMC, Utrecht, Netherlands

Abstract: Introduction Testosterone is a steroid hormone that plays a role in the regulation of sexuality, aggression, cognition and emotions. Several studies suggest that plasma testosterone levels are altered after acute physical and psychological stress. As of yet it is unknown whether testosterone levels are altered following prolonged exposure to high-intensity stress. Military deployment is a period of prolonged stress in which military personnel is often exposed to stressful experiences. The aim of the present study was to investigate the effect of military deployment on testosterone levels. In addition, the predictive value of testosterone levels on the development of posttraumatic stress symptoms was assessed.
Method This study is part of a prospective cohort study on deployment-related health problems in the Dutch armed forces. Morning plasma testosterone levels of 481 male soldiers were assessed before and 1 month and 6 months after deployment to Afghanistan. Participants were assigned to the PTSD or comparison group based on their scores on the Self-Rating Inventory for PTSD symptoms after deployment.
Results Preliminary results indicate that testosterone levels before and after deployment were not significantly different. In addition, there were no statistically significant differences in plasma testosterone levels before and after deployment between the participants with a high level of PTSD symptoms and the comparison group. However, the level of testosterone directly after deployment was found to predict the development of a high level of PTSD symptoms in the two years after deployment.
Discussion The finding that plasma testosterone levels are comparable between the group with a high level of PTSD symptoms and the comparison group is in agreement with other studies. The current study also showed that testosterone levels after deployment did not differ from the baseline measures. These results suggest that, whereas alterations were found in acute stress situations, the hypothalamic-pituitary-gonadal (HPG) system might adapt under prolonged psychological stress.

Title: Identifying mechanisms by which exercise prevents inescapable stress induced instrumental learning deficits

Authors: *P. J. CLARK[1], J. AMAT[2], P. R. GHASEM[3], S. O. MCCONNELL[3], S. F. MAIER[2], B. N. GREENWOOD[3], M. FLESHNER[3];
[2]Psychology & Neurosci., [3]Integrative Physiol., [1]Univ. of Colorado-Boulder, Boulder, CO

Abstract: The World Health Organization predicts depression will become the largest economic health burden on society by 2030. However, the neural mechanisms that underlie depression are not well understood. Exposure to uncontrollable stress is a major risk factor for developing mood disorders like depression. In rat models, exposure to inescapable stress (IS) produces a sequelae of depression-like behaviors including deficits in the shuttle box escape task, a form of instrumental learning. Shuttle box escape deficits following IS are dependent on sensitized serotonin (5-HT) activity at receptors in the dorsal striatum during the mild stress (foot shock) used to motivate task acquisition. Our lab has observed that shuttle box escape deficits following IS are prevented in rats that engage in voluntary wheel running for 6 wks prior to IS. Yet, comparatively less is known about how exercise prevents such deficits. One hypothesis is that exercise attenuates IS-sensitized 5-HT transmission in the dorsal striatum during mild stress, which may consequently impact activity of additional neurotransmitters critical for instrumental learning including dopamine (DA). Attenuated 5-HT and/or potentiated DA transmission in the striatum of running animals during stress may increase activity in populations of striatal neurons hypothesized to signal reward or reduce activity in neurons involved in aversion, which could provide protection against shuttle box deficits. The purpose of this experiment was two-fold. 1) Identify the effects of mild stress (two foot shocks, 0.8mA, 5s duration) applied 24h following IS on extracellular concentrations of 5-HT and DA in the dorsal medial and lateral striatum of running and sedentary adult male Fischer 344 rats using *in vivo* microdialysis. 2) Identify whether 6 wks of running in Fischer 344 rats alters neural activity (as measured by *c-fos*) elicited by IS in populations of dynorphin (reward signaling) and enkephalin (aversion signaling) expressing dorsal striatal medium spiny neurons using fluorescent *in situ* hybridization. Results indicate that IS-induced sensitization of extracellular 5-HT is blunted, and DA concentrations are potentiated in the dorsal medial striatum following mild stress of running compared to sedentary rats. Data collection for
the dorsal lateral striatum is currently underway. Moreover, preliminary results suggest 6 wks of running decreases the number of enkephalin neurons expressing the activity marker *c-fos* during IS compared to

sedentary rats. Taken together, these data provide a potential mechanism by which 6 wks of exercise prevents depression-like deficits in instrumental learning following IS.

Title: Reduced hypothalamic NOS activity and CB1 mRNA cannabinoid receptors are related to behavioral impairments in stressed rats

Authors: B. BURDET[1], D. G. MAUR[1], A. DE LAURENTIIS[1], V. RETTORI[1], *M. ZORRILLA ZUBILETE[2,1];
[1]Sch. of Medicine, Univ. of Buenos Aires, CEFYBO-CONICET, Buenos Aires, Argentina; [2]Sch. of Med., Depth. Pharmacology, Sch. of Medicine, U.B.A., Buenos Aires, Argentina

Abstract: Chronic stress leads to activation of the hypothalamo-pituitary-adrenal axis (HPA) and changes in different parameters in limbic areas associated with stress. The hypothalamus is the main brain structure involved in the neuroendocrine control of stress and anxiety and it has been demonstrated that nitric oxide (NO), a free radical produced by nitric oxide syntase (NOS), participates in these processes. On the other hand, there is evidence that endocannabinoid system can modulate stress responses. The aim of the present work was to study the effect of chronic restraint stress on behavioral impairments and the participation of the endocannabinoid system and NO in these effects (using a NOS inhibitor, L-NAME and a NO donor, Molsidomine). Restraint stress was applied to adult Sprague-Dawley male rats for two hours daily during 7 consecutive days (7d). Inhibitory avoidance and elevated plus maze tests, NOS activity, oxytocin and corticosterone plasma levels and cannabinoid receptor type 1 (CB1) levels in hypothalamus were evaluated. A significant decrease ($p<0.001$) in the activity of hypothalamic total NOS was found in stressed animals respect to control (C) animals. The expression of hypothalamic CB1

mRNA was significantly reduced ($p<0.05$) after restraint stress. Oxytocin and corticosterone plasma levels were significantly increased in stressed rats ($p<0.01$ and $p<0.05$ respectively). Moreover, we found a significant decrease in the latency to enter into the dark compartment in the 7d respect to C ($p<0.05$) as well as in 7d+Veh and C+L-NAME groups respect to C+Veh ($p<0.01$ and $p<0.05$ respectively) in the inhibitory avoidance test. Also, a significant increase in the percentage of entries and time spent in the open arms in the 7d respect to C ($p<0.05$) as well as in 7d+Veh and C+L-NAME groups respect to C+Veh ($p<0.05$) was found in the elevated plus maze test. In conclusion, our model of stress elicited anxiolytic-like behavior and a deficit in associative memory that could be related to the decrease in NO production and CB1 receptors levels in the hypothalamus. Also the increase in oxytocin plasma levels could contribute to the behavioral changes observed.

Abstract: Posttraumatic
Stress Disorder (PTSD) is an anxiety disorder that may develop following to an exposure to a highly traumatic event. Up to today, many researchers have proposed animal models to study the neurobiological mechanisms underlying PTSD. Most of these models have been derived from Pavlovian fear conditioning, and it is known that prior exposure to traumatic stress enhances conditional fear responding to subsequent mild stress. We previously reported that the multiple stress (MS) consisted of foot shocks and forced swimming had long-lasting (more than 2 weeks) effects on subsequent fear conditioning. And, these effects were not influenced by suppression of stress-induced secretion of glucocorticoids (GCs) by metyrapone or adrenalectomy. In this study, we examined whether pharmacologically blocking central CRF receptors would affect the effects

of the MS on subsequent contextual fear conditioning. Two different shock chambers, Context A chamber and Context B chamber, were used for delivering the MS and conducting the fear conditioning, respectively. These chambers differed in the context including illumination, background sound and so on. Male Wistar-Imamichi rats were exposed to the MS consisted of 4 spaced foot shocks (1 mA, 1 s) for 25 min in the Context A chamber and forced swimming for 20 min in a plastic bucket. Non-stressed control animals were placed in the Context A chamber and a plastic cage for the same amount of time as the MS animals without foot shocks and swimming, respectively. Either CRF receptor antagonist, alpha-helical CRF (5 or 20 μg, i.c.v.), or saline were administrated 20 min before exposure to the Context A chamber. Contextual fear conditioning was conducted 14 days after the MS. All animals were exposed 2 mild foot shocks (0.1 mA, 2 s) in the Context B chamber. Conditioned fear response (freezing) in the Contex B chamber was assessed in three retention tests, which were conducted on the next, 7 and 14 days after the conditioning. The results showed that the central administration of alpha-helical CRF did not affect the MS-induced enhancement of conditioned fear response. These results suggest that central activation of CRF receptors triggered by MS is not involved in regulating the long-term stress-induced sensitization of fear.

Title: Voluntary exercise during fear extinction reduces fear renewal: Role for activation of reward circuitry during extinction

Authors: *C. BOUCHET[1], A. MIKA[2], K. G. SPENCE[2], J. E. HELLWINKEL[2], S. CAMPEAU[3], H. E. W. DAY[3], M. FLESHNER[2], B. N. GREENWOOD[2];

Abstract: Recent efforts to treat anxiety and fear disorders focus on fear extinction. Exposure therapy in humans has limited efficacy, however, because fear memories often resurface when the extinguished conditioned stimulus (CS) is presented in a new context (fear renewal). Emerging evidence suggests that extinction involves both cognitive and affective processes. Cognitive extinction processes could support learning of a new CS-NoUS association; whereas affective processes could support the learning of a new (less aversive) emotional "state" assigned to the CS. Manipulations that target both the cognitive (such as noradrenergic (NE) signaling) and affective (such as activation of striatal reward circuits) extinction processes could strengthen extinction memories and make them resistant to contextual modulation during renewal. Acute exercise is both arousing (elevates NE) and rewarding (activates striatal reward circuits); thus could potentially act as an adjunct therapy during extinction to reduce fear renewal. To address this possibility, male F344 rats without (Locked) or with (Run) 3 nights of experience with running wheels, were conditioned to fear a tone CS. Fear extinction (15 CS presentations) took place the next day in the familiar, locked or mobile running wheels. Run rats ran during extinction, and this running was associated with a reduction in freezing and corticosterone during renewal tested in a novel context 1 week later. Run and Locked rats extinguished in a control context displayed identical levels of fear during renewal. Administration of naloxone (5.0 mg/kg; to block exercise reward) immediately prior to extinction reduced the effect of running during extinction on renewal tested 1 week later. These data suggest that exercise during extinction, but not a history of exercise per se, reduces renewal of extinguished fear through a mechanism involving exercise reward. Reward during extinction could reduce renewal by facilitating the learning of a new, less aversive, CS "state;" perhaps via second order conditioning. Consistent with this possibility, double fluorescent in situ hybridization revealed that CS exposure during renewal elicited greater activity (c-fos+) of the reward-associated direct pathway and an attenuation of activity of the aversion-associated indirect pathway of the striatum in rats that ran during extinction, relative to Locked rats. These data suggest that recruiting an affective extinction process could result in an extinction memory that is less susceptible to contextual modulation. Studies are underway to determine if CS value "state" can be coded by relative activation of direct and indirect striatal pathways.

Title: Modeling individual differences in behavioral stress responses to uncover neurobiological mechanisms for resiliency to PTSD

Authors: *M. A. WILSON, A. C. SHARKO, K. F. KAIGLER, A. HAND, A. KERSNOWSKI, M. P. KELLY, J. R. FADEL;

Abstract: Post-traumatic stress disorder (PTSD) is a severe anxiety disorder that can develop after experiencing a life-threatening trauma, such as combat service, assault, or a natural disaster. However, not everyone who experiences these types of traumas develops PTSD, suggesting that some neurobiological factors may confer resiliency, or risk, to the long-term negative effects of traumatic stressors. Research into the neurobiological mechanisms that underlie resiliency has been limited by a lack of animal models that naturally show differential sensitivity to traumatic stress. Previously, our laboratory has demonstrated that outbred Long-Evans rats show individual differences in unconditioned anxiety-like behavior, as measured on the elevated plus maze. To determine if this rat strain also shows individual differences in conditioned anxiety-like behavior, we tested several groups of rats using a conditioned freezing paradigm with or without a prior exposure to predator (ferret) odor as a traumatic stress. Conditioned freezing is useful for modeling the symptoms of re-experiencing trauma seen in patients with PTSD. One week after exposure to control or predator odor, we examined differences in acquisition of conditioned freezing, contextually conditioned freezing, and cue conditioned freezing, as well as latency to extinguish cue conditioned freezing behaviors over several trials of extinction learning. In several different cadres of animals, approximately one third of each group of 12-14 rats failed to completely extinguish the conditioned freezing behavior, even after 20 presentations of the conditioned tone cue, and also demonstrated poor retention of extinction learning 48 hrs and 1 week later. Individual differences between these groups were also seen in subsequent startle and risk-assessment behaviors, as well as neuronal activation in the prefrontal cortex using cFos immunohistochemistry in response to predator odor exposure. These results correlate with clinical statistics showing that approximately 30% of individuals who experience a traumatic event eventually develop PTSD. Additional studies are examining individual differences in patterns of neuronal activation in the prefrontal
cortex and extended amygdala associated with these behavioral patterns.

Title: Evaluating the stress-reducing potential of coffee volatiles in socially isolated mice using stress-induced hyperthermia and open-field tests

Authors: *Y. HAYASHI[1], S. SOGABE[1], M. SUZUKI[1], J. TANAKA[2];
[1]Notre Dame Seishin Univ., Okayama, Japan; [2]Naruto Univ. of Educ., Naruto, Japan

Abstract: We previously reported the stress-reducing potential of coffee volatiles in social mice using the elevated plus maze, pentobarbital-induced sleep and stress-induced hyperthermia tests. Social isolation induces anxiety, depression, and aggression in laboratory animals. Thus, socially-isolated mice appear to be a more suitable experimental model to study putative anxiolytic-like effects of chemical compounds. To further clarify the relationship between coffee volatiles and psychological stress, this study investigated the stress-reducing effects of coffee volatiles in socially-isolated mice using stress-induced hyperthermia and open field tests. Male ICR mice aged 4 weeks and weighing 18-23 g were used. Animals were kept either in social isolation (1 mouse per cage) or in social (5 mice per cage) groups for 10 weeks or more prior to testing. Fresh medium-dark roasted and moderately powdered Guatemalan coffee beans were used. The coffee powder was placed into several plastic cases in a test room with the temperature maintained at 25°C ± 1°C. Mice were exposed to coffee volatiles in the test room. Four hours after the beginning of the exposure period, stress-induced hyperthermia and open field tests were performed. In the stress-induced hyperthermia test, in the absence of coffee volatiles, body temperature elevation was significantly higher in the socially isolated group than in the social group. After four hours of coffee volatile exposure, body temperature elevation in the socially-isolated group was reduced and was similar to that of the social group. In the open field test, without coffee volatiles, defecation was increased in socially isolated mice; other parameters were the same as in the social group. Coffee volatiles decreased defecation in socially-isolated mice. These results suggest that volatile compounds in roasted coffee beans have stress-reducing effects in socially-isolated mice as well as in social mice.

Title: Wheel running produces widespread structural alterations within striatal and limbic regions involved in stress

Authors: *P. R. GHASEM[1], A. MIKA[2], E. A. SISNEROS[2], M. A. KEAG[2], S. M. ENGEL[2], P. J. CLARK[2], B. N. GREENWOOD[2], M. FLESHNER[2];

Abstract: Exercise increases resistance against stress-related disorders such as depression and anxiety, but the mechanisms remain unknown. Exercise produces neuro-plastic and functional adaptations within a variety of brain regions implicated in the behavioral consequences of stress. In the hippocampus, for example, wheel running produces increases in dendritic complexity that parallel improvements in contextual and spatial memory. The effects of exercise on neuronal structure within other brain regions affected by stress, however, remain unexplored. Among the behaviors impacted by stress that are prevented by prior exercise are anxiety-like behaviors (putatively involving the amygdala) and deficits in instrumental learning (putatively involving the dorsal striatum). We examined, therefore, the effects of voluntary wheel running on dendritic arborization in the amygdala and striatum. Adult, male Fisher (F344) rats (n=7/grp for hippocampal analysis and n=8/grp for striatum/amygdala analyses) were allowed either voluntary access to running wheels or remained sedentary for 6 weeks. Brains were immediately removed and processed in accordance with Golgi Stain protocols. Sholl analysis was used to quantify pyramidal cells with the CA3 region of the hippocampus and medium spiny neurons within the dorsal striatum. Wheel running increased dendritic complexity within the CA3 region of the hippocampus as well as within the dorsal striatum. Amygdala analyses are in progress. These data suggest that exercise produces extensive alterations in neuronal structure that may be involved in stress resistance.

Title: Impact of chronic variable versus acute stress experience on conditioned fear memory and sensitized acoustic startle responses in rats

Authors: S. SCHMELTZER[1,3], L. VOLLMER[2,1], C. DOULGAS[2,3], M. WEINERT[2], J. RUSH[2], R. SAH[2,1,3];

Abstract: Exposure to intense traumatic events on an acute or chronic scale can lead to posttraumatic stress disorder (PTSD). Recent studies have demonstrated a steep dose-response curve between trauma frequency and PTSD symptom severity, such that the more traumatic events a person experiences, the greater the intensity of PTSD symptoms. Although this observation has been around in the clinic, there is little evidence on underlying mechanisms. To investigate this phenomenon, rats were exposed to chronic, unpredictable aversive experiences that were superimposed with a primary or "index traumatic event" in the form of electric shocks (chronic variable stress-shock; CVS-S). The comparison group was an acute shock (AS) group which was exposed only to the index traumatic event (shocks). We hypothesized that the CVS-S group would have worse behavioral outcomes. To test this, we measured conditioned fear responses (freezing) and acoustic startle response, which measures sensitized responses. We also assessed neuronal activation using delta fosB and cFos immunoreactivity in fear regulatory brain areas. Consistent with our hypothesis, fear acquisition, recall, and reinstatement were significantly potentiated in the CVS-S rats. No differences were noted in peak startle responses; however CVS-S rats showed improved habituation to startle. These behavioral changes were accompanied by increased neuronal activity in the infralimbic prefrontal cortex and basolateral amygdala of CVS-S rats. In conclusion, our data suggest that chronicity and magnitude of stress or traumatic events worsens fear memory related conditioned responses but may facilitate adaptation to novel aversive encounters.

Title: Role of kynurenic acid in regulating neurochemical and behavioral responses to stress

Authors: *J. I. KOENIG[1], H.-Q. WU[1], T. FUKUWATARI[2], R. SCHWARCZ[1];
[1]Univ. Maryland Sch. Med., BALTIMORE, MD; [2]Food Sci. and Nutr., The Univ. of Shiga Prefecture, Hikone, Shiga, Japan

Abstract: Kynurenic acid (KYNA), one of the principal products of the kynurenine pathway of tryptophan degradation, is an endogenous antagonist of both the NMDA and the alpha-7 nicotinic receptor. In addition, KYNA is an important modulator of forebrain dopaminergic neurons. Stress exposure also modulates dopamine (DA) mechanisms and increases the release of DA in forebrain terminal regions, such as the prefrontal cortex (PFC). Glucocorticoid hormones (GC) appear to mediate stress-induced activation of the ascending DA neurons. These actions of GC on DA may be important in the etiology of depressive behaviors. However, there are also clinical situations when GC responses to stress are blunted, such as in PTSD, and our understanding of the consequences of an inadequate GC response to stress is limited. To test the possible role of KYNA - and specifically of KYNA-DA interactions - in this context, we studied neurochemical and behavioral responses to acute stress in adrenalectomized (ADX) rats. Adult, male animals were surgically ADX or sham operated and received saline to drink after surgery. Six days later, microdialysis guide cannulae were implanted over the PFC. The next morning, microdialysis probes were inserted, and perfusate samples were collected during a 2-hour baseline period, a 2-hour restraint stress and a 4-hour recovery period. Extracellular levels of KYNA and DA were then determined in the same microdialysate by HPLC. In sham rats, restraint stress elevated PFC DA while having no effect on KYNA. In stark contrast, in GC-insufficient ADX rats, DA levels were unaffected by stress exposure while KYNA levels were significantly elevated. Acute pretreatment of ADX rats with a selective, orally active inhibitor of KAT II (the enzyme responsible for KYNA synthesis), restored the DA elevation in response to restraint stress. Using a behavioral outcome measure (fear extinction), we found that ADX rats lacked the cognitive flexibility to extinguish freezing behavior in a long-term memory test. However, ADX rats readily learned the association between tone cues and foot shocks during conditioning trials, and displayed intact short-term memory for the pairing. Acute KAT II inhibition normalized fear extinction in ADX rats. Together, these studies reveal that removal of GC tone disrupts the dynamic regulation of DA mechanisms by endogenous KYNA in the PFC, leading to an inability to extinguish fear memories. Our results suggest that pharmacological down-regulation of KYNA formation may provide a fundamentally novel approach to thwart

dysfunctional memory extinction. This approach may be useful in the treatment of PTSD and other stress-related clinical conditions.

Abstract: Abstract
Substantial evidence indicates that after stressful life events, a high anxiety trait may develop into posttraumatic stress disorder (PTSD) or depression. By activation of the median and dorsal raphe nuclei, which send a major serotonergic input to the hippocampus, stressful events enhance serotonin levels in the dentate gyrus, a region highly susceptible to stress. Using an anxiety disorder model (Tsoory and Richter-Levin 2006), we assessed the effects of stress encountered in juvenility, adulthood and the combination thereof upon behaviour and, using whole cell recordings, examined the 5-HT-mediated modulation of cellular properties and synaptic inhibition of ventral dentate gyrus granule cells. Animals stressed as adults showed depressive-like behaviour in the open field test only after having been exposed to a stressful challenge in juvenility. In controls, serotonin hyperpolarized cells, decreased their input resistance and reduced the amplitude of evoked IPSCs via the 5-HT_{1A} receptor subtype. The latter effect was significantly reduced in animals stressed in juvenility or in adulthood but not in animals stressed

at both ages. Moreover, we found that stress applied in juvenility or in adulthood reduced miniature IPSCs (mIPSCs) and 5-HT-induced bursts of mIPSCs mediated by presynaptic 5-HT_3 receptors. In animals stressed both in juvenility and in adulthood, the reduction in mIPSCs and 5-HT-induced bursts of mIPSCs was significantly smaller. We hypothesize this effect might be due to a reduction in RNA expression levels of 5-HT_3 receptor transcripts found in singly stressed animals, an effect not seen in animals stressed twice. We conclude that in animals exposed to combined stress, the stressful reminder cue given in adulthood results in depressive-like behavior of the animals that is not accompanied with changes of the 5-HT_{1A} and 5-HT_3-induced modulation of synaptic inhibition. In contrast, the exposure of animals to a single stressful experience does not result in behavioral changes, but causes a decrease of 5-HT_{1A}-induced disinhibition and 5-HT_3-induced bursts of mIPSCs. We suggest that stress-induced changes of the serotonergic system and its impact on hippocampal inhibition may provide a protective molecular mechanism that prevents the expression of depressive-like behavior.

Title: Aggression in social contests in veterans with post-traumatic stress disorder

Authors: *L. ZHU[1,2], C. ROSOFF[1,2], K. MCCURRY[2,2], C. B. FRUEH[3], P. H. CHIU[1,2,4], B. KING-CASAS[1,2,4];
[1]The Virginia Tech. Carilion Res. Inst., Roanoke, VA; [2]Res. Service Line,, Salem Veterans Affairs Med. Ctr., Salem, VA; [3]Psychology, Univ. of Hawaii, Hilo, HI; [4]Dept. of Psychology, Virginia Tech., Blacksburg, VA

Abstract: Competitive social interactions involve detecting opponents' actions, extracting relevant information from those actions, and selecting behavioral reactions accordingly.

Dysfunction in receiving or processing behavioral signals from opponents during social contests may result in aberrant emotion regulation, aggression and violence. We tested this hypothesis by studying a large sample of veterans with combat-related post-traumatic stress disorder (PTSD), a group of individuals characterized by hyper-arousal symptoms such as irritability and outbursts of anger.
162 OEF/OIF/OND veterans were recruited in the metro Houston, TX and Southwestern Virginia areas. Participants included 103 veterans meeting criteria for current PTSD. We combined functional neuroimaging and computational modeling with a multi-round interpersonal resource competition that has successfully elicited social information learning signals among healthy subjects in the previous neuroimaging study. We formulated a social reinforcement learning model to examine how the brain encodes and computes social learning signals used to guide behavior in subsequent contests among veterans, to pursue the hypothesis that subjects with combat-related PTSD are pathologically perturbed in the processing of social signals related to opponent's actions, and hence demonstrate aberrant aggressive behavior during competitive social interactions.
Preliminary behavioral analysis suggested that the behavioral estimates of individual differences in social learning was significantly correlated with self-reported measures of anger and aggression, combat exposure, and current PTSD symptom status. These results suggest that the proposed computational model captures an important connection between behaviorally revealed aggression and PTSD symptom status, providing insights into the computational process underlying aberrant decisions at the behavioral level. Additionally, our findings point to further investigations into those decisions at a neuromechanistic level.

Title: The persistence of exercise-induced stress resistance depends on the developmental stage during which exercise is initiated

Authors: *A. MIKA, C. A. BOUCHET, K. G. SPENCE, B. N. GREENWOOD, M. FLESHNER;
Integrative Physiol., Univ. of Colorado, Boulder, Boulder, CO

Abstract: Exercise reduces the incidence of stress-related psychiatric disorders in humans and prevents the development of anxiety- and depressive-like behaviors in rodents, including exaggerated fear and deficits in shuttle box escape learning. When wheel running is initiated around puberty (PND 45-49), the protective effects of exercise persist for 15 days, but are lost by 25 days following forced cessation of exercise. The brain is especially plastic during the prepubertal period, such that the time before puberty could present a window of opportunity for exercise to produce adaptive, stable changes. We therefore examined the effects of exercise initiated in the prepubertal period on the persistence of the stress-protective effects of voluntary wheel running following exercise cessation. Adult (PND 70) and juvenile (PND 24) male, Fisher (F344) rats where allowed access to a running wheel or remained sedentary for 6 weeks. All wheels were then rendered immobile, and rats were exposed to no stress or uncontrollable stress 14 or 24 days later. 24 h following uncontrollable stress, behavioral testing for shock-elicited fear and shuttle box escape occurred, so that exercised rats were forced to remain sedentary for either 15 or 25 days prior to testing. When wheel running was initiated during adulthood (PND 70), the protective effects of exercise on exaggerated fear and shuttle-box escape deficits were lost by 15 days. Interestingly, when wheel running was initiated during the juvenile period (PND 24), the protective effects of exercise persisted longer, and showed no signs of attenuating at 25 days. These results suggest that exercise during early sensitive developmental periods can alter the trajectory of brain development to produce long-lasting stress resistance to the behavioral consequences of exposure to traumatic events during adulthood.

Title: Behavioral outcome of chronic social defeat in four inbred mouse strains

Authors: E. SOKOLOWSKA[1], S. KÄNGSEP[1], Z. MISIEWICZ[1], V. VOIKAR[2], *I. HOVATTA[1,3];
[2]Neurosci. Ctr., [1]Univ. Helsinki, Helsinki, Finland; [3]Mental Hlth. and substance Abuse Services, Natl. Inst. for Hlth. and Welfare, Helsinki, Finland

Abstract: Social defeat paradigm is a social stress model involving daily physical interaction and sensory contact with an unfamiliar aggressive male. This chronic stress results in behavioral changes including social impairment and increase in anxiety and depression-like behaviors. On a molecular level, these effects are mediated by the brain-derived neurotrophic factor in the nucleus accumbens and hippocampus and the corticotropin-releasing factor in the amygdala. However, also other mechanisms are likely important in these and other brain regions. Different inbred mouse strains show distinct responses to stressful stimuli, implying that genetic factors are important in determining susceptibility and resilience to stress. We subjected animals from four strains (C57BL/6NCrI, BALB/cAnNCrI, DBA/2NCrI, 129S2/SvPasCrI) to social defeat paradigm (10 days) by introducing them briefly into the home cage of an aggressive male (CD1) followed by sensory contact for 24 h. To evaluate consequences of repeated defeat we measured body weight, social preference, locomotor activity, and behavior in open field and light/dark box tests. Repeated defeat affected social preference in all four strains, however a larger number of innately non-anxious C57BL/6 mice were resilient to stress, while most of the innately anxious DBA/2 mice were susceptible (C57BL/6 > BALB/c >129S > DBA/2). Mice that experienced defeat had lower locomotor activity, except the 129S mice, which showed stress-related increase in activity. The defeat procedure did not affect normal increase in body weight, except that weight gain was slower in DBA/2 resilient mice (controls vs. resilient, $p<0.01$ and resilient vs. susceptible, $p<0.05$). Social defeat did not affect behavior in open field or light/dark box tests. Our results demonstrate strain-distinctive response to social defeat stress. Overall, innately anxious DBA/2, 129S, and BALB/c mice were more sensitive to social stress than non-anxious C57BL/6 mice, with different levels of behavioral changes in general locomotor activity and social aversion. The different coping strategies to social stress in different strains are likely partially mediated by genetic factors, reflected in perturbed gene regulatory networks amenable for identification with sequencing-based methods.

Title: Chronic quinpirole administration in rats reduces exploratory behavior and increases water contrafreeloading while preserving responsiveness to changing contingencies

Authors: *M. J. FREDERICK, S. E. COCUZZO, M. C. HILL;
Psychology, Hamilton Col., Clinton, NY

Abstract: INTRODUCTION
Contrafreeloading, or working for a freely available reward, is thought to be a form of exploratory behavior. In a putative model of compulsive checking, chronic treatment with the D2/D3 dopamine agonist quinpirole increases contrafreeloading for water in rats. In humans, compulsive checking is performed to reduce anxiety, and checking rituals may be altered or abandoned when the environment changes. Whether a similar degree of flexibility exists in drug-induced contrafreeloading remains unclear. Additionally, this effect of quinpirole could be explained by an increase in anxiety or by an elevated exploratory drive.
OBJECTIVES
We assessed the ability of quinpirole-treated rats with contrafreeloading experience to adapt to changing contingencies by requiring them to alternate between response levers for reinforcement. We then examined the effect of quinpirole on open arm exploration in the elevated plus-maze (EPM).
METHODS
In the contrafreeloading study, 12 saline- and 11 quinpirole-treated (0.5 mg/kg) rats were trained to lever press for water on a fixed ratio 5 (FR5) schedule of reinforcement. On days 1-8, water was available by pressing either of two levers. On days 9-16, free water was also available. On days 17-21, each time a reward was earned the associated lever was made inactive until the reward ratio was reached on the alternate lever. In the EPM study, 12 rats were tested daily for 5 minutes. Entries into and relative time spent on open arms were recorded. On days 4-13, rats received daily injections of quinpirole (0.5 mg/kg) or saline. On days 14-21, all rats received saline. Drug treatments were resumed for days 22-25.
RESULTS
Quinpirole increased contrafreeloading relative to vehicle. On the first two days requiring lever alternation, drug-treated rats earned significantly more rewards than controls. In the EPM, quinpirole reduced open arm time and entries relative to vehicle. On the 8 saline-only days, rats previously treated with quinpirole spent less time on the open arms and showed a trend toward fewer open arm entries compared to drug-naïve rats.
DISCUSSION
The greater number of rewards earned by the quinpirole-treated rats on the first two days of lever alternation indicates that the drug did not prevent learning of this new task, but rather facilitated it. The reduction in exploratory behavior shown in the EPM suggests that the drug's effects on contrafreeloading are due to an increase in anxiety rather than a heightened exploratory drive. These results support quinpirole-induced contrafreeloading as an animal model for compulsive

checking, which in humans tends to be anxiety-driven and somewhat flexible to environmental changes.

Title: Amygdala modulates the behavioral and hormonal consequences of the exposure to fearful reminders in a mice model of PTSD

Authors: *R. R. SOUZA[1,2], L. M. SILVEIRA[1], A. CANTO-DESOUZA[1,2,3];
[1]Dept. of Psychology, Univ. Federal De São Carlos, São Carlos, Brazil; [2]Grad. Program in Psychology, [3]Joint Grad. Program in Physiological Sci., Univ. Federal de São Carlos, São Carlos, Brazil

Abstract: We have recently demonstrated that the exposure of trauma reminders in mice results in long-term altered behavioral, autonomic and hormonal responses, which resemble the fear generalization symptoms seen in posttraumatic stress disorder (PTSD). Here we investigated if the behavioral and hormonal changes induced by trauma reminders exposure are modulated by GABA-benzodiazepine receptors within the amygdala. The experimental setup consisted of exposing male Swiss mice to an intense inescapable footshock (0.5 mA/10 s) followed by three weekly exposures to a cue-reminder (CR) or to a neutral chamber (control-group).The next day, all animals were stereotaxically implanted with guide cannulas bilaterally aimed to the amygdala (AM). Six days later, mice were tested in the elevated-plus maze (EPM). Our results demonstrated that mice exposed to CR spent less time in the open arms of the EPM, when compared to control group (CR= 7.3 ± 3.3%; Control= 31.6 ± 5.9%, $p < 0.05$). Both groups presented high levels of corticosterone (nmol/L) in comparison to a naïve group (CR= 2,46 ± 0,1; Control= 2,88 ± 0,1; Naïve= 0,45 ± 0,1). Interestingly, intra-amygdala infusion of the GABA/benzodiazepine agonist midazolam (MDZ, 30 nmol/0.1µl/side), reverted the anxiety-like behavior observed in the CR-group (time in open arms; MDZ= 58.0 ± 5.6%, Vehicle= 7.3 ± 3.3%, $p < 0.05$), as well as reduced corticosterone release (MDZ= 1,45 ± 0,1; Vehicle= 2,54 ±

0,1), suggesting that the amygdala modulates the high anxiety-like responses elicited by repeated exposure to fearful reminders. Altogether, these results suggest that GABA/benzodiazepine receptors within the amygdala may be critical for fear generalization in PTSD patients.

Title: The role of sleep deprivation in the acquisition of PTSD in the rat

Authors: *W. M. VANDERHEYDEN, G. POE;
Univ. of Michigan, Ann Arbor, MI

Abstract: In today's modern world, sleep deprivation has become increasingly common. It has been suggested that this perpetual state of sleep debt may enhance our susceptibility to diseases and neurological conditions. Indeed, disturbed sleep has been hypothesized to be both a precipitating and sensitizing factor in the development of Post-traumatic Stress Disorder (PTSD). Prospective studies in humans have shown that individuals who report nightmares and fragmented sleep prior to witnessing a traumatic event have increased rates of PTSD. These studies suggest that sleep and sleep timing may be playing a critical and poorly understood role in the acquisition of the neurological condition PTSD.
In order to test the role of sleep deprivation in acquisition of PTSD we used a validated and robust rodent model of PTSD called "single prolonged stress" (SPS). SPS consisted of 2 hours of restraint, followed by 20 minutes of forced swim. After a 15 minute recovery period from the swim, animals were exposed to ether in a bell jar until loss of consciousness. The animals were then allowed 7 days in isolation. SPS has been shown to produce behavioral and hormonal responses that model PTSD. Using this rodent model of PTSD allows for analysis of behavior while allowing for the role of sleep status and PTSD.
Ten, Male, Sprague Dawley rats (300-350g) were used. Five animals were REM sleep deprived for 3 consecutive days for 6 hours during their primary sleep phase using the inverted flower pot method. The other 5 animals were allowed to sleep undisturbed in their home cage. After 3 consecutive days of sleep deprivation or normal sleep, all ten animals underwent SPS followed by a fear conditioning paradigm. This fear conditioning paradigm assessed their ability to recall a

fear associated memory. Briefly, animals were fear conditioned to anticipate a 1 mAmp footshock paired to an auditory tone. In order to extinguish this fear associated memory, 24 hours later, animals were placed in a new environment and heard 30 tones without receiving foot-shock. Another 24 hours later, the animals were placed back into the environment where the memory was extinguished to assess recall of the fear extinguished memory. Previous work has shown that SPS treated rats have difficulty extinguishing this memory and freeze more on this last day.
Three days of acute REM deprivation prior to SPS exposure significantly reduced the level of freezing that occurred on the recall day. These data support the idea that sleep timing and quality may play an important role in regulating the acquisition of PTSD.

Title: Transient forebrain-specific CRF overexpression during early life increases vulnerability for PTSD-like symptoms in adulthood

Authors: *M. TOTH[1,2], M. GROSS[2], I. M. MANSUY[3], E. MERLO-PICH[4], R. ADAMEC[5], V. B. RISBROUGH[1,2];

Ctr., Verona, Italy; [5]Dept. of Psychology, Mem. Univ., St John's, NL, Canada

Abstract: Early life stress is a significant risk factor to develop anxiety disorders including post-traumatic stress disorder (PTSD), however, the underlying neurobiological mechanisms are still not well understood. Corticotropin releasing factor (CRF) is a major regulator of the autonomic, endocrine and behavioral response to stress. CRF concentration is elevated in human subjects diagnosed with PTSD or childhood trauma history. Hence, one can hypothesize that CRF may mediate some long-term detrimental effect of early life stress. To determine the causal

contribution of increased CRF signaling during childhood to increase susceptibility for PTSD, we induced transient CRF overexpression (CRFOE) in mutant mice during prepubertal periods and tested their response to the predator exposure model of PTSD in adulthood. Using a forebrain-restricted reverse-tetracycline system, CRFOE was restricted to forebrain regions to exclude changes of corticosterone concentrations. Developmental CRFOE increased arousal (increased startle reactivity and decreased startle habituation and prepulse inhibition) regardless of predator exposure. Predator stress induced enduring avoidance behavior in a sex-dependent manner. Male mice exposed to both developmental CRFOE and predator stress exhibited increased avoidance behaviors compared to groups receiving predator stress alone, suggesting males require a "double hit", i.e. both developmental CRF exposure and "trauma" exposure to induce a PTSD-like phenotype. Female mice however showed increased avoidance behavior regardless of CRFOE during development, suggesting "trauma" alone is sufficient to induce a PTSD-like phenotype in females. Our findings suggest (1) that increased CRF signaling during development is a significant vulnerability factor for PTSD; and (2) support the double hit hypothesis for PTSD vulnerability in males.

Title: Preexisting differences in the expression of plasticity-related immediate-early genes in the medial prefrontal cortex in a rat model of PTSD

Authors: K. M. BUNTING[1,2], G. PEREZ[2], R. I. NALLOOR[2], *A. I. VAZDARJANOVA[1,2]; [1]VA MEDICAL CENTER, AUGUSTA, GA; [2]Dept. of Pharmacol. and Toxicology, Georgia Regents Univ., Augusta, GA

Abstract: Post-Traumatic Stress Disorder (PTSD) is an anxiety disorder which manifests as generalized anxiety and elevated startle response accompanied by flashbacks and intrusive memories for a traumatic event. Individual susceptibility to developing PTSD exists, because it is manifested in only a portion of individuals exposed to the same traumatic event. Our research focuses on elucidating preexisting differences in the function of the limbic system and assessing whether they are risk factors for developing PTSD. We evaluate functional plasticity by combining behavioral testing in a rat model of susceptibility to a PTSD-like behavioral phenotype (Nalloor, Bunting and Vazdarjanova, 2010), with assessment of expression of two plasticity-related immediate-early genes (IEGs), *Arc* and *Homer 1a (H1a).*

Previously, we reported that rats classified as susceptible (Sus) prior to a traumatic event in our model show impaired fear extinction and lasting elevation in acoustic startle responses compared to rats classified as resistant (Res). Sus rats also have altered hippocampal IEG expression patterns prior to exposure to a traumatic event. Here we report that preexisting functional differences between Sus and Res rats are not restricted to the hippocampus, but are also present in the medial prefrontal cortex. After behavioral classification, Sus and Res rats were allowed to explore and learn about a novel place twice, with a 30 min rest between the exploration events. Their brains were collected for *Arc/H1a* catFISH (cellular-compartmental analyses of temporal activity using fluorescence *in*-situ hybridization) immediately after the second event.

While there were no significant gross differences in exploration behavior between Sus and Res rats, the patterns of IEG expression differed between the two groups. Res rats showed a consistent IEG expression in infralimbic cortex (IL or area 25) during both behavioral events. In contrast, Sus rats had a smaller IEG-expressing neuronal ensembles during both events, with a larger degree of the effect seen during the second event. No between group differences were observed in the prelimbic cortex (PreL or area 32): the second event induced a larger ensemble size than the first event in both groups.

These differences in patterns of IEG expression suggest that Sus rats have deficits in encoding and integration of sensory information in the limbic cortex (area 25) which exists before they experience a PTSD-inducing event. As area 25/IL is known to be necessary for fear memory extinction, an impairment found in PTSD patients, our findings further suggest that impaired functional plasticity in this region is a risk factor for PTSD.

Title: Sex differences in an animal model of PTSD

Authors: *M. MIKOSZ[1], K. ROKOSZ[2], W. SZADZINSKA[2], K. KONDRAKIEWICZ[2], E. KNAPSKA[2];
[2]Dept. of Neurophysiol., [1]Nencki Inst. of Exptl. Biol. PAS, Warszawa, Poland

Abstract: Posttraumatic stress disorder (PTSD) is a relatively common disorder developed following exposure to a traumatic event, afflicting 7-12% of the population within a lifetime. Women are consistently shown to be twice as likely as men to develop PTSD. Moreover, women were shown to have different susceptibility to PTSD following a trauma, depending on their hormonal status related to menstrual cycle. Clarification of the biological mechanism underlying sex differences in the susceptibility to PTSD is necessary to design sex-specific therapies. We addressed the issue of sex differences in susceptibility to PTSD using a valid animal model of acquisition, extinction and renewal of conditioned fear. We addressed two questions: (1) what is the impact of estrus cycle phase on fear memory acquisition, extinction and recall and (2) whether there are sex- and estrus cycle-dependent differences in the activation of the fear-controlling circuit, measured using c-Fos expression as a marker of neuronal activity. We hypothesized that hormonal status would influence memory formation and recall at all stages of the behavioral procedure. Therefore, we monitored estrus cycle phases in female rats and performed the study in a matrix design, carrying out fear conditioning, extinction and fear/extinction memory recall in either estrus or metaestrus phase. Males and gonadectomized animals of both sexes have been trained at corresponding time intervals. While estrus cycle phase of female rats during fear conditioning did not affect their behavior in response to initial CS's of the extinction training, hormonal status during both extinction and fear/extinction memory recall affected animals' freezing rates. Both intact and castrated males, as well as castrated females, showed higher freezing rates than intact females when exposed to CS's presented in the conditioning context. In groups of females differing significantly in their freezing rates during fear/extinction memory recall, the activity of the fear-controlling circuit was studied. Here we present the data concerning c-Fos expression in the circuit comprising of the amygdala, ventral hippocampus and medial prefrontal cortex in these animals.

Title: Effects of heavy alcohol use on frontal cortex activity and behavior during emotional processing in veterans with PTSD

Authors: *G. L. FORSTER[1], D. OLSON[1], L. A. BAUGH[1], J. M. HANSEN[1], R. GAHER[1], J. SIMONS[1], V. MAGNOTTA[2];
[1]Univ. South Dakota, VERMILLION, SD; [2]Univ. of Iowa, Iowa City, IA

Abstract: Emotionally-significant stimuli activate frontal cortical regions such as the anterior cingulate cortex (ACC) and medial prefrontal cortex (mPFC), thought to inhibit the activity of subcortical structures involved in the expression of fear and anxiety states. Many imaging studies suggest that posttraumatic stress disorder (PTSD) is associated with hypofunction of these frontal cortical areas. For example, Vietnam veterans with PTSD fail to show rostral ACC activation during the emotional counting stroop task (ECST) in conditions when combat-related words are presented (e.g. Shin et al., 2001). However, other studies show increased activation of the mPFC or ACC with combat-related imagery in veterans with PTSD (e.g. Hopper et al., 2007; Morey et al., 2008). Differences between studies have been attributed to variation in the tasks used, the chronicity of PTSD (i.e. Vietnam verses post 9/11 veterans), differences in PTSD symptomology, and regional differences in emotional processing within the ACC and mPFC. Another factor that could influence frontal cortex function is alcohol use. As many as 50-85% of individuals with PTSD have a comorbid alcohol use disorder, and heavy alcohol use is associated with reduced ACC activation during evaluation of emotional facial expressions. Therefore the current study aimed to determine behavioral and neural reactivity in response to the ECST in post 9/11 veterans with and without heavy alcohol use. Forty-one male and female right-handed veterans of Operations Enduring Freedom and Iraqi Freedom (OEF/OIF) were recruited, screened for neurological and health issues that would preclude them from the study, and were assessed for combat intensity, PTSD, alcohol use and alcohol dependence. Veterans participated in functional magnetic resonance imaging (fMRI) scanning while performing the ECST adapted for OEF/OIF veterans. At the conclusion of the scanning, participants provided arousal ratings for words comprising the ECST. Veterans with PTSD exhibited increased reaction times to combat-related words in the ECST, and provided higher arousal and negative ratings for combat words compared to veterans without PTSD. Analysis of imaging data thus far suggests increased activation of the ACC in response to combat-related words of veterans with PTSD sans heavy alcohol use or dependence, as compared to control veterans. Overall, the findings will assist in clarifying the relationship between PTSD and ACC function during

emotional processing in veterans, and will provide insight to the impact of alcohol on this relationship.

Title: Pharmacological and deep brain stimulation treatments in rodent models of post-traumatic stress disorder

Authors: E. JANEZIC[1], R. LAHOOD[1], D. STIDD[2], J.-P. LANGEVIN[4], *E. D. FRENCH[3], J.-M. FELLOUS[1];
[1]Psychology, [2]Neurosurg., [3]Univ. of Arizona, Tucson, AZ; [4]Neurosurg., Southern Arizona VA Hlth. Care Syst., Tucson, AZ

Abstract: Post-traumatic stress disorder (PTSD) is a psychiatric disorder marked by symptoms of re-occurrence, avoidance and hyperarousal that afflicts 8-10% of adults (Kessler et al., 1995). Currently only two FDA approved drugs, sertraline and paroxetine, are available for its treatment. However, patients treated with these selective serotonin reuptake inhibitors (SSRIs) rarely exceed response rates of 60% while less than 20-30% of them attain complete remission (Berger et al., 2009). Hyperactivity in the amygdala and a decrease in system-wide dopamine levels have been identified as neurophysiological changes in animal models of PTSD. Our study explores alternative treatments for PTSD by targeting dopamine pathways through pharmacological intervention (nicotine and oxytocin) as well as amygdala involvement via deep brain stimulation. Using a footshock model of PTSD in rats (Corral-Frias, et al, 2012), oxytocin was peripherally administered (SC 0.25mg/kg) immediately after footshock and after three subsequent situational reminders. Nicotine was administered through osmotic mini-pumps (6 mg/day for 17 days) starting 8 hours before the footshock. Deep brain stimulation (DBS) of the amygdala (4 hours/day for 14 days) was tested using a ball-burying PTSD model (Mikics et al., 2008).

The oxytocin group showed a significant increase from baseline in time spent in the center of the open field, and a significant difference from the saline treated group, along with a trend to spend more time in the white side of the black and white box. Nicotine did not produce significant differences from the saline control group in any test. Two weeks following DBS of the amygdala, the trauma associated object (ball) was buried less compared to the paroxetine-treated animals. However the DBS group exhibited greater background anxiety than the paroxetine group as measured by the elevated plus maze. Results from ongoing experiments involving chronic oxytocin treatment using osmotic minipumps will also be presented. The results from our animal model indicate that oxytocin may effectively attenuate the consolidation of the memory, but DBS of the amygdala may be more effective. Thus, oxytocin should further be evaluated as a treatment for PTSD. The decrease in anxiety from smoking as reported by PTSD patients was not confirmed in our animal model at this time.

Title: Sexual Conspecific Aggressive Response (SCAR): A model for sexual abuse and trauma in women during adolescence

Authors: *K. E. TOBON[1,2], G. DIFEO[1], M. CHANG[1], T. J. SHORS[1];
[1]Psychology & Collaborative Ctr. for Neurosci., Rutgers Univ., Piscataway, NJ; [2]Biochem. and Mol. Biol., RWJMS, Piscataway, NJ

Abstract: Sexual trauma during adolescence is extremely stressful and can result in post-traumatic stress disorder (PTSD) and/or major depressive disorder during adulthood (Shea et al, 2005). Women are especially vulnerable to these disorders and more likely to be sexually traumatized (Kessler et al, 2003, & Parker et al, 2010). In addition, the female brain is especially sensitive to stressful life experience (Shors et al., 2009). Little is known about the neuronal consequences of abuse because there is no established animal model. To meet this need, we

developed a model known as SCAR, which stands for Sexual Conspecific Aggressive Response. During puberty, a young female rat was exposed to an adult male for 30 minutes periods every third day for 22 days, for a total of 8 exposures. During each experience, the male pinned the female ~10 times with nearly 30 ano-genital sniffs. As the age of the juvenile female increased, the number of sniffs and mounts upon the juvenile female also increased. These behaviors indicate socially subjugation of the pubescent female, behaviors that were not highly expressed in adult rats of either sex. We hypothesize that the pubescent females will learn to avoid the context where the subjugation occurred, even as adults. To test this hypothesis, we employed a two arm chamber with specific visual and textile cues to differentiate the arms. Juvenile male or females were place in one designated arm of this novel chamber either by themselves, or with either an adult experienced breeder male or breeder female for the SCAR experience described above. At the end of the SCAR procedure (postnatal day 57), experimental animals were allowed to freely explore both arms of the two-arm chamber. The data suggest that the SCAR experience during pubescence decreased exploratory activity in females as adults. These and other data related to this novel model for early sexual trauma in females will be presented.

Title: Effect of pregabalin in the extinction re-call of fear conditioned exacerbated by neonatal maternal separation with early weaning in C57BL6/N mice

Authors: *S. M. MARCELLO;
LOC. PISCINAMANNA, PULA, Inst. Di Farmacologia Traslazionale CNR UOS Pula (CA), PULA (CA), Italy

Abstract: Post traumatic stress disorder (PTSD) can occur following to strong traumatic events. Nevertheless, only a few of the people who experiencing traumatic events get PTSD. Thus, it were identified pre-traumatic risk factors that can explain the development of the disorder. Among these, adverse childhood experiences, such as periodic maternal separation, can evolve in an increase of vulnerability factors toward PTSD diagnosis. Fear conditioning has been

extensively used to model anxiety disorders, including PTSD and to develop new therapies but “normal” animals are usually employed, however, it would be of great utility to use animals with intrinsec vulnerability to the disease. Therefore, we wanted to recreate a validated experimental "platform" including a protocol for neonatal maternal separation with early weaning (MSEW), on which the effect of anxiolytic treatment on fear conditioned extinction re-call will be tested. In this study we investigated, by fear conditioning paradigm, if 30 mg/kg chronic therapy whit pregabalin, would improve fear memory during extinction re-call test respect to chronic therapy whit the anticonvulsant/anxiolytic drug diazepam (1mg/kg i.p.), respect to chronic therapy whit the anticonvulsant/anxiolytic drug diazepam (1mg/kg i.p.), in C57Bl6/N adult mice previously exposed to the MSEW, respect to the mice brought in standard conditions. When adults, C57/BL6/N mice were tested prior in fear conditioning, in order to allow the learning and the expression of cue fear conditioned. 72 hours after fear conditioning learning, the mice were exposed to extinction training to allow and assess the expression of fear-conditioned extinction. The same day, the mice were subdivided in three groups and for 21 days with 30-mg/kg pregabalin or two crescent diazepam doses (0,25-1mg/kg) or vehicle chronically were treated. So, the day of last drug administration, the fear extinction re-call test was assessed. We found that the MSEW model, coupled with the fear-conditioning paradigm could provide a degree of face validity for the model of PTSD, by reproducing the aspect of vulnerability of desease. Finally, the chronic pregabalin treatment improved the extinction re-call respect to vehicle-treated mice and diazepam-treated mice, previously stress-sensitisation by MSEW. These results suggest a new pharmacological therapy adjuvant to cognitive behaviour therapy (CBT) for PTSD.

Title: Noradrenergic fibers in the cerebellar cortex of adolescent female rats become more varicose following 7 days of voluntary wheel running

Authors: *K. TATEYAMA[1,2], H. NEDELESCU[3,4], T. CHOWDHURY[2], G. WABLE[2], G. ARBUTHNOTT[3], C. AOKI[2];
[1]Columbia Univ., NEW YORK, NY; [2]New York Univ., New York City, NY; [3]Okinawa Inst. of Sci. and Technol. Grad. Univ., Okinawa, Japan; [4]Univ. of Antwerp, Antwerp, Belgium

Abstract: The Norepinephrine (NE) system plays an important role in acquisition of motor learning via ascending projections to the cerebellum, mostly originating from the locus coeruleus, an area involved in arousal, vigilance, and responses to stress and panic. Despite the fact that NE fibers innervate practically all parts of the cerebellar cortex, including the molecular layer where the dendritic tree of Purkinje cells reside, it has received little attention. The goal of our study was to determine whether NE innervation is altered in response to mild voluntary exercise on the wheel (ca 5 km/day), and whether this is different from the voluntary hyper-exercise (ca 15 km/day) that is evoked by the stressful situation of food restriction in a paradigm called activity-based anorexia (ABA). Previous studies have shown that hyper-exercise exhibited by ABA rats is maladaptive, in that it causes negative energy balance to the point of death, unless removed from the ABA-inducing environment. To quantify the effect of exercise on NE innervation, three rats were singly housed in the presence of a running wheel starting P36 until P44 (EX group), while four other rats were ABA-induced by allowing voluntary wheel access and limiting food availability to 1 hr/day. In addition, three other rats were singly housed without a wheel but with ad libitum food access (CON group) for the matching ages to obtain baseline values. We used the primary antibody dopamine-β-hydroxylase (DBH from EugeneTech) and subsequently visualized NE fibers and their varicosities with 3,3'-diaminobenzidine (DAB) as the immunolabel. We acquired image stacks of the DAB labeled NE fibers using a confocal microscope equipped with a Photo Multiplier Tube (PMT) for digitization of the microscopic image. Next, using the Neurolucida Software (MBF Bioscience), we traced each NE fiber and added a marker at each encountered varicosity. The inter-varicosity distances were 9.01 ± 0.8 um for the CON group (N =3) and reduced to 6.56 ± 0.2 um for the EX group (N = 3) and also reduced to 6.93 ± 0.3 for the ABA group (N =4). In addition, the total number of varicosities were increased for both the EX and ABA group. This difference across the groups suggests that voluntary wheel running during adolescence increases the amount of NE released in the molecular layer of the cerebellum. Interestingly, the ABA group demonstrated shorter NE axonal total lengths and smaller number of axons, while the EX group exhibited longer fibers and a larger number of NE axons. This latter finding suggests that NE fiber growth may be stunted by hyper-EX and/or food restriction but is enhanced by mild EX.

Abstract: Anecdotal evidence suggests that undergraduate students who take the University of Redlands course Seminar on Compassion exhibit behaviors consistent with improved academic success: enhanced focus, goal-setting, resilience to stress, and general well-being. The course includes the practice of contemplative methods designed to generate compassion, such as those taught by Mother Teresa, Gandhi, and the Dalai Lama. We are using psychological measures of a variety of clinical and nonclinical outcomes such as anxiety, depression, self-compassion, compassion for others, locus of control, and general well-being. Additionally, we are measuring the physiological stress response in the laboratory. We modified the Trier Social Stress Test (TSST) in an attempt to closely mimic academic stress. We replaced the interview portion of the TSST with verbal GRE analogy questions, and included a neutral question period to control for the effect of speaking. Our pre-meditation course data shows that our altered version of the TSST was effective in reducing parasympathetic nervous activation (reduced high frequency heart rate variability), and increasing systolic and diastolic blood pressure, heart rate, and galvanic skin response. It did not induce a surge in salivary cortisol. This provides baseline physiological data which can be correlated to academic success before and after the meditation-based Seminar on Compassion course, so the effects of this course can be quantitated over time.

Title: Sex differences in mu-opioid receptor regulation of reversal learning in the California mouse (Peromyscus californicus)

Authors: *S. A. LAREDO[1], M. Q. STEINMAN[2], C. F. ROBLES[3], E. FERRER[3], G. D. GREENBERG[4], A. LAMAN-MAHARG[4], B. C. TRAINOR[5];
[1]Psychology, Animal Behavior, [2]Psychology, MCIP, [3]Psychology, [4]Psychology, Neurosci., [5]Psychology, Animal Behavior, MCIP, Neurosci., Univ. of California Davis, Davis, CA

Abstract: Cognitive flexibility, the ability of an animal to change its behavioral patterns to better adapt to the surrounding environment, is widely known to be impaired following stressful situations in male rodents. The literature surrounding cognitive flexibility following stress in females, however, remains largely unexplored. Psychological stressors often rely on intra-specific aggression, and in most rodent species, females do not display intra-specific aggression. Utilizing a monogamous rodent, the California mouse, we are able to employ a potent psychological stressor, social defeat, in both males and females since both sexes demonstrate territorial aggression. We previously showed that following social defeat, male mice demonstrated impaired reversal learning in a Barnes Maze paradigm, but females did not. Further analyses indicated that the reason for poor male performance was due to perseverative behaviors, as stressed males were more likely to return to the original target location during reversal trials. Previous studies have demonstrated that the mu-opioid receptor (MOR) is modulated by social defeat stress, and can play a role in spatial learning behavior. When we injected control mice with the MOR antagonist beta-funaltrexamine (β-FNA), they showed a similar phenotype in reversal learning as did mice that had undergone social defeat. Males injected with β-FNA also showed a perseverative phenotype, and returned to the acquisition hole more often than females injected with β-FNA. Based on these data we tested whether defeat decreased MOR gene expression in the hippocampus and prefrontal cortex. Relative gene expression of MOR was not different between sexes or treatments in any brain region examined. Unexpectedly, pro-enkephalin mRNA (a precursor to an MOR ligand), was significantly upregulated in the dentate gyrus of stressed females. The current data suggest that mu-opioid systems are affected by defeat, but not likely at the level of gene expression in the hippocampus or prefrontal cortex. Ongoing studies are therefore examining the effects of defeat on the number

of available MOR binding sites in the hippocampus and prefrontal cortex via autoradiography. This work has important clinical applications for patients suffering from PTSD and depression since a persistent symptom of these diseases is perseveration on negative thought processes. These data thus allow a better understanding of how mental disorders manifest differently in males and females.

Title: P2X7 receptor-driven neuroinflammation plays a role in causing alcohol related brain damage

Authors: *L. ASATRYAN[1], S. KHOJA[1], K. RODGERS[1], H. TSUKAMOTO[2], R. L. ALKANA[1], D. L. DAVIES[1];
[1]Sch. of Pharm., [2]Keck Sch. of Med., USC, Los Angeles, CA

Abstract: The mechanisms leading to brain damage caused by chronic alcohol abuse (alcohol related brain damage or ARBD) remain poorly understood. Recent genetic studies using post-mortem human brain tissue samples and animal models of drinking suggest that neuroinflammation is an important path leading to ARBD. ATP-gated purinergic P2X7 receptors (P2X7Rs) are expressed in neuroimmune cells such as glia and astrocytes and play a critical role in microglia activation and release of pro-inflammatory cytokine IL-1β, a known mediator of neurodegeneration. As such, growing evidence implicates P2X7Rs in the pathophysiology of neurodegenerative and neuropsychiatric disorders. We began testing the hypothesis that P2X7Rs contribute to alcohol-induced neuroinflammation leading to ARBD. Our initial studies found that alcohol can differentially alter P2X7R expression in alcohol-sensitive brain regions depending on the length and amount of alcohol exposure. However, the low blood ethanol concentrations (BECs) used in these studies did not produce neuroinflammatory responses. To overcome this limitation, the current study used mouse models of alcohol exposure that are characterized by

BECs that reach as high as ~ 400 mg/dL (or ~ 100 mM) and that are known to produce significant liver damage resembling human alcoholic liver disease (provided by Southern California Research Center for ALPD and Cirrhosis). We predicted that these models will also lead to increased neuroinflammation. The base model (Hybrid) is generated by intragastric ethanol diet infusion combined with ad libitum feeding of a Western high fat diet for a period of 8 weeks. The effect of ethanol is further amplified by addition of weekly binge events in the Hybrid+Binge model. We tested the expression of P2X7Rs in alcohol-sensitive brain regions from Hybrid and Hybrid+Binge models and compared to those from pair-fed Control animals (given isocaloric dextrose and diet). We found a significant increase in P2X7R expression in Hippocampus, Striatum and Midbrain for Hybrid+Binge as compared to the Control. There was also a significant increase in P2X7R levels in Hybrid compared to the Control in Striatum. Histological changes that occurred in the same brain regions were typical for neuroinflammation in Hybrid and Hybrid+Binge models. The results support the hypothesis and suggest that alcohol induced changes in P2X7R-driven neuroinflammatory processes may cause or modulate ABRD. The findings also identify P2X7Rs as potential new therapeutic targets for developing new drugs to prevent or reduce brain damage associated with chronic alcohol abuse and dependence.

Title: Epigenetic modifications in frontal cortex of HS/Npt mice following chronic intermittent exposure to ethanol

Authors: *G. GORINI[1], S. BLOCH[1], J. C. CRABBE[2], R. A. HARRIS[1], I. PONOMAREV[1]; [1]Waggoner Ctr. Alcohol Addiction Res., The Univ. of Texas at Austin, Austin, TX; [2]Portland Alcohol Res. Center, VA Med. Center, and Dept of Behavioral Neurosci., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Alcohol dependence results from alcohol's effects on various brain targets. Altered patterns of gene/protein expression following excessive alcohol exposure suggest molecular changes at the epigenetic level, which underlies a wide range of adaptations in brain function. Previous evidence from our laboratory showed that neuropathology and neuroadaptations contributing to alcohol addiction and dependence are, at least in part, mediated by alcohol-induced epigenetically mediated changes in gene expression. Here, we investigated the changes in global histone 3 lysine 4 tri-methylation (H3K4me3) and H3 acetylation (H3Ac) in cerebral frontal cortices (FC) of genetically heterogeneous (HS/Npt) female mice subjected to a chronic intermittent ethanol (CIE) paradigm that represents a model for alcohol dependence. Mice were given 4 weeks of 2-hour daily limited access to 15% ethanol and water, under two-bottle choice (2BC) conditions, to measure baseline ethanol drinking and preference. Mice were then exposed to 3 consecutive episodes consisting of 4 days of either ethanol vapor (CIE) or Air (Control) for 16h/day followed by 5 days of 2BC drinking. The CIE paradigm resulted in ~80% statistically significant increase in ethanol drinking during the last 5 days (CIE group compared to Control). Brains were isolated 24 hours after the last drinking session, flash-frozen and sliced, and micropunches from FC were collected for each sample. Total histone extracts were prepared from tissues of 20 Control and 19 CIE mice and levels of H3K4me3 and H3Ac were measured using colorimetric assays. In our initial experiments, CIE exposure induced a statistically significant decrease in H3Ac (-18%; $p<0.05$). In addition, levels of H3K4me3 were inversely correlated with ethanol consumption across all samples ($p=0.05$). We are currently replicating these assays and profiling samples from the same animals to investigate changes in gene expression in response to the CIE treatment. These results advance our understanding of the complex relationship between genetic, epigenetic, and environmental factors affecting gene expression in alcohol dependence.

Title: Changes in the expression of protein phosphatase 2A in ethanol relapse

Authors: *K. MIZUO, R. KATADA, S. OKAZAKI, S. WATANABE;
Dept. of Legal Med. and Mol. Alcohology, Sapporo Med. Univ., Sapporo, Japan

Abstract: Recent studies suggest that the epigenetic regulation of gene expression such as histone acetylation may play an important role in alcohol dependence. We previously found that the decrease of histone H3 acetylation and increase of histone deacetylase 5 (HDAC5) in ethanol relapse. Several studies have shown that protein phosphatase 2A (PP2A) may regulate the HDAC5 nuclear shuttling. In the present study, we investigated the expression of PP2A in the mouse ethanol relapse model. Mice were treated with liquid diet containing ethanol for 10 days. Using the escalating ethanol dosage schedule, the mice were fed the ethanol diet as follows: 1st day: 1 w/v%; 2nd and 3rd day: 3 w/v%; 4th and 5th day: 4 w/v% and from the 6th to 10th day: 5 w/v% ethanol diet, respectively. The control mice were given the same volume of ethanol-free liquid diet with glucose substituted in isocaloric quantities for ethanol. The mice chronically treated with ethanol revealed severe withdrawal signs. Ten days after withdrawal, we performed a conditioned place preference to evaluate ethanol relapse. At the dose of 0.5 g/kg of ethanol, which produced neither preference nor aversion in control group, the alcohol group showed significant rewarding effects. Under these conditions, the mice were killed by decapitation and the limbic forebrain (containing nucleus accumbens) was dissected. PP2A was increased in limbic forebrain at ethanol relapse state. Our findings suggest that the increase in PP2A caused dephospholylation of HDAC5, resulting in the increase of HDAC5 nuclear transport in ethanol relapse.

Title: Neurotoxicity and synaptic transmission alterations in immature and mature rat organotypic hippocampal slice cultures exposed to ethanol

Authors: *D. PELLEGRINI-GIAMPIETRO[1], E. GERACE[1], E. LANDUCCI[1], T. SCARTABELLI[1], F. MORONI[2], G. MANNAIONI[2];

[1]Dept. of Hlth. Sci., [2]Dept. of Neuroscience, Psychology, Drug Res. and Child Hlth. (NeuroFarBa), Univ. of Florence, Florence, Italy

Abstract: Chronic ethanol consumption causes persistent molecular alterations and morpholgical injury in brain cells and affects the maturation of neuronal circuits by mechanisms that are not fully understood. To comprehend the mechanisms by which ethanol modulates excitatory glutamatergic synaptic transmission, we studied the expression of pre (vGlut1, vGlut2, CB1 receptor, synaptophysin) and postsynaptic (GluA1, GluA2, NR2A, NR2B) proteins, the electrophysiological changes and the ultrastructural modifications in immature (2 days in vitro) or mature (10 days in vitro) organotypic rat hippocampal slices exposed to chronic ethanol (150 mM ethanol for 7 days) or following ethanol withdrawal (150 mM ethanol for 7 days following 24 h ethanol withdrawal). We observed no changes in the expression levels of vGlut1, vGlut2 and CB1 receptor proteins neither in immature nor in mature hippocampal slices. Immature organotypic hippocampal slices showed a decreased in synaptophysin, GluA1 and NR2A expression levels both in chronic ethanol and ethanol withdrawal thus suggesting an impairment in glutamatergic synaptic transmission. On the other hand, mature organotypic hippocampal slices showed a significant increase in GluA1 expression following ethanol withdrawal which may underlie increased toxicity to glutamate. Whole cell patch-clamp recordings both in chronic ethanol and ethanol withdrawal showed a significant reduction in the frequency but not in the amplitude of spontaneous excitatory post synaptic currents (sEPSCs) and a significant increase in the amplitude but not in the frequency of sEPSCs in CA1 pyramidal cells from immature and mature organotypic hippocampal slices, respectively. Finally, electron microscope analysis revealed that immature organotypic hippocampal slices exposed chronically to ethanol showed a clear disorganization of dendritic microtubuli, while mature hippocampal slices displayed an apoptotic cell death pattern after chronic and ethanol withdrawal. These findings suggest that chronic ethanol treatment promotes abnormal glutamatergic synaptic transmission especially in immature hippocampal neurons and that ethanol withdrawal leads to cell death of mature but not immature CA1 pyramidal cells.

Title: Mice selectively bred for High Drinking in the Dark exhibit reduced sensitivity to the ataxic and hypnotic effects of ethanol but do not differ in acute functional tolerance relative to progenitor HS/Npt mice

Authors: *K. A. CORDERO[1,2], B. M. FRITZ[2], A. M. BARKLEY-LEVENSON[1], P. METTEN[1], J. C. CRABBE[1], S. L. BOEHM, II[2];

Abstract: Initial sensitivity to ethanol and the capacity to develop acute functional tolerance (AFT) to both ataxia and hypnosis may influence the amount of alcohol an individual consumes and may also mediate the development of alcoholism. The goal of the current study was to assess sensitivity and AFT to the ataxic and hypnotic effects of ethanol in the first replicate of High Drinking in the Dark (HDID-1) mice. This mouse line is selectively bred for high blood ethanol concentrations following limited access to ethanol in the Drinking in the Dark (DID) paradigm. Mice from the HS/Npt progenitor stock were tested as controls. Ataxia was assessed by the static dowel task which requires animals to balance on a wooden dowel. Ethanol-induced hypnosis was assessed by the method of Ponomarev and Crabbe (2002), using modified restraint tubes to measure the loss of righting reflex (LORR). HDID-1 mice exhibited reduced initial sensitivity to both ethanol-induced ataxia ($p < 0.001$) and hypnosis ($p < 0.05$) as evidenced by significantly higher BEC values at loss of function in both tasks relative to HS/Npt mice. AFT was calculated for both tasks by subtracting the BEC at loss of function from the BEC at recovery. The dowel test yielded no line differences in AFT, but HS/Npt mice developed slightly greater AFT to ethanol-induced LORR than HDID-1 ($p < 0.05$).These results suggest that HDID-1 mice exhibit blunted initial sensitivity to ethanol relative to Hs/Npt mice which may influence their subsequent high ethanol intake in the DID paradigm.

Title: Evaluation of TLR4 inhibitor T5342126 as a potential candidate drug for treatment of alcoholism

Authors: *M. BAJO[1], A. J. ROBERTS[2], H. YIN[3], L. N. CATES[2], T. NADAV[2], K. CHENG[3], S. COULUP[3], S. MADAMBA[1], G. R. SIGGINS[2], M. ROBERTO[1];
[1]CNAD, [2]Mol. and Cell. Neurosci., Scripps Res. Inst., La Jolla, CA; [3]BioFrontiers Inst., Univ. of Colorado Boulder, Boulder, CO

Abstract: The toll-like receptor 4 (TLR4) inflammatory pathway has been shown to play a critical role in enhanced alcohol consumption and the progression to alcoholism. Thus, inhibitors of TLR4 have emerged as promising candidate drugs for the treatment of alcoholism. We evaluated a drug-like small-molecule compound, T5342126, that inhibits TLR4 signaling via the disruption of TLR4/MD-2 (myeloid differentiation protein-2) complex. We used C57BL/6J mice and a chronic intermittent ethanol, two bottle choice (CIE-2BC) method to induce ethanol dependence and assess T5342126 effects on ethanol drinking. We administered T5342126 (82 mg/kg, i.p.) 30 minutes prior to 2BC tests for three consecutive days during the 2BC period, and we performed testing after the 3rd and 5th ethanol exposure episodes (each episode lasting 5 days). T5342126 had no effect on ethanol drinking in control mice in any of the weeks examined. In ethanol dependent mice, T5342126 significantly decreased ethanol intake on the second day of the administration after the 3rd ethanol exposure episode (vehicle: 2.51 ± 0.29 g/kg, n = 10; and T5342126: 1.36 ± 0.42 g/kg, n = 8) as well as after the 5th exposure episode (vehicle: 2.6 ± 0.16 g/kg, n = 10; and T5342126: 1.32 ± 0.34 g/kg, n = 8). We examined withdrawal symptoms after the 4th ethanol exposure episode, by focusing on handling-induced convulsions (HICs) and body temperature. We administered T5342126 1 hour after removal from the vapor chambers on the last 3 days of the ethanol exposure, and tested for withdrawal symptoms on the final day within 12 hours post-withdrawal. In control mice, T5342126 had no significant effects on HICs or body temperature, but reduced HICs in the ethanol dependent mice

compared to ethanol-vehicle mice, reaching significance at the 6 and 12 hr time points (1.13 ± 0.13, n = 10; compared to 1.6 ± 0.16, n = 8, at both time points). We detected hypothermia in ethanol dependent mice (36.82 ± 0.20 °C, n = 10) compared to control mice (37.63 ± 0.15 °C, n = 12), and further reduction in body temperature of T5342126-treated ethanol dependent mice (35.98 ± 0.23 °C, n = 8) at 2 hours into withdrawal. These results suggest the potential efficacy of T5342126 and our treatment paradigm in reducing drinking associated with dependence as well as alcohol withdrawal severity.

Title: Ethosuximide, a T-type calcium channel antagonist, as a potential treatment for alcohol dependence and withdrawal

Authors: *M. RIEGLE[1], E. CARTER[2], J. WEINER[1], D. GODWIN[1];
[1]Neurosci. Program, [2]Physiol. and Pharmacol., Wake Forest Hlth. Sci., Winston-Salem, NC

Abstract: Approximately 18 million Americans abuse or are dependent on alcohol which results in an economic burden of $184 billion. Individuals abusing alcohol frequently cycle between drinking and withdrawal states which can result in increased anxiety, delirium tremens, insomnia, seizures, and other adverse symptoms. Withdrawal symptoms are a major component

of relapse and represent a significant barrier to recovery. Increasingly, studies indicate a role for anticonvulsants as treatment for alcohol withdrawal symptoms as well as alcohol dependence. While the use of anticonvulsants appears to be a promising strategy, different anticonvulsants possess different mechanisms of action. Our lab has identified a disruption in the thalamic T-type calcium channel isoform, $Ca_V3.2$, during withdrawal that may underlie the generation and propagation of withdrawal symptoms. These results led us to our current hypothesis, that targeting T-channels may ameliorate alcohol withdrawal symptoms. To test this, we performed a series of experiments evaluating the use of ethosuximide, an anticonvulsant that targets T-type calcium channels. We tested the effects of ethosuximide on alcohol withdrawal seizures, anxiety measures, and alcohol consumption. Our results suggest that ethosuximide decreases alcohol withdrawal seizures, modestly reduces ethanol intake, and has little effect on general anxiety-like behavior. Further investigation is necessary to determine the role of T-channels and effectiveness of ethosuximide in alcohol withdrawal-induced anxiety. Overall these studies provide implications for targeting T-type calcium channels and the potential use of ethosuximide as a treatment option for alcohol withdrawal symptoms.

Title: Ethanol drinking in ethanol dependent and non-dependent mice: Role of dopamine and glutamate neurotransmission in the dorsolateral striatum

Authors: *W. C. GRIFFIN, III, H. L. HAUN, C. E. MAY, C. HAZELBAKER, V. RAMACHANDRA, C. B. HAWKINS, H. C. BECKER;
Med. Univ. South Carolina, CHARLESTON, SC

Abstract: Repeated cycles of chronic intermittent ethanol (CIE) exposure significantly increases ethanol intake in C57BL/6J mice. Previously, we found that CIE-exposed (dependent) mice were more sensitive to the effects of reducing glutamate neurotransmission in the nucleus accumbens (NAC) on ethanol drinking than non-dependent mice. In the current study, we tested the

hypothesis that changes in glutamatergic and dopaminergic neurotransmission in the dorsolateral striatum (DLS) contribute to escalation of drinking in this model. After implanting bilateral guides above the DLS, mice were trained to drink ethanol (15% v/v) in a 2-bottle choice, limited access paradigm. After establishing stable ethanol intake, mice received 4 weekly cycles of CIE (16 hr/d for 4d) to ethanol vapor (EtOH group) or air (CTL group) in inhalation chambers, with each exposure cycle alternating with a week of limited access drinking test sessions. As expected, ethanol drinking increased in EtOH compared to CTL mice over cycles (2.8±0.2 vs 1.5±0.1 g/kg). During test periods, mice were microinjected with vehicle (PBS), the mGluR2/3 agonist LY379268 (LY; 5nmol/side) or the DRD2/3 agonist quinpirole (QU;0.5 & 1 µg/side) into the DLS 30 min prior to ethanol access. After PBS, EtOH mice continued to drink more than CTL mice (2.8±0.3 vs. 1.6±0.2 g/kg; $p<0.01$). LY reduced drinking in EtOH mice (53% decrease, $p<0.01$) and to a lesser extent in CTL mice (43% decrease; $p=0.09$) compared to vehicle. Microinjection of 0.5 µg QU into the DLS did not affect drinking in EtOH mice but slightly reduced ethanol intake in CTL mice (2.9±0.2 vs 1.4±0.2 g/kg; $p<0.01$). The higher dose of QU reduced drinking more strongly in EtOH mice compared to CTL mice (1.9±0.3 vs 1.2±0.2 g/kg, respectively). Finally, preliminary results from a microdialysis study found that extracellular dopamine levels were similar in the DLS of EtOH and CTL mice (0.86±0.2 vs 0.75±0.2 nM, respectively). Collectively, these data indicate that dopaminergic and glutamatergic neurotransmission in the DLS are altered in this model of ethanol dependence and relapse drinking. Ongoing studies are expanding the dose response range of QU & LY on ethanol drinking as well as investigating expression levels of the cognate receptors in ethanol dependent and non-dependent mice in both regions. Supported by AA010761 & VA Medical Research.

Title: Cortical glutamate and NMDA receptors during withdrawal from intermittent alcohol

Authors: *L. S. HWA[1], A. SHIMAMOTO[1], A. J. NATHANSON[1], J. TAYEH[1], J. F. DEBOLD[1], K. A. MICZEK[1,2];
[1]Psychology, Tufts Univ., Medford, MA; [2]Neurosci., Tufts Univ., Boston, MA

Abstract: Alcohol withdrawal includes behavioral hyperexcitability that may be based on kindled glutamate activity. Negative affect during abstinence from a previous exposure to alcohol may be expressed by increased aggression and social impairments. This study examines glutamate and other amino acids in the medial prefrontal cortex (mPFC) during the transition from low drinking to excessive drinking. The mPFC is involved in executive control and impulsivity, and its glutamatergic efferents project to limbic structures. Outbred CFW male mice were given intermittent access to 20% w/v ethanol and water for 1-2, 4-6, or 8-10 weeks, and changes in glutamate, glutamine, and GABA were measured using in vivo microdialysis over the course of withdrawal. Levels of extracellular glutamate were significantly decreased in mice that were experiencing alcohol withdrawal from both 1-2 and 8-10 weeks intermittent access. Alcohol withdrawal induced an enhancement in glutamine levels in the mPFC and was significantly greater than glutamate levels. In an effort to challenge mPFC glutamate during withdrawal, systemic injection of the uncompetitive NMDA receptor antagonist memantine increased glutamate in mice with a history of 8 weeks of alcohol. In different groups of mice, aggression and non-aggressive interactions toward a male conspecific were also investigated. A further aim was to assess the effects of the memantine on aggression during withdrawal from ethanol. Memantine did not have a significant effect upon withdrawal aggression after 1-2 or 4-6 weeks of intermittent alcohol drinking, but a 5 mg/kg dose significantly escalated withdrawal aggression after 8-10 weeks. Mice showed differences in baseline aggression and social behavior across the transition to escalated drinking. Specifically, after 1-2 weeks of drinking mice exhibited decreased attack bites and increased contact with the intruder. After 8-10 weeks intermittent alcohol, mice showed increased baseline aggression. In accordance with the glutamate kindling hypothesis, these findings suggest that glutamine levels in the mPFC are sensitized during withdrawal, which may point to an alteration in glutamate recycling. In conclusion, we have been able to reveal several novel indicators of withdrawal from intermittent access to alcohol. Further tests will probe the exact nature of the social deficit or anxiety during withdrawal as well as measure concentrations of NMDAR in the mPFC.

Title: KOR blockade attenuates escalated alcohol self-administration in alcohol dependent rats: Dissociation between the central amygdala and nucleus accumbens

Authors: *J. KISSLER, A. WILLIAMS, B. WALKER;
Psychology, Washington State Univ., Pullman, WA

Abstract: Recent evidence has established that the kappa opioid receptor (KOR) / dynorphin (DYN) system is upregulated in alcohol dependence. Specifically, increased KOR signaling and DYN A-like peptide expression in the central amygdala (CeA) following alcohol dependence are thought to contribute to excessive operant alcohol self-administration and increased negative affective-like states. Previous data from this lab has established that blockade of the KOR/DYN system selectively reduces alcohol self-administration in alcohol dependent rats. Furthermore, this lab has also demonstrated that administration of a KOR antagonist into the nucleus accumbens (Acb) selectively attenuates alcohol self-administration in alcohol dependent rats. The primary purpose of this experiment was to examine a possible dissociation in alcohol consumption following KOR blockade into the CeA and Acb. Wistar rats (N = 22) were trained to self-administer alcohol and implanted with cannula guides targeting the CeA or Acb. Following recovery, subjects received four weeks of intermittent alcohol vapor exposure resulting in escalated self-administration. Testing occurred 6-8 hours into withdrawal where animals received intra-CeA or -Acb infusion of the KOR antagonist, nor-binaltorphimine (nor-BNI; 0, 2, or 6µg). A 2-way ANOVA revealed that intra-CeA and -Acb nor-BNI significantly reduced alcohol consumption in dependent animals ($p<0.05$). Another 2-way ANOVA analyzing percent change indicated that nor-BNI was more potent when infused into the Acb ($p<0.05$). This indicates a possible dissociation in regulatory mechanisms of alcohol dependence in the CeA and Acb. These results add to the field's understanding of the neurobiological mechanisms underlying alcohol dependence and highlight important areas for future research.

Title: Influence of kappa opioid receptor activation on forced swim behavior in C57BL/6J mice with a history of chronic intermittent ethanol exposure

Authors: *R. I. ANDERSON[1], L. L. SNYDER[1], R. L. MCCANN[1], J. L. HOPKINS[1], M. F. LOPEZ[1], H. C. BECKER[1,2];
[1]Ctr. for Drug and Alcohol Programs, Med. Univ. of South Carolina, Charleston, SC; [2]Ralph H. Johnson Veterans Admin. Med. Ctr., Charleston, SC

Abstract: Previously we have shown that ethanol dependence induced by repeated cycles of chronic intermittent ethanol (CIE) exposure results in significantly reduced immobility in the forced swim test (FST) compared to nondependent mice. The same results were obtained in ethanol-naïve mice after central administration of CRF. While kappa opioid receptor (KOR) activity is known to modulate behavior in the FST, little is known about how alterations in KOR activity may influence behavioral response to the FST stressor in the context of ethanol dependence. Thus, the present study was designed to examine the effects of the KOR agonist U50,488 on forced swim behavior in CIE-exposed (dependent) and control mice. Adult male C57BL/6J mice were exposed to 2 or 4 weekly cycles of ethanol vapor exposure (CIE group) or air exposure (CTL group) in inhalation chambers (16 hrs/day for 4 days). At 72 hr after final CIE (or air) exposure, subjects were administered either saline or U50,488 (10 mg/kg, i.p.) prior to a 10-min FST. A subset of subjects administered U50,488 were pretreated with the KOR antagonist nor-binaltorphimine (norBNI; 10 mg/kg, i.p.). Swim testing was repeated daily for 5 days, with saline and U50,488 injections given 10 min prior to each FST. Results indicated that behavioral responding in the FST was dependent on the number of CIE cycles, with ethanol-exposed mice demonstrating reduced immobility after 4 (but not 2) CIE cycles in comparison to CTL mice. The altered behavioral response to FST stress in 4-cycle CIE subjects was reversed in subjects administered U50,488. Further, U50,488 increased immobility in both CIE and CTL groups, an effect that was blocked by norBNI pretreatment. Given the independent and interactive roles of dynorphin (the endogenous ligand for KORs) and CRF in stress responsiveness and ethanol dependence, future work will explore interactions of CRF administration and KOR blockade on behavioral response to FST stress in ethanol dependent and control mice.

Title: Kappa opioid regulation of depressive-like behavior and reward seeking during acute and protracted withdrawal from ethanol

Authors: S. K. JARMAN, A. M. HANEY, *G. R. VALDEZ;
Dept Psychol, Grand Valley State Univ., ALLENDALE, MI

Abstract: Withdrawal from alcohol is often characterized by enhanced negative affect, such as symptoms of depression and anxiety, and increased reward seeking. These behavioral changes can be long-lasting in nature, which further contributes to the challenge of the long-term management of alcoholism. Recent evidence from animal models suggests that the increased activity of the dynorphin (DYN)/kappa opioid receptor (KOR) system leads to an increase in depressive-like behaviors and reward seeking following withdrawal from ethanol. The objective of the present experiments was to determine the role of the KOR system in the regulation of depression-related behaviors and saccharin reward following chronic exposure to ethanol. In the first experiment, male Wistar rats were fed an ethanol or control liquid diet for approximately four weeks. To assess the ability of the KOR antagonist nor-BNI to attenuate increases in depressive-like behavior, animals were examined in the forced swim test. Immediately after removal of the diet, rats were injected with nor-BNI (20 mg/kg, i.p.), and 24 h later, were exposed to a 10 min session of forced swim stress. The following day, rats were given a 5 min forced swim session that was recorded and examined for time spent immobile. In the second set of experiments, male Wistar rats were trained to self-administer saccharin, and following stable intake, were exposed to an ethanol or control liquid diet as described above. The ability of the nor-BNI to decrease saccharin self-administration was examined during acute withdrawal and protracted abstinence from ethanol. Following removal of the diet, rats were injected with saline, and 24 h later, were allowed to self-administer saccharin. Immediately following this initial self-administration session, animals were pretreated with nor-BNI (20 mg/kg, i.p.), and were again

allowed to self-administer saccharin 24 h later. This saccharin self-administration procedure was repeated three weeks later after rats received injections of saline and nor-BNI as described. In the forced swim test, ethanol dependent rats displayed a characteristic increase in time spent immobile compared to controls, an effect that was reversed by pretreatment with nor-BNI. nor-BNI also selectively decreased saccharin intake in ethanol dependent rats without affecting responding in controls at 48 h and 3 weeks following withdrawal. These results suggest that KOR blockade reverses depression-related behaviors and general reward seeking associated with withdrawal from ethanol following both acute and protracted periods of abstinence.

Title: Drinking status, subjective response, and craving for alcohol: A translational examination of Koob's allostatic model in humans

Authors: *S. BUJARSKI, J. JENTSCH, L. A. RAY;
UCLA, Los Angeles, CA

Abstract: Translational studies in human populations stand to provide much needed clarity about the development and maintenance of alcoholism. Koob's allostatic model conceptualizes addictive pathophysiology of as a cycle of progressive neurobiological dysregulation, beginning with preoccupation and anticipation (reflecting positive reinforcement) and ending with withdrawal mediated alcohol use (reflecting negative reinforcement). To date, clinical research has not directly tested hypotheses about SR to alcohol (SR) derived from Koob's allostatic model. The present study aims to test neurobiologically-derived hypotheses about the moderating role of drinking status (i.e. heavy drinker, HDs vs. alcohol dependent, ADs) on SR in the lab (consisting of stimulation, sedation and tension relief domains) and on the relationship between SR and craving for alcohol. Thus the present study represents a translational test of key behavioral predictions derived from Koob's allostatic model. This study examined SR in HDs (n=49) vs. ADs (n=42) and tested whether HDs and ADs differ in terms of the association between SR and alcohol craving. Alcohol was administered intravenously and participants completed self-report measures of SR and craving at BrAC's of 0.02, 0.04, and 0.06 g/dl. Latent growth curve modeling was utilized for hypothesis testing. ADs reported significantly higher

sedation and craving at the start of the alcohol infusion and exhibited a blunted response along escalating BrAC. ADs also exhibited greater tension at the start of the infusion but did not differ in tension reduction from HDs. Furthermore, stimulation was associated with alcohol craving to a significantly greater extent in HDs as compared to ADs ($\beta = 0.718$, 0.169 respectively, difference $p < 0.05$). Furthermore, tension at the start of the alcohol infusion was positively associated with craving in ADs ($\beta = 0.386$, $p < 0.05$), but not in HDs ($\beta = 0.004$, $p > 0.10$).This study extends the literature by demonstrating that HDs and ADs differ in their subjective experience of alcohol as well as in the association between SR and craving for alcohol. Hypotheses derived from Koob's allostatic model of alcoholism etiology were partially supported. Critically, analysis revealed that, while ADs and HDs did not differ in the magnitude of positive hedonic response to alcohol, there was a relative disconnect between subjective reward and craving in ADs as compared to HDs. These results are consistent with the notion that acute reward from alcohol is more salient as a determinant of craving (and of drinking) during sub-clinical heavy drinking as compared to during clinically significant alcohol dependence.

Title: Increased emission of rat ultrasonic vocalization (USV) over the course of alcohol dependence

Authors: *C. L. BUCK[1,2], J. E. SCHLOSBURG[2], L. J. LIPPERT[1], G. F. KOOB[2], L. F. VENDRUSCOLO[2];
[1]UCSD, LA JOLLA, CA; [2]Committee on the Neurobio. of Addictive Disorders, The Scripps Res. Inst., La Jolla, CA

Abstract: Rats made dependent on alcohol by chronic, intermittent alcohol vapor exposure exhibit increased alcohol self-administration and compulsive-like alcohol intake compared with

nondependent rats. We have found that alcohol dependent rats display increased emission of 50 kHz USVs, which are associated with positive affective-like states, during anticipation of alcohol self-administration, and increased stress-induced 22 kHz USVs, an index of negative affective-like states, during acute alcohol withdrawal, compared with nondependent rats. We tested the hypothesis that anticipatory 50 kHz and 22 kHz USVs would follow a pattern consistent with escalation of alcohol self-administration during the development of alcohol dependence. Over the course of vapor exposure, we observed that rats displayed a transient increase in anticipatory 50 kHz USVs, whereas stress-induced 22 kHz USVs exhibited a more sustained increase. Additionally, the benzodiazepine chlordiazepoxide, a class of drugs used for alcohol detoxification, decreased stress-induced 22 kHz USVs. Together, these findings suggest that 50 kHz and 22 kHz USVs represent distinct behavioral indicators of increased motivation for alcohol self-administration during alcohol dependence and can help to dissect the neurobiological mechanisms of compulsive-like alcohol drinking. Ongoing studies are investigating the effects of glucocorticoid receptor antagonism, which has been reported to decrease compulsive-like alcohol drinking, on 22 kHz USVs during acute withdrawal in dependent and nondependent rats.

Title: Voluntary ethanol intake in ethanol-dependent and nondependent NR2B conditional KO mice

Authors: *M. F. LOPEZ[1], R. L. MCCANN[1], J. L. HOPKINS[1], M. P. OVERSTREET[1], E. DELPIRE[2], P. J. MULHOLLAND[1], H. C. BECKER[1];
[1]Psychiatry, Med. Univ. of South Carolina, CHARLESTON, SC; [2]Vanderbilt Univ. Med. Ctr., Nashville, TN

Abstract: Repeated cycles of chronic intermittent ethanol (CIE) exposure produces escalation of voluntary ethanol drinking in C57BL/6J mice. Given the role of glutamate/NMDA receptor activity in ethanol dependence, this study evaluated the effect of CIE exposure in conditional NR2B KO mice. Conditional NR2B KO mice were generated by crossing homozygous-floxed mice carrying CAMKIIa-tTA and mice with the tetO-driven CRE transgene while breeding pairs were maintained on a doxycycline containing diet. Deletion of the NR2B gene was induced by removing the doxycycline diet at 45 days of age, and evidence for reduced expression was verified in cortex and striatum by Western blots at 75 and 200 (but not 45) days of age in KO mice. At adulthood, mice were tested for voluntary ethanol intake using a limited access (2 hr/day) procedure, with the ethanol concentration gradually increased from 3 to 15% (v/v) over several days. During this period, female NR2B KO mice showed higher levels of intake compared to female WT controls. Male KO and WT mice had a similar level of intake. Once stable baseline intake of 15% ethanol was observed, NR2B KO and WT mice from both sexes received 4 weekly cycles CIE vapor exposure (EtOH group) or air exposure (CTL group) (16 hr/day x 4 days) alternated by 5-day drinking test cycles (C57BL/6J male mice were included as positive controls). As expected, CIE exposure induced a significant increase in voluntary ethanol intake in C57BL/6J male mice. Ethanol intake increased from 2 g/kg at baseline to 3 g/kg during Test 4 in the EtOH group, while intake remained stable throughout all test periods in CTL mice. Although, NR2B KO and WT males had a lower baseline intake level than C57BL/6J mice (~1.2 g/kg), CIE exposure also induced a significant increase in voluntary ethanol intake in these mice. In females, CIE exposure induced higher voluntary ethanol intake only in KO mice. Further evaluation of these mice indicated that female NR2B KO mice showed higher levels of locomotor activity in an open field compared to female WT and male KO and WT. Female KO mice also failed to adapt (continued to struggle and swim) to repeated daily testing in the Porsolt forced swim test. Overall, these results indicate that deletion of the NR2B receptor subunit influences locomotor activity, adaptation to repeated stress, and voluntary ethanol intake in ethanol dependent and nondependent, with more robust effects observed in female mice.

Title: Ceftriaxone-induced upregulation of GLT-1 isoforms and xCT attenuates in part relapse-like ethanol-drinking behavior in male alcohol-preferring (P) rats

Authors: H. ALHADDAD, *Y. SARI;
Univ. of Toledo, Col. of Pharm., Toledo, OH

Abstract: Studies from our laboratory demonstrated that ceftriaxone-induced upregulation of glutamate transporter 1 (GLT-1) in prefrontal cortex (PFC) and nucleus accumbens (NAc) reduced ethanol intake after five weeks of free-choice ethanol drinking paradigm in male alcohol-preferring (P) rats. GLT-1 exists in two splice variant isoforms: GLT-1a and GLT-1b. Of these variants, GLT-1a is predominantly in astrocytes and neurons, and GLT-1b is mainly expressed in astrocytes. In this study, we investigated the effect of ceftriaxone on the levels of GLT-1 isoforms and other glial cell proteins such as glutamate aspartate transporter (GLAST) and cysteine/glutamate exchanger (xCT) in relapse-like ethanol-drinking behavior. P rats were exposed to free choice of 15% and 30% ethanol and to water for five weeks. Then they were treated with ceftriaxone (100 mg/kg, i.p.) or saline vehicle during the last five days of the two-week deprivation period. We found that ceftriaxone treatment induced significant attenuation in relapse-like ethanol-drinking behavior that persisted for nine days upon re-exposure to ethanol. However, water intake increased significantly in ceftriaxone-treated rats compared to saline-treated rats. Importantly, ceftriaxone-mediated attenuation in relapse-like ethanol-drinking behavior was associated with upregulation of the levels of GLT-1a and GLT-1b isoforms, and xCT in PFC and NAc. We did not observe any significant differences in GLAST expression among all groups, which revealed the specific action of ceftriaxone in GLT-1 isoforms and xCT expression. Ceftriaxone-induced upregulation of GLT-1 isoforms and xCT, associated in part with the attenuation of relapse-like ethanol-drinking behavior, may suggest the potential therapeutic uses of this drug in the treatment of relapse to alcohol consumption.

Title: Differential patterns of expression of Neuropeptide Y throughout withdrawal in outbreed Swiss mice classified as susceptible or resistant to locomotor sensitization induced by ethanol

Authors: *L. S. COELHO[1], R. DE PAULI[3], N. F. CORREA-NETTO[2], J. G. SANTOS-JUNIOR[2];
[1]FCMSCSP, São Paulo, Brazil; [2]FCMSCSP, Sao Paulo, Brazil; [3]Federal Univ. of São Paulo, Sao Paulo, Brazil

Abstract: Several studies in drug addiction have focused on the negative emotional state emerging from withdrawal. In this scenario NPY plays an important role, given its involvement in drug addiction, anxiety and mood disorders. Locomotor sensitization is a useful animal model to investigate the neuronal plasticity induced by drugs of abuse and there is an important behavioral variability in outbreed Swiss mice to develop ethanol induced locomotor sensitization. We investigated whether this variability is also applied to the NPY expression during withdrawal. Outbreed Swiss mice were daily treated with ethanol (or saline) for 21 days. According to locomotor activity after last injection, ethanol group was classified as sensitized (EtOH_High) or non-sensitized (EtOH_Low). Furthermore, after 5 days of withdrawal, some animals were challenged with ethanol. To evaluate NPY expression, mice were sacrificed at 18 hours or 5 days of withdrawal, as well as 1.5 hours after challenge. At 5 days of withdrawal, NPY increased in the orbital cortex, dorsomedial striatum, piriform cortex and dentate gyrus of EtOH_High group. These changes were counteracted by ethanol challenge. In EtOH_Low group, increases on NPY in the dentate gyrus occurred early (18 h of withdrawal). Ethanol challenge also decreased (EtOH_High) and increased (EtOH_Low) NPY in piriform cortex. Finally, NPY decreased in the prelimbic cortex of EtOH_Low group at 5 days of withdrawal, and this decrease was reversed by ethanol challenge. In conclusion, these results suggest that behavioral variability in the locomotor sensitization seems to be useful to study neurobiological mechanisms of ethanol withdrawal. Furthermore it is possible that the changes on NPY expression during withdrawal could play both adaptive and pathological consequences. For example, in mice susceptible to locomotor senstitization, increased NPY in striatum and orbitofrontal cortex could be considered as an allostatic mechanism, while in the piriform cortex and dentate gyrus a homeostatic mechanism. Moreover, similar homeostatic features could be hypothesized for the decreased NPY expression in the prelimbic cortex of mice that did not develop locomotor sensitization. Therefore, besides the well established effects of chronic drug exposure over NPY expression, withdrawal also plays a pivotal role determining expressive changes in NPY expression.

Title: Cannabinoid receptor 1 activation selectively inhibits ethanol withdrawal induced potentiation of NMDA neurotoxicity

Authors: *D. J. LIPUT, M. A. PRENDERGAST, K. NIXON;
Univ. of Kentucky, Lexington, KY

Abstract: Excessive alcohol intake, characteristic of alcohol use disorders (AUDs), results in neurodegeneration which is theorized to influence the transition to addiction. Therefore, it is hypothesized that neuroprotective agents will have utility for the treatment of AUDs. The endocannabinoid (eCB) system has emerged as a potent neuroprotective target for a wide range of neurodegenerative disorders; however few reports have investigated the eCB system in models of alcohol induced neurodegeneration. Therefore, the current study investigated the effect of cannabinoid 1 receptor (CB1R) activation on withdrawal-induced excitotoxicity in an organotypic hippocampal slice culture (OHSC) model. OHSCs were prepared from 8 day old Sprague-Dawley rat pups and were matured ex vivo for 5 days before drug treatments. At 6 days, slices were exposed to either 50 mM ethanol (EtOH) or control media for 10 days. Following EtOH exposure, slices underwent a 24 hr EtOH withdrawal (EWD) in the presence of different drug combinations and propidium iodide (PI, 2.5 μg/mL) to assess toxicity. Following withdrawal, cultures were imaged for PI uptake using fluorescence microscopy and analyzed for optical density in CA1, CA3 and the dentate gyrus (DG) regions of the hippocampus. As shown previously, ethanol exposure potentiated NMDA (5μM) toxicity in CA1 ($p < 0.001$), while toxicity was not observed in CA3 or the dentate gyrus (DG) in either NMDA or EWD+NMDA cultures. Application of the CB1R agonist, CP55940, dose dependently blocked EWD potentiation of NMDA toxicity in CA1 compared to EWD+NMDA treated cultures, which was significant at 1.0 μM ($p < 0.05$) and 10.0 μM ($p < 0.01$). Furthermore, co-application of the CB1R antagonist SR141716 (10.0 μM) completely abrogated CP55940 mediated neuroprotection ($p < 0.01$). Interestingly, neuroprotection was specific to toxicity associated with EWD as CP55940 failed to block toxicity following NMDA application alone. In contrast to CP55940, the FAAH inhibitor URB597 (50 nM - 500 nM) failed to block EWD potentiation of NMDA toxicity in preliminary experiments. The current study found that the eCB system is a

viable target for preventing ethanol withdrawal induced neurotoxicity. As CB1 agonism has low therapeutic utility, due to an unfavorable side effect profile, future studies will evaluate other strategies to target the eCB system, such as blocking 2-AG catabolism and duel blockage of AEA and 2-AG catabolism. In conclusion, the eCB system may be a viable target to prevent neurotoxicity associated with alcohol withdrawal. Title: The role of beta1 adrenoceptors in the development of alcohol dependence

Authors: *P. M. KLENOWSKI[1], J. HOLGATE[1], M. BELLINGHAM[2], P. MOLENAAR[1], S. BARTLETT[1];
[1]Queensland Univ. of Technol., Brisbane, Australia; [2]Univ. of Queensland, Brisbane, Australia

Abstract: There is significant evidence supporting the hypothesis that stressors play an important role in the development of alcohol dependence. Many investigators are dissecting the molecular mechanisms that underpin the role of stress in the development of alcohol dependence to improve upon the current pharmotherapeutics. Compounds that block norepinephrine receptors such as alpha1-adrenergic receptors using prazosin (Walker et al., 2008) or beta-adrenoceptor using propranolol have all shown promise as potential therapeutic agents (Gilpin and Koob, 2010). We have extended these studies to characterize the role of the beta1-adrenoceptor (AR) in ethanol consumption using the drinking in the dark (DID) protocol in mice and using to radioligand binding experiments to characterize the receptor in the brain of naïve and ethanol consuming mice. Briefly, mice were housed individually in a reverse light-dark cycle room and given access to 1 bottle of 20% ethanol (v/v) and 1 bottle of filtered water for a 2 hour period, 5 days a week, 3 hours into the dark cycle. Bottles were weighed 30 min and 2 hours after presentation to determine daily ethanol consumption. The beta1-adrenoceptor contains two binding sites, beta1H and beta1L, corresponding to high and low-affinity binding sites respectively. Receptor activation can occur through both binding sites. Some beta-blockers typified by (-)-CGP 12177 block beta1AR and beta2ARs, but can also activate beta1LARs at higher concentrations than those required to cause blockade (Kaumann and Molenaar, 2008).

The role of beta1LARs have been extensively characterized in the heart. The mammalian brain is also an area of high beta1AR expression, however it is unknown whether beta1LARs exist in this region nor its role in stress and ethanol consumption. We show that there is high beta1AR expression in mouse brain using radioligand binding studies with (-)-[3H]-CGP 12177 to label beta1AR binding sites in brains from C57BL/6 mice. We then show that (-)-CGP 12177 reduces ethanol consumption in mice consuming ethanol using the DID protocol. We are currently screening a series of compounds with activity at beta1HAR and beta1LARs to determine their effect on ethanol consumption using an adapted drinking-in-the-dark paradigm established in our lab. Of particular interest is our data showing that the beta1LAR partial agonist (-)-CGP 12177 decreases ethanol consumption in C57BL/6 mice. Activation of the beta1AR through the beta1L site may represent a novel therapeutic strategy for the management of alcohol addiction.

Title: MeCP2 regulates ethanol sensitivity and intake

Authors: *J. CHEN[1], V. REPUNTE-CANONIGO[1], C. LEFEBVRE[2], T. KAWAMURA[1], M. KREIFELDT[1], O. BASSON[1], A. ROBERTS[1], P. P. SANNA[1];
[1]The Scripps Res. Inst., LA JOLLA, CA; [2]Columbia Univ., New York, NY

Abstract: We have investigated the expression of chromatin-regulating genes in the prefrontal cortex and in the shell subdivision of the nucleus accumbens during protracted withdrawal in mice with increased ethanol drinking after chronic intermittent ethanol (CIE) vapor exposure and in mice with a history of non-dependent drinking. We observed that the methyl-CpG binding protein 2 (MeCP2) was one of the few chromatin-regulating genes to be differentially regulated

by a history of dependence. As MeCP2 has the potential of acting as a broad gene regulator, we investigated sensitivity to ethanol and ethanol drinking in MeCP2308/Y mice, which harbor a truncated MeCP2 allele but have a milder phenotype than MeCP2 null mice. We observed that MeCP2308/Y mice were more sensitive to ethanol's stimulatory and sedative effects than wild-type (WT) mice, drank less ethanol in a limited access 2 bottle choice paradigm and did not show increased drinking after induction of dependence with exposure to CIE vapors. Alcohol metabolism did not differ in MeCP2308/Y and WT mice. Additionally, MeCP2308/Y mice did not differ from WT mice in ethanol preference in a 24-hour paradigm nor in their intake of graded solutions of saccharin or quinine, suggesting that the MeCP2308/Y mutation did not alter taste function. Lastly, using the Gene Set Enrichment Analysis algorithm, we found a significant overlap in the genes regulated by alcohol and by MeCP2. Together, these results suggest that MeCP2 contributes to the regulation of ethanol sensitivity and drinking.

Title: Ethanol-induced epigenetic modifications mediate behavioral plasticity

Authors: *G. L. ENGEL[1], B. M. ZIMAN[1], K. R. KAUN[2], S. MARELLA[3], E. C. KONG[3], F. W. WOLF[1];

Abstract: Alcohol is the most widely abused drug, with high social and economic costs to humanity. Despite this, the mechanisms by which alcohol affects brain function and behavior are not yet fully understood. Epigenetic regulation of transcription may be a key mechanism for regulating the behavioral plasticity induced by exposure to drugs of abuse. Our lab uses a rapid ethanol tolerance paradigm in Drosophila melanogaster to study the cellular and molecular mechanisms of ethanol-induced behavioral plasticity. Using this model we discovered that a highly conserved histone/protein deacetylase (HDAC) plays a critical role in the behavioral

response of the flies to ethanol. In HDAC mutant adults there is a decrease in both the development of tolerance and of reward, two behavioral responses to ethanol that play an important role in its addictive properties. These behavioral deficits can be rescued by restoring HDAC expression in neurons, and can be phenocopied by decreasing brain HDAC expression in wild-type flies. Further, HDAC expression is reduced and specific histone modifications are increased in an HDAC-dependent manner following ethanol exposure. Combined, these data indicate an important role for an HDAC in the orchestration of ethanol behaviors and suggest an epigenetic mechanism for the induction of behavioral plasticity in response to drugs of abuse.

Title: Cell type-specific alterations in tonic GABAA receptor transmission in the central amygdala of CRF receptor-1 reporter mice following chronic ethanol exposure

Authors: *M. A. HERMAN, C. CONTET, M. ROBERTO;
CNAD, The Scripps Res. Inst., La Jolla, CA

Abstract: We have previously shown that there is cell-type specific tonic GABAA receptor conductance in the central amygdala (CeA) of a CRF receptor-1 reporter mouse model. Specifically, neurons containing the CRF1 receptor (CRF1+) are composed of both the low threshold bursting (LTB) and regular spiking (RS) cell types and display a significant baseline tonic conductance that is action-potential dependent and insensitive to acute ethanol. Neurons lacking the CRF1 receptor (CRF1-) are composed of RS and late spiking (LS) cell types and do

not display baseline tonic conductance but do possess the potential for a tonic conductance that is enhanced by acute ethanol. The present study was undertaken to examine changes in baseline tonic conductance following chronic intermittent ethanol (CIE) exposure. CRF1:GFP mice were subjected to 4-5 weeks of CIE in ethanol inhalation chambers or air/pyrazole control treatment and whole cell voltage-clamp recordings were performed in CRF1+ and CRF1- CeA neurons immediately following exposure or 5-7 days into withdrawal. Consistent with what was observed in naïve mice, CRF1+ neurons of both LTB and RS cell types from control mice displayed a significant tonic conductance following focal application of 100 μM gabazine (LTB: 14.2 ± 2.1 pA, n = 8; RS: 17.0 ± 2.9 pA, n = 5). However, this tonic conductance was not observed in LTB or RS CRF1+ neurons from CIE-treated mice immediately following ethanol exposure or 5-7 days into withdrawal. Conversely, CRF1- CeA neurons of both LS and RS cell types from control mice did not display a baseline tonic conductance, but a significant tonic conductance was observed following focal application of 100 μM gabazine in LS CRF1- neurons from CIE-treated mice immediately following ethanol exposure (11.1 ± 1.3 pA, n = 6) and 5-7 days into withdrawal (14.5 ± 2.7 pA, n = 10). No change in tonic conductance was observed in RS CRF1- neurons, suggesting that the upregulation of tonic conductance by CIE occurs only in a specific subpopulation of CRF1- CeA neurons. Consistent with this hypothesis, RS CRF1- neurons displayed a significantly lower sensitivity to the δ-subunit preferring GABAA receptor agonist THIP than LS CRF1- neurons in control mice. Collectively these data demonstrate that cell-type specific alterations in tonic GABAA receptor signaling occur in the CeA following chronic ethanol exposure. These alterations likely have significant effects on the overall activity of the CeA and this disrupted activity may contribute to cycle of negative reinforcement that leads to the behavioral manifestation of alcohol dependence.

Title: Distinct metabolic alterations in reward related brain areas of rats with a history of alcohol dependence

Authors: *M. MEINHARDT[1], D. C. SÉVIN[2], M. L. KLEE[1], S. DIETER[1], U. SAUER[2], W. H. SOMMER[1];
[1]Psychopharmacology, Central Inst. of Mental Hlth., Mannheim, Germany; [2]Inst. of Mol. Systems Biol., ETH Zürich, Zürich, Switzerland

Abstract: Recently, we demonstrated the critical importance of frontostriatal circuits for the expression of addiction like behavior in a rat model of alcoholism. Specifically, the infralimbic cortex seemed to be a highly sensitive target for alcohol-induced pathology. However, the underlying neurobiology of these region-specific changes is poorly understood. Mass-spectroscopy allows assessing global metabolic profiles in specific brain regions, and thus provides a tool to search for novel pathophysiological mechanisms.
Here we tested the hypothesis that a history of alcohol dependence manifest itself in an altered cerebro-metabolic phenotype in frontostriatal brain regions. We induced alcohol dependence in rats in using intermittent alcohol vapor exposure for seven weeks. Following three weeks of abstinence, rats had access to alcohol (8% v/v) and tap water for seven weeks, before two frontal (infralimbic and prelimbic) and two striatal (nucleus accumbens core and shell) brain areas were micro-dissected for a global metabolic screening.
2D-Principal component loadings of the dataset displayed that the infra- and prelimbic cortex have a metabolic phenotype that is distinct from the two accumbal regions, which do not separate. Among the top 50 compounds explaining most of the variance to separate the brain regions, are known neuroactive compounds such as N-Acetylaspartate, glutamate, glutamine, creatinine, GABA, myo-Inositol and dopamine. Next, with the use of a metabolic pathway enrichment analysis, we found the valine, leucine and isoleucine biosynthesis pathways in the cortical as well as the nicotinate and nicotinamide metabolism is highly enriched in accumbal structures. Finally, with a targeted analysis, the intensities of several compounds known to be involved in addiction were extracted from the data set and compared with control rats. We found several metabolites significantly altered in both cortical regions, including GABA, MET-enkephalin and dopamine. Strikingly, dopamine concentrations highly correlated with the amount of alcohol consumed in the two bottle-free-choice paradigm.
Together, these data point towards profound alterations in all analyzed brain structures, in particular within the cortical regions. In addition, we could show that two anatomical similar structures as the pre- and infralimbic cortex express a completely different metabolic phenotype, which has to be taken into consideration for future studies in the field of neurophysiological investigations.

Title: Profound and selective decrease of dendritic spines in the nucleus accumbens of ethanol dependent rats

Authors: *S. SPIGA[1], G. MULAS[1], G. MUGGIRONI[2], G. FOIS[2], C. CANNIZZARO[4], M. DIANA[3], M. DIANA[3];

Abstract: Neuronal refinement and stabilization are hypothesized to confer resilience to poor decision-making and addictive-like behaviors, such as excessive ethanol drinking and dependence. Accordingly, structural abnormalities are likely to contribute to the appearance of alcohol withdrawal signs and symptoms, that occur from suddenly ceasing the use of alcohol after chronic ingestion, thus perpetuating the addictive cycle. Here we show that ethanol dependent rats display a loss of dendritic spines in medium spiny neurons of the Nacc, accompanied by a reduction of TH-positive terminals and PSD-95 positive elements. Further analysis indicates that 'long thin', but not 'mushroom', spines are selectively affected. These changes are restricted to the withdrawal phase of ethanol dependence suggesting their relevance in the genesis of signs and/or symptoms affecting ethanol withdrawal, and thus the Whole addicting cycle. Overall these results highlight the importance of spine function on the evolution of alcohol dependence and suggest that the selective loss of 'long thin' spines may affect learning dysfunctions and significantly contribute to further 'impoverish' the already deficient dopaminergic transmission whose hypofunctionality is a major factor for the emergence of the harmful consequences of alcohol abuse/dependence.

Title: Homeostatic changes in NMDA receptors and Kv4.2 channels following chronic ethanol exposure is accompanied by alterations in FMRP phosphorylation

Authors: *K. SPENCER, P. MULHOLLAND, L. CHANDLER;
Neurosci. and Psychiatry, Med. Univ. of South Carolina, Charleston, SC

Abstract: Exposure to chronic ethanol results in significant, long-term adaptations at glutamatergic synpases that alter signal transduction and cellular responses. Specifically, prolonged ethanol exposure increases synaptically expressed NMDA receptor protein levels as well as NMDA receptor activity. However, the mechanism by which these homeostatic changes occur is unknown. In previous studies, the mRNA-binding protein fragile-X mental retardation protein (FMRP) alters both NMDA receptors and the voltage-dependent Kv4.2 channel in an activity-dependent manner. Increases in FMRP phosphorylation stimulate binding to Kv4.2 mRNA and thus decrease translation. In organotypic hippocampal slice cultures, we examined the effect of NMDA receptor activity on FMRP phosphorylation. Exposure of 100 μM NMDA for 5, 15, and 30 minutes reduced FMRP phosphorylation, but did not alter total protein levels. Incubating slice culture media with the NMDA receptor antagonist AP-V altered FMRP phosphorylation levels in a dose-dependent manner. Because chronic and acute ethanol exposure have previously been shown to alter NMDA receptor expression and activity, we next examined the effect of 75 mM ethanol exposure on total FMRP protein levels as well as changes in FMRP phosphorylation. Twenty-four hour exposure to ethanol increased phosphorylated FMRP while total protein levels remained unchanged. This increase in phosphorylation without a change in total protein persisted following a chronic (8-day) exposure to ethanol. We also observed a decrease in Kv4.2 surface expression that is mirrored by an increase in NMDA receptor expression following this 8-day ethanol exposure paradigm. Additionally, the hyperexcitability initiated by the removal of ethanol from the culture media is accompanied by a decrease in FMRP phosphorylation. These data are consistent with the model that FMRP phosphorylation may influence NMDA receptor activity-dependent changes in Kv4.2 following chronic ethanol exposure.

Title: BK channel beta1 and beta4 subunits play differential roles in the physical and motivational effects of ethanol withdrawal

Authors: *C. CONTET[1], D. LE[1], M. KREIFELDT[1], S. N. TREISTMAN[2], A. J. ROBERTS[1], G. F. KOOB[1];
[1]Scripps Resch Inst., LA JOLLA, CA; [2]Inst. of Neurobio., Univ. of Puerto Rico, San Juan, PR

Abstract: Alcohol dependence has devastating health and societal consequences. One of the well-established molecular targets of ethanol is the large conductance calcium-activated potassium (BK) channel. BK channels play a key role in several aspects of neuronal physiology. Ethanol is a potent activator of BK channel gating, but in vivo evidence for a causal relationship between BK channel potentiation and ethanol's behavioral effects is scarce. Interestingly, association of the auxiliary beta1 or beta4 subunit with the pore-forming alpha subunit reduces ethanol-induced potentiation of BK currents in vitro. In the present study, we investigated whether BK beta1 and beta4 subunits influence the physical and motivational effects of ethanol withdrawal using knockout mice. Handling-induced convulsions (HIC) were assessed following i.p. injection of 4 g/kg ethanol, before and after exposure to chronic intermittent ethanol (CIE) in inhalation chambers. Owing to their C57Bl/6J background, wildtype mice exhibited minimal physical withdrawal under both conditions. Deletion of BK beta4 subunit significantly increased HIC severity both in naïve and CIE-exposed mice. BK beta1 knockout mice did not differ from their wildtype littermates pre-CIE, but displayed HIC earlier in withdrawal post-CIE. To assess the motivational aspect of withdrawal, independent cohorts of mice were first trained to drink ethanol in a limited-access two-bottle choice (2BC) paradigm. BK beta1 or beta4 deletion did not affect baseline levels of drinking. Weeks of 2BC were then alternated with weeks of CIE (dependent mice) or air (non-dependent mice) exposure. A gradual escalation of voluntary

ethanol intake was observed in dependent wildtype mice, while intake remained stable in non-dependent wildtype mice. In contrast, CIE exposure did not alter the ethanol consumption of BK beta4 knockout mice. Conversely, ethanol drinking increased after fewer CIE cycles in BK beta1 knockout mice than in wildtype mice. In conclusion, absence of either BK beta1 or beta4 exacerbates physical withdrawal from ethanol, but deletion of BK beta4 prevents, while deletion of BK beta1 accelerates, the escalation of ethanol drinking during withdrawal from CIE. These results highlight the functional dissociation between mechanisms mediating the physical and motivational effects of ethanol withdrawal. In addition, our data suggest that BK beta1 and beta4 have an opposite influence on the negative reinforcing properties of ethanol withdrawal. Modulating the expression, cellular distribution or interaction properties of BK channel auxiliary subunits may represent a novel avenue for the treatment of alcoholism.

Title: Differential effects of ghrelin antagonists on alcohol drinking following chronic intermittent ethanol vapor exposure in mice

Authors: *J. L. GOMEZ, C. SNELLING, D. A. FINN, A. E. RYABININ;
Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Alcohol addiction is a medical disease that causes both personal problems and takes a vast toll on society. It is imperative to find treatments that suppress alcohol drinking in individuals who suffer from this disorder. Recent research has shown that ghrelin receptor antagonists have the ability to suppress drinking and alleviate some neurological changes caused by excessive alcohol consumption. In this study, we used 3 days of chronic intermittent ethanol

vapor exposure (CIE), which is an established technique for increasing alcohol consumption in dependent C57BL/6 mice. We tested whether two different ghrelin receptor antagonists (DLys3-Ghrp-6 and JMV2959) would suppress the increase in ethanol consumption following CIE. Male C57BL/6 mice were randomly assigned to six groups based on drug and vapor exposure: Vehicle-Air, Vehicle-CIE, JMV-Air, JMV-CIE, DLys-Air, and DLys-CIE. Using a 2-bottle choice drinking-in-the-dark procedure, baseline drinking of 15% v/v ethanol was established before any drug or vapor exposure, with no statistical differences found between pre-assigned groups. Following both the first and second cycles of 3 days of intermittent vapor exposure, we found that both ghrelin antagonists suppressed ethanol consumption regardless of vapor exposure; however, the effects were transient. On day-1, ethanol intake after the first vapor or air exposure was suppressed by JMV and DLys. Intake returned to vehicle levels by day-3 in the DLys group, but the JMV group continued to show reduced intake. After the second vapor or air exposure, the drug effects were the same, with JMV and DLys suppressing intake. However, by day-2 (DLys) and day-3 (JMV) the drug groups returned to control levels of drinking. The preferences and total fluid intake data during the 2-hour ethanol exposure overall reflected the measured ethanol intake. However, the DLys treated mice showed a decrease in preference and the JMV mice showed a reduced total fluid intake. Thus, the drugs appear to differ in specificity of their actions on ethanol intake. It is possible that this difference reflects previous findings indicating that JMV has more pharmacologically specific effects on ghrelin receptors than DLys. It should be noted that over a 24-hour period, water and food consumption was not different between groups. In conclusion, while ghrelin antagonists might be adequate at suppressing increased ethanol intake by exposure to CIE, the effects were transient. Therefore, future research will attempt to reduce ghrelin receptor expression in specific regions on a longer term basis to determine if targeting this receptor can be used for alcohol abuse and dependence treatment.

Title: Dopamine system adaptations in alcohol abstinence: Evidence from humans and rats for a hyperdopaminergic state

Authors: *N. HIRTH[1], M. W. MEINHARDT[1], L. BROCCOLI[1], S. PERREAU-LENZ[1], S. UHRIG[1], R. RIMONDINI[2], C. HARPER[3], M. HEILIG[4], R. SPANAGEL[1], W. H. SOMMER[1], A. C. HANSSON[1];
[1]Psychopharmacology, Central Inst. of Mental Hlth., Mannheim, Germany; [2]Univ. of Bologna, Bologna, Italy; [3]The Univ. of Sydney, Sydney, Australia; [4]Natl. Inst. on Alcohol Abuse and Alcoholism (NIAAA), Bethesda, MD

Abstract: The mesocorticolimbic dopamine (DA) system is critically involved in addiction and undergoes pronounced neuroadaptations after chronic alcohol consumption. Acute withdrawal from alcohol has consistently been shown to down-regulate DAergic neurotransmission while reports on the state of the mesocorticolimbic DA system in abstinence are contradictory. Human positron emission tomography studies on abstinent alcoholics suggest mostly attenuated striatal DRD2 and DA levels. The DA receptor D1 (DRD1) has so far been less studied.
Here, we investigated the expression of DRD1 and DRD2 as well as the DA transporter (DAT) on both the mRNA and the protein level using post-mortem striatal brain tissue of human male alcoholic and control subjects by qRT-PCR and receptor autoradiography. To gain further insight into underlying mechanisms we compare these data to three weeks abstinent rats in which alcohol dependence was induced by chronic intermittent alcohol vapor exposure. In these animals, we analyzed expression of DRD1, DRD2, DAT and tyrosine hydroxylase (TH) by in situ hybridization and receptor autoradiography. Extracellular DA levels were measured within the nucleus accumbens of PD rats and controls by in vivo microdialysis.
We found highly significant down-regulation of DRD1 and DAT binding in the ventral striatum and nucleus caudatus of human alcoholics, while DRD2 was unaffected. Also in alcohol abstinent rats we found reduced striatal DRD1 levels as well as increased mRNA expression of the DA synthesizing enzyme TH in the substantia nigra pars compacta. Together these data point to a hyperdopaminergic state during abstinence from alcohol dependence. This hypothesis was confirmed by in vivo microdialysis showing increased extracellular DA levels in the Acb shell region of abstinent rats.
Our data indicate increased DA levels during alcohol abstinence and support the hypothesis of a hyperdopaminergic state in abstinent alcoholics that may exist at least in a subgroup of alcoholics. Future studies are needed to reveal the mechanisms underlying the altered DA transmission in alcohol dependence.

Title: Pharmacodynamic interactions of a solid formulation of sodium oxybate and alcohol in healthy volunteers

Authors: *N. PROSS[1], N. FAUCHOUX[2], H. HADJDUCHOVA[3], C. DENOT[2], A. DUFOUR[4], A. PATAT[2], P. VIVET[3];
[1]BIOTRIAL Neurosci., Didenheim, France; [2]Biotrial, Rennes, France; [3]D&A Pharma, Paris, France; [4]Univ. of Strasbourg, Strasbourg, France

Abstract: *Introduction:* A liquid formulation of Sodium oxybate (SO) has been approved for the treatment of alcohol dependence (AD) in Europe. The pharmacological effects of SO have a number of similarities with those of alcohol. This present study evaluated the pharmacodynamic interaction of SMO.IR (a bioequivalent solid immediate release formulation of SO) and alcohol to test whether this interaction potentiates or diminishes the effects of both SMO.IR and alcohol and to what extent.
Methods: 24 healthy volunteers of either sex participated in a randomized, double-blind, double-dummy, and crossover trial. Study participants randomly received the four study treatments with an at least two-day interval between each administration: a) 2.25 g of SMO.IR and placebo alcohol preparation, b) 2.25 g of SMO.IR and alcohol (0.7 g/kg alcohol for males and 0.57 g/kg alcohol mixed with apple juice), c) 2.25 g of SMO.IR matching placebo and alcohol, d) 2.25 g of SMO.IR matching placebo and placebo alcohol preparation. Study endpoints were objective and subjective cognitive tests, adverse events, vital signs assessed before, and 15 and 165 minutes after oral study drug administration. Cognitive tests included: Body Sway Test, Saccadic Eye Movement, Choice Reaction Time, Critical Tracking Test, Digit Vigilance, Numeric and, Spatial Working Memory, Bond & Lader VAS, ARCI 49, and Biphasic Alcohol Effects Scale.
Results: Alcohol produced the expected significant impairment in cognitive performance as well as the expected subjective sedation rapidly after intake (from 15 min). The effects of a single dose of SMO.IR produced a few significant objective and subjective sedative effects which were more pronounced 165 min post dose. Subjective complaints were related to lesser stimulation and greater sedation, but 165 minutes after administration this subjective sedation feeling was lesser with SMO.IR than with alcohol. There was a significant interaction between SMO.IR and

alcohol, at 15 min, that resulted in an increase in alertness and stimulation and a decrease in sedation. In addition, an isolated mild decrease in digit vigilance accuracy occurred at 165 min post dose after combination.
When SMO.IR was administered together with alcohol there was a slight increase in the total number of the TEAEs (46 in total) than when either SMO.IR alone (30) or alcohol alone were administered (34). No significant changes in heart rate, blood pressure, oxygen saturation, and routine laboratory tests were observed.
Conclusion: SMO.IR and alcohol have a distinct adverse effect profile. Sedative effects of SMO.IR are much less marked than those of alcohol and no reciprocal potentiation was observed.

Title: Glial regulation of alcohol behavioral responses in *Drosophila*

Authors: *S. PARKHURST[1], A. V. LEGENDRE[2], E. C. KONG[3], F. W. WOLF[2,3];
[2]Mol. Cell Biol., [1]Univ. of California, Merced, Merced, CA; [3]Ernest Gallo Clin. and Res. Ctr., Emeryville, CA

Abstract: Increased alcohol intake is facilitated by the development of tolerance, a simple form of behavioral plasticity that can be simply defined as the acquired resistance to the aversive effects of the drug. While the role of neurons in alcohol tolerance is well documented, little is known about the contribution of glia. In the fruit fly Drosophila, glia are thought to perform many of the same roles as their vertebrate counterparts, although much of their function remains unknown. Studies in flies and mice provide evidence that glia and neurons communicate and that glia are crucial for regulation of complex behaviors. We discovered that a glia-specific gene responds to acute ethanol exposure and is required for the development of ethanol tolerance in the glia that make up the blood-brain barrier. These findings led us to test the role of currently known glial functions in ethanol behaviors. Our results indicate that the astrocyte-like glia that are in contact with brain synapses both recieve and transmit signals to promote the development of ethanol tolerance. These data indicate that two distinct types of glia regulate ethanol behaviors and suggest that glial-neuronal communication is crucial for the expression of one form of behavioral plasticity.

Title: Nicotine aerosol delivery to rodents in a self-administration model mimics nicotine intake during cigarette smoking and can be used to screen smoking cessation pharmacotherapies

Authors: X. M. XIE[1], L. YANG[1], C. PASCUAL[1], B. ZOU[1], A. MALIK[1], L. TOLL[2], N. ZAVERI[3], Y. ZHU[4], *X. M. SHAO[5];

Sci., Univerisity of California Los Angeles, Los Angeles, CA; [5]Neurobio., David Geffen Sch. Med. at UCLA, LOS ANGELES, CA

Abstract: Cigarette smoke is an aerosol with tiny particles that contain nicotine. Smoke aerosol particles within the respirable size range carry nicotine into the alveoli of the lungs, leading to a rapid increase in arterial blood nicotine concentrations and nicotine reaches the brain in 8-10 s. The high-arterial-peak concentration pattern of nicotine pharmacokinetics plays an important role in development of dependence. The determination of efficacy for smoking cessation drugs under development typically uses the intravenous (i.v.) self-administration (SA) of nicotine in freely-moving rats. The i.v. SA is invasive and does not recapitulate the nicotine delivery route of cigarette smoking. To generate higher predictive validity in nicotine addiction models, we developed a novel system for delivering nicotine to rodents using alveolar region-targeted aerosol technology. The aerosol SA chamber consists of the SmartCageTM, a versatile homecage behavior monitoring system, equipped with special software which allows nicotine aerosol delivery to rodents trained to self-administer nicotine by pressing levers or by a scheduled passive delivery. The system also consists of a nebulizer, a food dispenser, two flowmeters and a pressure gauge. The aerosol droplet size distribution was determined that had a mass median aerodynamic diameter of 2.03 μm with a geometric standard deviation of 1.52, which is within the range of respirable diameter. With aerosol generated using 0.5 % nicotine solution in the nebulizer, the time-course of arterial plasma nicotine concentrations during and after 2 min aerosol inhalation in rats showed a peak level of 57 ng/ml within 1 to 3 min from the start of aerosol exposure and the nicotine level declined over the next 20 min. The magnitude and kinetics mimic humans smoking a cigarette. By operating levers rats obtain nicotine aerosol and develop dependency over a period of 3-4 weeks. This system was evaluated by investigating whether the clinically used smoking cessation pharmacotherapy, varenicline, and a recently published alpha3beta4 nicotinic acetylcholine receptor (nAChR) ligand, AT-1001, which have both been shown to inhibit nicotine self-administration in a typical i.v. SA paradigm, also showed efficacy when nicotine was delivered via aerosol in our SA chamber. Both varenicline and AT1001 reversibly blocked nicotine aerosol SA similar to their action using i.v. nicotine SA. Enhancement of the system and SA validation studies are currently ongoing in order to develop predictive in vivo screening systems for phenotypic drug discovery for smoking cessation.

Title: Hypocretin modulation of nicotine-mediated alterations in brain reward function are dependent on required level of effort

Authors: *C. D. FOWLER, P. J. KENNY;
Mol. Therapeut., The Scripps Res. Inst., JUPITER, FL

Abstract: Our laboratory has previously shown that hypocretin (orexin) modulates nicotine reinforcement in rodents. Specifically, blockade of hypocretin receptors in rats or genetic ablation of the hypocretin-1 receptor gene in mice results in decreased motivation to self-administer nicotine. Since other reports with varying experimental conditions have not demonstrated alterations in behavioral responding for nicotine with blockade of hypocretin-1 receptors, we sought to more fully investigate the involvement of hypocretin on brain reward function under varying effort requirements. As such, we examined the effects of the selective hypocretin-1 receptor antagonist SB-334867 on intracranial self-stimulation (ICSS) thresholds and intravenous nicotine self-administration (SA) in rats while manipulating effort requirements for each procedure. Adult male Wistar rats were surgically implanted with bipolar cranial electrodes and subsequently trained in a discrete trial current threshold ICSS procedure. Concurrently, subjects were also trained to press an active lever to receive food reward under a fixed ratio 5, time out 20 sec schedule of reinforcement (FR5 TO20sec). Thereafter, the rats were surgically implanted with intravenous catheters into the right jugular vein. After a recovery period, the subjects were permitted daily access to respond for intracranial self-stimulation (pre-SA ICSS), followed by an 1-hr nicotine SA session, and subsequently a second self-stimulation session (post-SA ICSS). After achieving stable levels of responding, the procedural requirements were manipulated to make the task less rigorous. For nicotine SA, the FR5 requirement was modified to a FR1 requirement; for ICSS, the number of trials per current intensity, inter-trial interval duration, and within-trial duration were decreased. We found that administration of SB-334867 decreased nicotine self-administration under the more effortful FR5 SA conditions, as previously reported, but was ineffective under the less strenuous FR1 requirements. Further, under the more effortful ICSS conditions, SB-334867 significantly attenuated the nicotine-induced lowering of brain reward thresholds, whereas when the procedure conditions required less rigorous, SB-334867 was ineffective in altering nicotine-induced lowering of brain reward

thresholds. Together, these data indicate that hypocretin signaling mediates nicotine's effects on brain reward function only when higher levels of motivation are required, and as such, therapeutics targeting hypocretin transmission for smoking cessation may be more efficacious when access to the drug is limited.

Title: A hypocretin-regulated "value attribution" circuit in dorsal thalamus controls compulsive nicotine use

Authors: *J. A. HOLLANDER, B. R. LEE, L. M. TUESTA, E. KOESEMA, P. J. KENNY; The Scripps Res. Inst., JUPITER, FL

Abstract: Tobacco addiction occurs when the motivation to obtain nicotine reward persists at the expense of alternative sources of reward, but the underlying mechanisms remain poorly understood. Hypocretin (Hcrt) is a recently discovered lateral hypothalamic neuropeptide that is emerging as an important regulator of reward and motivation. While Hcrt has been hypothesized to control nicotine by modulating its rewarding properties, we investigated the possibility that Hcrt instead regulates the motivational "value" of nicotine, reflected in the amount of effort that will be expended (price paid) to obtain the drug. First, we found that that mice with a null mutation in the Hcrt-1 receptor decreased intravenous nicotine self-administration (SA) compared to their wildtype littermates (WT) when the fixed-ratio schedule was increased (which requires greater effort to receive drug reward). Using a Hcrt-1 receptor reporter mouse line (OX1-eGFP) we identified a previously uncharacterized population of GABAergic cells in the thalamus located adjacent to the lateral habenula. Intriguingly, we found that virus-mediated re-expression of these genetically ablated receptors in this region entirely rescued the deficits in nicotine intake observed in the KO mice. Further, thalamic infusion of the Hcrt-1 receptor antagonist, SB-334867 decreased nicotine SA. Based on these observations, we hypothesized that disruption of Hcrt-1 transmission may result in local thalamic hyperexcitability, which

decreases the value of nicotine without impacting its rewarding effects. Consistent with this idea, increased excitability of local thalamic activity by Designer Receptors Exclusively Activated by Designer Drugs (DREADD) reduced nicotine SA, whereas DREADD-mediated inhibition of activity triggered compulsive-like responding even when its delivery was accompanied by aversive footshock. Our findings identify a novel hypocretin-controlled thalamic circuit that attributes value to nicotine by allocating resources to obtain the drug. Further, excessive activation of this pathway may explain why smokers persist in the habit despite awareness of the potential fatal consequences.

Title: Brain glucagon-like peptide-1 regulates the reinforcing properties of nicotine

Authors: *L. M. TUESTA, C. D. FOWLER, B. R. LEE, P. BALI, Q. LU, P. J. KENNY; Mol. Therapeut., The Scripps Res. Inst., Jupiter, FL

Abstract: Cigarette smoking is a principal cause of preventable death and disease in developed nations, with approximately $160 billion being spent yearly in the United States to cover direct health care costs from resulting diseases. Nicotine is the major reinforcing component in tobacco smoke that contributes to the development of the harmful smoking habit in humans. The reinforcing actions of nicotine are mediated through various subtypes of nicotinic acetylcholine receptors located within brain reward circuitries. Central glucagon-like peptide-1 (GLP-1) is a neuropeptide produced in the nucleus of the solitary tract (NTS), a brain stem structure abundant in nicotinic acetylcholine receptors. Whilst noradrenergic efferents from the NTS have been implicated in drug dependence processes, the potential contribution of GLP-1 output from the NTS in this process has not been investigated.
We found that GLP-1 receptor KO mice consume more nicotine when compared to wildtype

littermates, across all doses tested. Conversely, GLP-1 neuron-specific stimulation via cre-inducible M3 DREADDs show that brain-derived GLP-1 reduces the reinforcing properties of nicotine. Our results suggest that GLP-1 transmission serves as a negative regulator of nicotine reinforcement. Recently, our laboratory reported that excitatory inputs from the medial habenula to the interpeduncular nucleus (IPN) also serve to negatively regulate nicotine intake. Intriguingly, GLP-1 receptors are densely expressed in IPN. Electrophysiological recordings coupled with optogenetic or electrically evoked activity revealed that GLP-1 receptors located on presynaptic terminals enhanced activity of IPN neurons. Further, stimulation of GLP-1 receptors in IPN via microinfusion of the GLP-1 receptor agonist, Exendin-4, reduces nicotine intake in rats through a cAMP-dependent mechanism.
These data identify a new brain circuit - IPN-projecting GLP-1 neurons - that negatively regulate nicotine intake. Moreover, these findings suggest that modulation of GLP-1 receptor transmission may be viable target for the development of novel therapeutics for smoking cessation.

Title: Inactivation of the central nucleus of the amygdala reduces the stress-induced amplification of relapse to nicotine-taking

Authors: *G. YU, Z. HUANG, H. CHEN, B. M. SHARP;
Pharmacol., Univ. of Tennessee Hlth. Sci. Ctr., MEMPHIS, TN

Abstract: Quitting smoking is very challenging and often unsuccessful due to multiple factors that promote relapse after abstinence. Stress is an important factor that increases the likelihood of relapse. In rodents, stress-induced reinstatement of nicotine-seeking (non-reinforced) after extinction of operant nicotine self-administration (SA) is well established. Recently, we established an animal model demonstrating the amplification of relapse to nicotine-taking (reinforced) by repetitive exposure to stress during abstinence. However, the underlying mechanism is unknown. The central nucleus of the amygdala (CNA) plays a critical role in

stress-induced reinstatement of nicotine-seeking. Therefore, we determined the effect of CNA inactivation on the amplification of relapse to nicotine-taking by stress. Adult male SD rats acquired nicotine SA (0.03 mg/kg, 23h/d) under an FR 5 schedule of reinforcement. Restraint stress (30 min) was administered on alternate days (total of 4 stress sessions) during abstinence from nicotine SA. Thereafter, animals reacquired nicotine SA, beginning 24 h after the final stress. A mixture of baclofen and muscimol (B/M = GABAb and GABAa agonists; 0.3 and 0.03 nmol/side) was injected into CNA 30 min prior to the nicotine SA test session (i.e.,reacquisition). Withdrawal per se increased the reacquisition of nicotine SA (i.e., active lever presses and nicotine intake; $p<0.05$). Repetitive stress further amplified the reacquisition of nicotine SA ($p<0.05$), and induced nicotine-taking during the behaviorally inactive phase (i.e., lights on) of the 24 h light/dark cycle. In rats exposed to repetitive stress, inactivation of CNA reduced active lever presses and nicotine intake ($p<0.05$) to their pre-withdrawal baseline levels. These data show that CNA is a critical neural substrate involved in the amplification of relapse to nicotine-taking by chronic stress.

Title: Histone deacetylase inhibition amplifies reacquisition of nicotine SA and contributes to the stress-induced amplification of relapse to nicotine-taking

Authors: G. YU, Z. HUANG, H. CHEN, *B. M. SHARP;
Dept Phamacol, Univ. Tennessee Hlth. Sci. Ctr., MEMPHIS, TN

Abstract: Stress promotes relapse to smoking. Recently, we established an animal model demonstrating the amplification of relapse to nicotine-taking by stress during abstinence from nicotine SA. Further studies of this model may elucidate mechanisms underlying stress-induced relapse to smoking. Epigenetic modifications, such as histone acetylation, are involved in the long-term effects of both drugs of abuse (i.e. cocaine) and stress. However, the potential role of epigenetic mechanisms in the stress-induced amplification of relapse to nicotine-taking is unknown. Therefore, we determined the effect of histone deacetylase (HDAC) inhibitors on the reacquisition of nicotine SA in rats exposed to repetitive stress during abstinence. Adult male SD

rats acquired nicotine SA (0.03 mg/kg, 23h/d) under an FR 5 schedule of reinforcement. Restraint stress (30 min) was administered on alternate days (total of 4 stress sessions) during abstinence from nicotine SA. Thereafter, animals reacquired nicotine SA, beginning 24 h after the final stress. HDAC inhibitors, 4-phenylbutyrate (4-PB, 20 mg/kg) or trichostain A (TSA, 0.3 mg/kg) were administered (i.v.) 30 min prior to each restraint or sham-stress session. Neither 4-PB or TSA altered the effects of stress on reacquisition of nicotine SA (i.e., active lever presses and nicotine intake; $p>0.05$). In contrast, an injection of 4-PB or TSA on alternate days of abstinence (total of 4 injections) amplified the reacquisition of nicotine SA in unstressed rats ($p<0.05$). These data show that inhibition of histone deacetylase amplifies relapse to nicotine-taking to the same extent as stress, but does not alter the enhancing effects of stress. Therefore, the effect of stress on relapse to nicotine-taking may be mediated by inhibition of histone deacetylase.

Title: Interoceptive conditioning with the nicotine stimulus slowed by lesions to posterior but not anterior dorsomedial striatum

Authors: *S. CHARNTIKOV, S. PITTENGER, K. VESTAKIS, R. A. BEVINS;
Dept of Psychology, Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Tobacco use is the leading cause of preventable deaths worldwide. This habit is not only debilitating to individual users but also to those around them (second-hand smoking). Nicotine is the main addictive component of tobacco products and is a potent stimulant and a reinforcer. Importantly, besides its unconditional effects, nicotine also has conditional stimulus effects that may contribute to the tenacity of the smoking habit. Investigation of learning processes involving nicotine as a conditioned stimulus (CS) is an understudied area relevant to nicotine dependence. A preliminary study assessing neurobiological loci involved in nicotine-evoked conditioned response (CR) found that activation (as revealed through elevation of c-Fos) of dorsomedial caudate putamen (dmCPu) was dependent on learning history with nicotine. Therefore, the current study examined the effect of permanent neurotoxin lesions of either

anterior (a-) or posterior (p-) dmCPu on acquisition of the nicotine-evoked CR. In this experiment, rats received excitotoxic (NMDA) or sham lesions (vehicle) of either a-dmCPu or p-dmCPu before nicotine CS training. During nicotine CS training (20 total daily sessions), the nicotine stimulus (0.4 mg/kg; injected SC) was paired 100% of a time with intermittent access to sucrose deliveries (36 per session); sucrose was not available on intermixed saline days. Using this protocol, the nicotine CS readily acquired control of a goal-tracking CR (anticipatory food-seeking response) in the shams and in the a-dmCPu lesioned animals. Acquisition of conditioned responding was slowed in rats with lesions to p-dmCPu. Thus, permanent excitotoxic lesions to p-dmCPu and not a-dmCPu blunted acquisition of conditioned association between the nicotine stimulus and the appetitive sucrose reward. This finding, in part, supports an assumption of compartmentalized involvement of dmCPu in the acquisition and expression of conditioned behaviors where the posterior portion of dmCPu is predominantly involved in the acquisition and the anterior portion in expression. A follow-up experiment is underway in our laboratory to determine whether the a-dmCPu is involved in the expression of appetitive interoceptive conditioning with the nicotine stimulus.

Title: The effect of switching pharmacological intervention on nicotine-evoked conditioned responding in extinction

Authors: *S. T. PITTENGER, L. C. ZEPLIN, R. A. BEVINS;
Univ. of Nebraska-Lincoln, Lincoln, NE

Abstract: Nicotine dependence is a costly economic and societal burden. Several pharmacotherapies have been developed to aid in smoking cessation. While these medications increase successful quit attempts compared to no cessation aid, attempts to quit often fail. A relapse or threat of relapse to smoking is often met with a change in the smoking cessation aid. Although this practice is becoming common, very little is known about the behavioral or pharmacological effects of switching pharmacotherapies. To begin to fill this gap, the present

study examined the effects of switching pharmacotherapies on interoceptive conditioning involving the nicotine stimulus. This question is of import given the role interoceptive stimuli play in addiction maintenance and relapse.
Utilizing a discriminated goal-tracking task, male Sprague Dawley rats (n=60) were trained to discriminate nicotine from saline. We paired 0.4 mg/kg nicotine injections (SC) with intermittent sucrose access during a 20-min session in a conditioning chamber. On intermixed days, saline (0.9%; SC) was administered before sessions and no sucrose available. Following discrimination training was the extinction phase. Rats receive their assigned ligand before the start of the 20-min session and sucrose was no longer available. Rats were separated into 5 groups for this extinction phase: Sal-to-Sal, Nic-to-Nic, 5.6Nor-to-5.6Nor, 5.6Nor-to-1.0Var, and 5.6Nor-to-0.3Var (n=12 per group; Sal = saline; Nic = 0.4 mg/kg nicotine; 5.6Nor = 5.6 mg/kg nornicotine; 1.0Var = 1.0 mg/kg varenicline; 0.3Var = 0.3 mg/kg varenicline). The first part of group names denote what drug was administered on the first 3 days of extinction training; the second part represent what was administered on the last 3 days of extinction. We also investigated how this extinction history with stimuli that share stimulus effects with nicotine would affect appetitively-motivated behavior controlled by nicotine establishing a cumulative dose-effect curve.
Rats readily discriminated nicotine from saline sessions with nicotine evoking a robust goal-tracking response. Nornicotine partially substituted for nicotine in the early extinction sessions. Rats that were switched from nornicotine to varenicline displayed attenuated responding relative to those that continued to receive nornicotine throughout extinction. This suggests that early extinction with nornicotine is sufficient to extinguish nicotine-like responding evoked by varenicline. These group differences in extinction, however, did not translate into difference in the cumulative nicotine dose-effect curve on the transfer test.

Title: Cooling sensation of menthol is a conditioned reinforcer for nicotine

Authors: *H. CHEN, T. WANG, B. WANG;
Dept Pharmacol, Univ. Tennessee Hlth. Sci. Ctr., MEMPHIS, TN

Abstract: Menthol is the most common tobacco additive. It induces multimodal sensory stimulation that includes a cooling sensation, minty odor, and bitter taste. Approximately 30% US smokers prefer menthol cigarettes over non-menthol ones. The use of menthol in cigarettes facilitates smoking initiation and enhances nicotine dependence. Smoking menthol cigarettes is also associated with less responsiveness to medication and greater difficulty in quitting, especially in minority ethnic populations. Despite the rapid accumulation of clinical data, a mechanistic understanding of menthol's effect is still lacking, partly due to the lack of animal models. We hypothesized that the cooling sensation of menthol, but not its olfactogustatory stimulation, is a conditioned reinforcer for nicotine reward. We tested the hypothesis by using licking as the operant behavior for nicotine self-administration (SA). Adolescent female Sprague-Dawley rats were given daily 3 h SA sessions with two drinking spouts; licking on the active spout delivered 60 µl menthol (0.01% w/v) and i.v. nicotine (30 µg/kg/infusion) on a fixed-ratio 10 reinforcement schedule. Licking on the inactive spout had no programmed consequence. The number of infusions significantly increased ($p < 0.005$) over the test sessions, gradually reached ~10 infusions around day 7, and maintained that level thereafter. In contrast, rats self-administered saline with menthol cue or nicotine with vehicle as cue (0.01% Tween 80) failed to shown an increase in nicotine infusion (ps < 0.05). The number of infusions was significantly higher in nicotine menthol rats compared to saline menthol ($p<0.001$) and nicotine-vehicle ($p<0.001$) rats, demonstrating that menthol as a sensory cue supports nicotine SA. Rats yoked to the nicotine-menthol group emitted significantly fewer active licks ($p<0.01$). Unsweetened grape Kool-Aid (0.1% w/v), a flavor that is mostly odor did not support nicotine SA. These rats avoided the active spout ($p < 0.001$) and self-administered less than 2 infusions per session. Last, WS-23, a compound induces similar cooling effect as menthol but has no detectable odor also supported nicotine SA (active lick > inactive lick, $p < 0.05$, mean infusion = 11.4 ± 1.3 for the last four days). Together, these data demonstrated that although menthol per se is not reinforcing, classical conditioning between its cooling, but not the olfactogustatory properties, with nicotine enhances the motivation to obtain the drug.

Title: Carbon Disulfide mediates socially-acquired nicotine self-administration

Authors: *S. GONG, T. WANG, H. CHEN;
Dept pharmacology, Univ. of Tennessee Hlth. Sci. Ctr., Memphis, TN

Abstract: Social environment plays critical roles in smoking initiation. The majority of first time cigarette uses occurred in the presence of friends; peer smoking was one of the strongest predictors of smoking initiation. Further, befriend with smokers increased the likelihood of becoming a smoker, while discouraging from the social network was negatively associated with smoking status. We previously reported that rats developed conditioned taste aversion (CTA) to an appetitive olfactogustatory (OG) cues contingent with self-administered i.v. nicotine. However, sustained self-administration (SA) of nicotine was developed in the presence of a demonstrator rat that had access to the same OG cue (but not receiving nicotine). This socially-acquired SA behavior required nicotine contingent odor cue but the signal mediating social learning was unknown. We hypothesized that carbon disulfide, a chemical detected in rats' breath and involved in social transmission of food preference, also mediates socially-acquired nicotine SA. We tested this hypothesis by placing solo rats in operant chambers equipped with two lickometers. Licking on the active spout meeting fixed-ratio 10 schedule resulted in the simultaneous delivery of an olfactogustatory cue (0.4% saccharin and 0.1% unsweetened grape Kool-Aid) containing 0.01% carbon disulfide to the active spout and i.v. nicotine (30 µg/kg/inf). In contrast to the development of CTA, these rats self-administered an average of 10.3 ± 1.0 nicotine infusions per 3 h daily sessions during the last three days of test, which was almost identical to the number of infusions self-administered by rats placed with demonstrator rats. Repeated measures ANOVA found a significant interaction between session number and spout ($p<0.001$) in rats had access to the OG cue and carbon disulfide. During sessions 1-5, the number of active licks was significantly less than inactive licks ($p<0.05$), while during sessions 6-10, the number of active licks were higher than inactive licks ($p=0.05$). Therefore, these data demonstrated for the first time that carbon disulfide mediates socially-acquired nicotine SA.

Title: Acute administration of the α4β2* nAChR agonist ABT-089 and the α7 nAChR agonist ABT-107 attenuates nicotine seeking in rats

Authors: *B. A. KIMMEY, A. C. ARREOLA, A. M. LEE, H. D. SCHMIDT;
Dept. of Psychiatry, Univ. of Pennsylvania, Philadelphia, PA

Abstract: Nicotine addiction is a chronic relapsing disorder that represents the single-most preventable cause of death in the United States today. While two-thirds of the tobacco-smoking population expresses a desire to quit, only 3% of smokers successfully quit on their own. Current FDA-approved smoking cessation medications maintain long-term smoking abstinence in only 25% of smokers attempting to quit. Therefore, there is a critical need to develop more efficacious smoking cessation medications. Nicotine is the primary psychoactive component in tobacco smoke that binds to and stimulates nicotinic acetylcholine receptors (nAChRs). A large body of evidence indicates that increased nAChR signaling plays a critical role in nicotine self-administration and the reinstatement of nicotine-seeking behavior in rats, an animal model of nicotine craving and relapse in human smokers. Here, we examined the effects of acute administration of the α4β2* nAChR agonist ABT-089 and the α7 nAChR agonist ABT-107 on nicotine taking and seeking in rats. Rats were trained to self-administer intravenous infusions of nicotine (30 μg/kg/59 μL). Acute administration of ABT-089 (0, 1.2 and 12.0 mg/kg, i.p.) and ABT-107 (0, 0.03 and 0.3 mg/kg, i.p.) prior to the start of an operant session had no effect on self-administration of nicotine when rats were maintained on a fixed-ratio 5 (FR5) schedule of reinforcement. In contrast, acute administration of ABT-089 (12 mg/kg, i.p.) or ABT-107 (0.3 mg/kg, i.p.) prior to a nicotine reinstatement test session attenuated nicotine-seeking behavior. These effects did not generalize to other reinforced behaviors, as neither ABT-089 nor ABT-107 affected sucrose self-administration or the reinstatement of sucrose seeking. This is the first study to assess the effects of ABT-089 and ABT-107 on nicotine self-administration and reinstatement of nicotine seeking in rats. Our results indicate that stimulation of nAChRs during withdrawal is sufficient to attenuate nicotine seeking.

Title: Repeated administration of an acetylcholinesterase inhibitor attenuates nicotine taking in rats

Authors: *A. C. ARREOLA, B. A. KIMMEY, L. E. RUPPRECHT, A. M. LEE, M. R. HAYES, H. D. SCHMIDT;
Univ. of Pennsylvania, Philadelphia, PA

Abstract: Nicotine craving and cognitive impairments represent core symptoms of nicotine withdrawal that predict relapse in abstinent smokers. These findings suggest that cognitive-enhancing medications may prevent drug craving and relapse, in part, by reversing or normalizing nicotine withdrawal-induced cognitive impairments. Acetylcholinesterase inhibitors (AChEIs) are FDA-approved to treat cognitive deficits in patients with Alzheimer's disease. Previously, we demonstrated that acute administration of the AChEIs galantamine and donepezil attenuates nicotine taking and seeking in rats. However, chronic studies of AChEI administration on nicotine taking are needed in order to model the dosing regimen that is likely to be prescribed to smokers attempting to quit. Therefore, the goal of these experiments was to determine the effects of repeated AChEI administration on nicotine self-administration in rats, an animal model of voluntary nicotine taking in human smokers. Rats were trained to self-administer intravenous infusions of nicotine (0.03 mg/kg/0.59mL) on a fixed-ratio 5 (FR5) schedule of reinforcement. Once rats maintained stable nicotine taking, galantamine (0, 0.5 and 5.0 mg/kg, i.p.) was administered 20 minutes prior to 10 consecutive daily nicotine self-administration sessions. Repeated administration of 5.0 mg/kg galantamine attenuated nicotine taking in rats. In order to determine if the effects of repeated galantamine generalize to other reinforced behaviors, a separate group of rats was trained to self-administer sucrose pellets. No differences in sucrose self-administration were noted between rats pretreated with galantamine when compared to saline treated controls. Malaise symptoms, including nausea and vomiting, are commonly reported adverse effects of AChEIs administration in humans. Therefore, the effects of repeated galantamine administration on ad libitum food intake and pica, an animal model that is used to

assess rodent consumption of non-nutritive substances (i.e. kaolin clay) in response to emetic agents, were tested in a separate cohort of rats. No effects of repeated galantamine administration on pica or normal feeding behavior were observed. Taken together, these results indicate that repeated AChEI administration attenuates nicotine taking and that these effects are not due to adverse malaise-like symptoms.

Title: Juvenile play experience attenuates the initial level of nicotine consumption

Authors: *B. T. HIMMLER[1], E. SNOW[2], A. MCMICKLE[2], S. M. PELLIS[1], B. KOLB[1], K. D. BIONDOLILLO[2];
[1]Univ. of Lethbridge, Lethbridge, AB, Canada; [2]Arkansas State Univ., Jonesboro, AR

Abstract: Nicotine given in adulthood increases the dendritic arbor of the neurons of the medial prefrontal cortex (mPFC). Juvenile play experience increases this neural response to nicotine and behavioral testing for drug sensitization suggests that this play-induced plasticity initially attenuates the effects of nicotine. The objective of the present study was to determine if prior play experience influences the voluntary consumption of nicotine. Post-weaning rats were reared with either three other juvenile rats (play group) or one adult female rat (no play group), and in adulthood, half of each group was exposed to nicotine. Following this exposure, all groups received a multiple bottle arrangement consisting of two concentrations of nicotine (5µg/ml or 8µg/ml) and water, which were all freely available for consumption. The total amount consumed of each was measured. While all groups preferred the lower dose (5µg/ml) compared to the higher dose (8µg/ml) of nicotine, animals with prior play experience exhibited an initial attenuation in their consumption of nicotine. Therefore, the play-induced plasticity of the mPFC

appears to serve, at least initially, as a protective change both in the sensitization to nicotine and also in the consumption of nicotine.

Title: Loss of Cd81 function increases nicotine preference, but decreases depression- and anxiety-like behavior in mice

Authors: R. L. MURPHY, L. L. LOCKLEAR, M. H. NIAZ, R. WALTON, *K. J. FRYXELL; Sch. of Systems Biol., George Mason Univ., MANASSAS, VA

Abstract: There are poorly understood connections between mental health disorders and drug abuse, likely reflecting both causes (i.e., some mental health disorders cause increased emotional needs and/or vulnerability to drug dependence) and effects (i.e., drug addiction may produce negative emotional or cognitive effects). As an example, nicotine dependence has been shown to be statistically associated with depression, anxiety, schizophrenia, and ADHD. Our laboratory and others have previously shown that the *Cd81* gene is implicated in the behavioral and gene expression response to drugs of abuse, including cocaine and nicotine, but does not affect cognitive abilities in the Morris water maze. Here we show that the loss of *Cd81* function significantly increased the voluntary nicotine consumption of adult female C57BL/6J mice. The voluntary nicotine consumption of both *Cd81* -/- and +/+ mice increased steadily for 4 weeks, and then reached a plateau that was maintained for another 4 weeks, suggesting that *Cd81* did not affect the aversion to higher doses of nicotine. We further show that loss of *Cd81* function significantly increased struggling in the forced swim test and the tail suspension test, two models of depression. Finally, loss of *Cd81* function in male mice significantly increased their preference for the light side of the light/dark box, a model of anxiety. These results indicate that

CD81 (an adaptor protein involved in assembly of signaling complexes) plays a key role in both drug reward and emotional behaviors.

Title: Nicotine enhances conditioned approach behavior measured by a pavlovian autoshaping procedure and responding for conditioned reinforcement

Authors: *E. G. GUY[1], P. J. FLETCHER[2];
[1]Psychology, Univ. of Toronto, Toronto, ON, Canada; [2]Psychiatry, Ctr. for Addiction and Mental Hlth., Toronto, ON, Canada

Abstract: Nicotine reinforcement is thought to be, at least in part, due to an effect on enhancing the attractive and motivating properties of other, non-nicotinic reward stimuli. Our lab and others have shown that nicotine facilitates approach to a reward delivery receptacle in the presence of a conditioned stimulus (CS) during Pavlovian association trials, but this latter effect is not always observed. This may be due to differences in conditioned response trajectories under the influence of nicotine, with some animals attracted toward the CS itself rather than the goal receptacle. 40 water-restricted rats received nicotine (n = 20) or saline (n = 20) injections prior to 6 daily Pavlovian autoshaping trials, where an illuminated lever-CS was inserted into the test chamber just prior to the delivery of a water reinforcer. Animals that received nicotine exhibited higher levels of conditioned responding directed toward the lever-CS. Next, a subgroup of nicotine-exposed (n = 10) and saline-exposed (n = 10) animals were switched to saline or nicotine pretreatments for 6 additional trials. Removing nicotine decreased responding on the lever. Responding in the water receptacle was unaffected by nicotine. In a test of the motivating properties of the lever-CS, presentations of the lever supported the acquisition of a new operant response and nicotine enhanced this effect in animals with a history of nicotine exposure. Together, these data suggest that nicotine reinforcement is dually influenced by effects on enhancing both the attractive and motivating properties of CSs.

Title: Enhanced nicotine reward in a mouse model of the P129T FAAH gene polymorphism

Authors: *L. A. NATIVIDAD[1], I. Y. POLIS[1], D. G. STOUFFER[1], B. F. CRAVATT[2], L. H. PARSONS[1];
[1]Committee on the Neurobio. of Addictive Disorders, [2]Dept. of Chem. Physiol., The Scripps Res. Inst., La Jolla, CA

Abstract: A single nucleotide polymorphism (SNP) of the human fatty acid amide hydrolase (FAAH) gene leads to a missense mutation that substitutes a proline residue for threonine (P129T; C385A). The product of this mutation is a variant of the FAAH protein, an enzyme involved in the metabolism of anandamide and other fatty acid ethanolamides. Clinical studies report an association between the P129T mutation and problem drug use, including nicotine. The current study employed a P129T knock-in (KI) mouse model to characterize the effects of this SNP on the rewarding effects of nicotine using conditioned place preference (CPP), intravenous self-administration (IVSA), and in-vivo microdialysis procedures. For the CPP study, P129T KI and wild-type (WT) mice received 3 days of drug conditioning with both nicotine (0 - 0.7 mg/kg, sc) and saline injections paired with distinct environments in a 3-chamber maze each day. On the test day, the mice were allowed to explore all chambers of the maze in a drug-free state, and the time spent in the drug-paired environment was indexed as a measure of drug reward. In the IVSA studies, the nicotine dose-effect function (0.05 - 0.25 mg/kg/infusion) was characterized under an FR-1 schedule in P129T KI and WT mice, followed by evaluations of the motivation for nicotine intake under a progressive ratio (PR) schedule of reinforcement. The influence of CB1 receptor signaling in nicotine reward was investigated in pretreatment tests employing the CB1 antagonist/ inverse agonist SR141716A (0.1 - 3 mg/kg). The microdialysis study employed a nicotine exposure regimen identical to the conditioning procedure in the CPP study, with nucleus accumbens (NAc) microdialysates collected on the third and final day of drug exposure, and subsequently assayed for monoamine content. The results revealed genotypic differences

such that P129T KI mice exhibit enhanced sensitivity to low doses of nicotine reward relative to WT in the CPP paradigm. P129T KI mice also acquired nicotine IVSA more quickly, displayed an upward shift in the dose response, and achieved higher breakpoints during the PR probe. Pretreatment with SR141716A dose-dependently reduced nicotine IVSA in both mouse strains, but did not alter the genotypic difference in nicotine intake. Finally, P129T mice exhibit enhanced nicotine-induced elevations in NAc DA levels than their WT counterparts. Collectively, these data suggest that nicotine reward is enhanced in mice expressing the P129T mutation. The mechanisms by which genetic disruption of FAAH enhance sensitivity to nicotine do not appear to involve CB1 receptors, but likely involve dopamine transmission in terminal regions of the mesolimbic pathway.

Title: Neuropathic pain alters nicotine self-administration in rats

Authors: A. CIPPITELLI, J. SCHOCH, D. MERCATELLI, J. WU, K. GAIOLINI, *L. TOLL; Torrey Pines Inst. For Mol. Studies, Port Saint Lucie, FL

Abstract: Tobacco addiction and chronic pain represent highly prevalent and comorbid conditions that engender considerable burdens upon individuals and systems. Experimental studies suggest that nicotine has analgesic properties while epidemiologic evidence shows that smoking is a risk factor for chronic pain. Here, we tested the hypothesis that chronic/neuropathic pain alters the abuse potential of nicotine. Sprague Dawley rats were implanted with intravenous catheters and subjected to L-5 spinal nerve ligation (SNL). A second group, not receiving the SNL (Sham) was employed as a behavioral control. All rats were then allowed to self-administer various doses of nicotine (0, 3, 10, 30 µg/rat/0.1ml infusion) under both a fixed (FR-3) and a progressive ratio (PR) schedule of reinforcement. Results showed an inverted U-shaped dose-response curve in both groups. However, SNL rats showed an increased nicotine-reinforced lever pressing than Sham on FR-3 when the higher nicotine dose was offered. Furthermore, a

markedly increased motivation to obtain nicotine was observed in SNL rats at the 30 µg/rat dose as assessed on PR schedule while break point at lower dosages was not modified. Initial experiments suggested that this increased motivation to obtain nicotine was probably not due to nicotine's analgesic properties, as sensitivity to von Frey filaments, a measure of mechanical allodynia, was equal before and after the nicotine self-administration session. These data suggest that high dosages of nicotine may be perceived as less aversive in rats with neuropathic pain. Current experiments are aimed at further investigating whether the observed increased nicotine intake and motivation is due to the antinociceptive properties of nicotine that may serve as a coping strategy for the pain, or due to pain-induced neuroadaptations that may ultimately lead to increased vulnerability to nicotine addiction. The behavioral paradigm described here, in which animals with chronic pain increase nicotine self-administration may serve as a unique tool to explore neurobiological substrates of both neuropathic pain and nicotine reinforcement.

Title: Stress and immediacy effects on reward anticipation

Authors: *L. COSAND[1,2], D. CLEWETT[2], K. VEKARIA[2], K. REYES[2], X. CORDOVA[2], J. MONTEROSSO[2];
[1]Neurosci., Pomona Col., Claremont, CA; [2]USC, Los Angeles, CA

Abstract: Compulsive reward-seeking, seen in addiction and related disorders, has been linked to stress in animal models as well as human populations. One purported mechanism is an increased sensitivity to a reward's incentive salience (motivational strength). Incentive salience is also sensitive to a reward's immediacy, and stress-induced myopia may enhance this effect. The present study hypothesized that subjective stress would increase fMRI BOLD signal in brain regions associated with reward anticipation. Further, this hypothesized stress effect was predicted to interact with reward immediacy such that more dramatic increases were expected during anticipation of immediate rewards than during anticipation of rewards delayed by one week. To test these hypotheses, neuroimaging and behavioral data were collected while 17

overnight-abstinent male cigarette smokers engaged in a reward anticipation task. During the task, which was an adaptation of the monetary incentive delay paradigm (MID; Knutson, Westdorp, Kaiser, & Hommer, 2000), participants attempted to win prizes varying in immediacy (now or in seven days) and type (money or nicotine vapor). When a participant won immediately-available nicotine vapor, he was allowed draw one puff of nicotine vapor before the subsequent trial began. Participants were scanned twice; once after stress induction using the cold pressor task (Lovallo, 1975) and once after a control task. Reward immediacy was associated with faster reaction times (RT) and stronger blood oxygen level-dependent (BOLD) signals in the bilateral insula and anterior cingulate cortices. Under greater stress, however, the immediacy-related anterior cingulate BOLD signal was significantly lower than in the control condition. Furthermore, slower RTs in the stress condition suggested that stress decreases incentive salience of anticipated rewards. These results were unexpected, and may be related to research findings that link anhedonia, addiction, and stress.

Title: Enhanced rewarding effects of nicotine in diabetic rats

Authors: *J. A. PIPKIN[1], J. JUARDO[1], L. NATIVIDAD[1], L. CARCOBA[1], A. NAZARIAN[2], L. O'DELL[1];
[1]Dept. of Psychology, Univ. of Texas at El Paso, El Paso, TX; [2]Western Univ. of Hlth. Sci., Pomona, CA

Abstract: Epidemiological studies have demonstrated that patients with diabetes display greater vulnerability to tobacco use. However, it is presently unclear if they experience greater rewarding effects of nicotine. To examine this question, we compared the rewarding effects of nicotine in diabetic and healthy control rats using place conditioning (Experiment 1) and intravenous self-administration (IVSA; Experiment 2) procedures. Briefly, diabetes was induced using systemic administration of streptozotocin (STZ), a drug that is toxic to insulin-producing cells in the pancreas. As a result, this drug produces hyperglycemia in rats. Experiment 1 compared place preference in diabetic and healthy control rats that received various doses of nicotine (0, 0.1, 0.2, 0.4, 0.6 mg/kg, SC) in one of two distinct compartments of our conditioning apparatus. Experiment 2 compared IVSA behavior in diabetic and healthy control rats that performed operant responses for increasing doses of nicotine (0.03, 0.06, 0.09 mg/kg/0.1 mL infusion) on a fixed ratio-1 schedule of reinforcement. Nicotine intake was compared in the same rats prior to and following STZ administration. The results from Experiment 1 revealed that diabetic animals displayed a more robust place preference produced by nicotine as compared to healthy controls. Consistent with this, Experiment 2 revealed that diabetic animals displayed a dose-dependent increase in nicotine intake that was higher than healthy controls. In conclusion, the results from both studies revealed that diabetic rats display increased rewarding effects of nicotine as compared to healthy controls. These results suggest that enhanced rewarding effects of nicotine may contribute to greater vulnerability to tobacco use in persons afflicted with diabetes.

Title: Nine generations of selection for high nicotine intake in outbred sprague dawley rats

Authors: *T. NESIL[1], L. KANIT[2], S. POGUN[2], M. D. LI[1];
[1]Psychiatry and NB Sci., Univ. of Virginia, Charlottesville, VA; [2]Ctr. for Brain Res., Ege Univ., Izmir, Turkey

Abstract: Previous animal studies have revealed significant involvement of genetics in nicotine intake; however, the extent of the genetic contribution to this behavior has not been well addressed. Here, we report the first study of nine generations of selection for high and low voluntary nicotine intake in outbred Sprague Dawley rats. Repeated bidirectional mass selection resulted in progressively greater nicotine consumption in the high responder group (or called nicotine-preferring group) but not progressively decreased nicotine intake in the low or non-nicotine responder group (or called nicotine non-preferring group). Our estimated realized heritability for high voluntary nicotine intake is 0.25 vs. close to zero for low voluntary nicotine intake. No response to selection for low or non-nicotine intake behavior could be explained by selecting a not-expressed phenotype, as these animals consumed small amounts of nicotine. These selected lines may provide useful animal models for identifying susceptibility genes and variants for controlling high voluntary nicotine intake in rodents, although we recognize that more generations of selection may be needed to fully realize its power.

Title: Blockade of nicotine and cannabinoid reward and reinstatement by a cannabinoid CB1-receptor inverse agonist/antagonist and a CB1-receptor neutral antagonist in squirrel monkeys

Authors: S. R. GOLDBERG[1], G. H. REDHI[1], *A. MAKRIYANNIS[2], J. BERGMAN[3], Z. JUSTINOVA[1];
[1]Preclinical Pharmacol. Section, NIDA, IRP, NIH, DHHS, Baltimore, MD; [2]Ctr. Drug Discovery, Northeastern Univ., BOSTON, MA; [3]Preclinical Pharmacol. Lab., McLean Hospital, Harvard Med. Sch., Belmont, MA

Abstract: Nicotine, the main psychoactive component of tobacco, and delta-9-tetrahydrocannabinol (THC), the main psychoactive ingredient in marijuana, play major roles in tobacco and marijuana dependence by acting directly as reinforcers of drug-seeking and drug-taking behavior. Drugs that act as inverse agonist/antagonists at cannabinoid CB1 receptors in the brain attenuate the rewarding and addictive effects of nicotine in rats and of THC in squirrel monkeys, but their clinical use is hindered by potentially serious emotional side effects. Recently developed neutral CB1-receptor antagonists may provide an alternative approach to the treatment of nicotine and cannabinoid dependence. Here we compare attenuation of nicotine and THC reward and reinstatement in squirrel monkeys by the CB1-receptor inverse agonist/antagonist rimonabant and by the recently developed neutral CB1-receptor antagonist AM4113. Both rimonabant and AM4113 reduced two behavioral effects of nicotine and THC that play major roles in tobacco and marijuana dependence: 1) maintenance of high rates of drug-taking behavior, and 2) drug- or cue-induced reinstatement of previously extinguished drug-seeking behavior (relapse). By contrast, neither rimonabant nor AM4113 modified cocaine-reinforced or food-reinforced operant behavior when cocaine or food was available under similar conditions. These findings point to neutral CB1-receptor antagonists as a new class of medications for treatment of both tobacco and marijuana dependence.

Title: Behavioral effects of cannabinoid-1 receptor agonist in the bed nucleus of the stria terminalis depends on the stage of voluntary nicotine self-administration in rats

Authors: *S. CAILLE[1], M. CADOR[1], F. GEORGES[2], A.-R. REISIGER[1];
[1]Inst. des Neurosciences Cognitive et Intégrative d'Aquitaine, CNRS UMR 5287, Bordeaux cedex, France; [2]Inst. interdisciplinaire de Neurosciences, CNRS UMR 5297, Bordeaux cedex, France

Abstract: We have previously shown that the synaptic potentiation of the network including the infralimbic cortex, bed nucleus of the stria terminals (BNST) and ventral tegmental area is

important for the associative learning process underlying nicotine intravenous self-administration (IVSA) in rats and depends on activation of cannabinoid-1 (CB1) receptors in the BNST. However, it is unknown whether the role of CB1 receptors depends on the level of learning and/or level of nicotine intake. Therefore, we examined the behavioral implication of BNST CB1 receptors at different stages of nicotine IVSA.
In group 1, the CB1 agonist WIN55,212-2 (WIN55) was administered before each session of the first 6 days of acquisition after which IVSA was continued to test for any long-term effects of WIN55. In group 2, the effect of intra-BNST WIN55 was tested after 5 weeks of nicotine IVSA on maintenance and motivation to nicotine. In group 3, 1 week of extinction training was performed after 5 weeks of nicotine IVSA and WIN55 effects were tested on reinstatement.
In group 1, we found that BNST CB1 receptors stimulation impairs transiently the first stage of nicotine IVSA learning mainly due to acute reduced locomotion. This effect disappeared as soon as the treatment ceased. However, later on, WIN55 pretreated rats were unable to adapt to increasing workload to obtain nicotine, both during day to day increased fixed ratio and during progressive ratio schedule of reinforcement. Hence, this early WIN55 pre-treatment prevents later nicotine induced reinstatement while leaving nicotine-associated cue induced reinstatement intact.
In group 2, we observed that stimulation of CB1 receptors in the BNST after 5 weeks of nicotine IVSA does not affect operant responding during fixed ratio and progressive ratio schedule of reinforcement.
In group 3, WIN55 injection blocks both cue-induced and nicotine-induced reinstatement in extinction conditions.
These data imply that CB1 receptor stimulation in the BNST before long-term exposure to nicotine induces protracted behavioral inflexibility and decreased motivation, without altering nicotine intake. Moreover, rats treated with WIN55 during acquisition phase of nicotine IVSA are still sensitive to the reward-associated cue, but not to nicotine itself. However, after a history of nicotine, while CB1 agonist in the BNST does not affect motivation to nicotine and nicotine-taking, it blocks the incentive properties of both nicotine and nicotine-paired stimulus.

Title: Predictors of drug-seeking behavior in rodent reinstatement models of relapse

Authors: *S. M. GOEBEL-GOODY, E. DUNN-SIMS, D. B. HORTON, A. ROSADO, A. FOOTE, C. TYSZKIEWICZ, J. K. DASILVA, N. NAWREEN, A. N. MEAD;
Global Safety Pharmacol., Pfizer Inc., Groton, CT

Abstract: Reinstatement of drug-seeking behavior in rats previously trained to self-administer drugs of abuse is widely used for studying relapse to addiction. There is considerable face and criterion validity for the reinstatement model, given that conditions which induce reinstatement in rats (e.g., exposure to drug, associated environmental cues, or stressors) also provoke relapse in humans. Even so, the extent of reinstatement can vary depending on the conditions used to induce reinstatement (e.g., cues only, prime only or combined cues and prime), as well as various factors during training (e.g., drug training dose, presence of secondary auditory reinforcers such as clickers or tones). Oftentimes, individual rats also show variability in the magnitude of the reinstatement response. These findings pose the question as to whether there are specific endpoints during drug self-administration training or the subsequent extinction phase that may predict reinstatement of drug-seeking behavior. In an initial study, rats were trained to respond for intravenous nicotine (0.015 mg/kg/infusion) under a fixed ratio schedule of reinforcement. We analyzed whether the extent of each animal's response (i.e., number of active lever presses) under a combined nicotine cue- and prime-induced reinstatement condition directly correlated with the following endpoints obtained from the last two self-administration training sessions: average number of infusions, average active lever presses, and average selectivity for the active lever over the inactive lever. Infusion stability for the last two sessions, number of active lever presses on the first extinction session, and total number of sessions required for training were also examined. Of these, only the average number of infusions was significantly correlated with the reinstatement response, where infusions were positively correlated with the number of active lever presses during reinstatement ($r = 0.31$, $P < 0.005$). These results indicate that rats with the highest reinstatement also had the greatest drug intake during the last two self-administration sessions. A similar positive correlation was observed in studies with higher training doses of nicotine (0.03 mg/kg/infusion) ($r = 0.64$, $P < 0.0001$). Together, these findings suggest that session drug intake (measured by number of infusions) during self-administration training may be particularly important for predicting reinstatement of nicotine-seeking behavior. Further studies will determine whether this direct correlation persists across different reinstatement conditions and drugs of abuse, such as fentanyl.

Title: Attenuating combined cue and prime-induced reinstatement of nicotine-seeking using the novel D3-receptor antagonist PF-04363467

Authors: *E. R. DUNN-SIMS[1], A. SAWANT-BASAK[2], M. VANASE-FRAWLEY[1], A. ROSADO[1], C. STEPPAN[1], N. STRATMAN[2], C. TYSZKIEWICZ[1], T. WAGER[2], A. MEAD[1]; [1]Pfizer Inc, Groton, CT; [2]Pfizer, Cambridge, MA

Abstract: Learned associations between the rewarding properties of drugs of abuse and environmental cues contribute to craving and relapse in humans. Dopamine D3-receptors are preferentially expressed in mesocorticolimbic DA projection areas: areas of the brain highly associated with reward-related learning induced by drugs of abuse. Nicotine dependence is a chronic relapsing disorder and increasing evidence supports a model for which D3-receptor activity is implicated in the relapse-related cellular and behavioral effects underlying nicotine-seeking behavior. In the past, pharmacological studies aimed at differentiating the role and contribution of D3 receptors in nicotine-dependence was limited by the lack of D3-selective compounds. The principle purpose of this study was to determine whether the novel D3-receptor antagonist PF-04363467, and the prototype D3 antagonists GSK598809 and SB277011-A, could attenuate reinstatement of nicotine-seeking in rats under different test conditions. Male Sprague-Dawley rats were initially trained to self-administer nicotine, I.V., under a fixed ratio schedule of reinforcement using a standard 2-lever choice design, with infusion-paired cues. Following acquisition, an extinction period commenced to dissociate the act of lever pressing from delivery of nicotine. Reinstatement tests were then conducted using a within-subjects design, with reinstatement induced by both a nicotine prime and a combination nicotine prime and cue. For reinstatement tests, animals were treated with PF-04363467, GSK598809 or SB277011-A prior to each session. Congruent with the literature implicating D3-receptors with the rewarding/reinforcing effects of drugs, and specifically the association between drugs of abuse and drug-associated environmental stimuli, the present findings suggest D3-receptor antagonists can attenuate reinstatement of nicotine seeking in rats under certain test conditions. The effect of these antagonists in blocking reinstatement of nicotine-seeking behavior was compared to their affinity to bind to, and occupy, the dopamine D3-receptor. Taken together, these observations

support the potential use of novel D3-receptor antagonists in preventing nicotine-relapse and craving in humans.

Title: D1 dopamine antagonist treatment with SCH 23390 to decrease nicotine self-administration in rats

Authors: S. SLADE, C. WELLS, *R. D. SCHWARTZ-BLOOM, A. H. REZVANI, J. E. ROSE, E. D. LEVIN;
Duke Univ. Med. Ctr., DURHAM, NC

Abstract: Dopaminergic systems in the brain have long been known to be critically involved with drug addiction in general and nicotine addiction in particular. However, D2 antagonist treatment has not been found to effectively reduce nicotine self-administration. In fact the D2 antagonist haloperidol has been shown to increase smoking. The other principal subtype of dopamine receptors, the D1 receptor, has not been as extensively investigated. Adult female Sprague-Dawley rats were trained to self-administer nicotine IV at 30 µg/kg/infusion. Acute SC doses of 10-50 µg/kg of the D1 antagonist SCH 23390 significantly reduced nicotine self-administration but this dose range also significantly reduced food motivated responding (N=6). However, a lower dose range of SCH 23390 (1.25-5 µg/kg) was found to significantly reduce nicotine self-administration without a significant effect on food motivated responding (N=20). Interestingly, there was the appearance of a non-monotonic, dose-effect function in this lower dose range of 1.25-5 µg/kg with a significant quadratic effect over that range with a slight increase in nicotine self-administration at the lowest dose tested (1.25 µg/kg). A critical locus of action for D1 antagonist effects may be the insular cortex. We have found that local infusion of SCH 23390 into the insular cortex significantly decreased nicotine self-administration. This study provides information supporting the involvement of D1 receptor systems in the control of

nicotine self-administration and the efficacy of systemic administration. D1 antagonists hold promise of as potential treatment for smoking cessation.

Title: The α4β2 nicotinic desensitizing agent VMY 2-109 significantly decreases nicotine self-administration in rats

Authors: *E. D. LEVIN[1], S. SLADE[2], C. WELLS[2], S. A. BRIGGS[2], G. ZHANG[2], A. H. REZVANI[2], Y. XIAO[3], K. J. KELLAR[3], V. M. YENUGONDA[3], M. PAIGE[3], M. BROWN[3]; [1]Duke Univ. Med. Ctr., DURHAM, NC; [2]Psychiatry, Duke Univ., Durham, NC; [3]Georgetown Univ., Washington, DC

Abstract: Nicotinic receptor desensitization holds promise as an effective treatment of tobacco addiction. Previously, we found that sazetidine-A which desensitizes α4β2 nicotinic receptors of all configurations and is an agonist at the α4(2) β2(3) receptor configuration significantly decreased nicotine self-administration in rats. We also found that its analog VMY-2-95 likewise significantly decreased nicotine self-administration. In the current study we tested another compound VMY 2-109 with similar effects, desensitizing α4β2 nicotinic receptors. Young adult female Sprague-Dawley rats were fitted with IV catheters and were trained to self-administer nicotine (0.03 mg/kg/infusion) on a fixed ratio 1 schedule for ten sessions. VMY-2-109 was administered SC ten minutes before the start of 45-minute sessions in a counterbalanced design which was conducted two times. VMY-2-109 at 3 mg/kg significantly ($p<0.025$) reduced nicotine self-administration. This is the same effective dose as previously seen with sazetidine-A and VMY-2-95. There was a significant ($p<0.05$) interaction of VMY-2-109 x baseline level of nicotine self-administration (below or above the median level of self-administration during pre treatment baseline training). The reduction in nicotine self-administration caused by acute VMY-2-109 was particularly evident ($p<0.0005$) in rats with high pre-treatment baseline levels of nicotine self-administration (N=14) but not in those with low baseline levels (N=15). Food motivated responding was significantly decreased by both the 1 and 3 mg/kg acute doses of

VMY-2-109, indicating that the effect was not specific to nicotine. We have not yet tested it on other drugs of abuse, but previously we have found that sazetidine-A significantly reduces self-administration of a variety of drugs of abuse including alcohol, cocaine and methamphetamine. The reduction in nicotine self-administration by VMY-2-109 did not appear to be due to sedative effects. Like VMY-2-95, VMY-2-109 caused significant increases in activity at all three doses tested 0.3, 1 and 3 mg/kg. These studies show that acute VMY-2-109 reduces nicotine self-administration at a dose level that does not cause sedative effects. VMY-2-109 holds promise as a novel aid for smoking cessation and should be further studied to determine its safety and efficacy for being used as a novel aid for smoking cessation.

Title: Effects of methamphetamine and nicotine on the habituation of reinforcing effectiveness of sensory stimuli

Authors: *D. R. LLOYD, J. B. RICHARDS;
Res. Inst. On Addictions, Buffalo, NY

Abstract: Background:
Visual stimuli (VS) determined to have primary reinforcing effects are classified as sensory reinforcers to differentiate them from other more biologically important primary reinforcers (e.g. food and water). VS are weak reinforcers and their reinforcing effects rapidly habituate. The psychomotor stimulants methamphetamine (METH) and nicotine (NIC) increase the reinforcing effectiveness of VS. We examined the effects of METH and NIC on the habituation of the

reinforcing effectiveness of VS.
Methods:
The effects of saline (n = 10), NIC (0.40 mg/kg, n = 10) and METH (0.75 mg/kg, n = 9) on habituation of reinforcing effectiveness were evaluated. Phase 1 (10 sessions) examined the operant level of responding, phase 2 (10 sessions) examined the effects of drug on the operant level of responding, and phase 3 (5 sessions) examined the combined effects of drug and a response contingent VS on the rate of responding. In all three phases within-session changes in the reinforcing effectiveness of VS were examined by plotting and analyzing responding in successive 8 min epochs of each 40 minute test session.
Results:
Nicotine decreased habituation rate and did not affect response rate, while METH decreased habituation rate and increased response rate. Introduction of a novel VS decreased habituation rate and increased responding.
Conclusions:
Habituation of reinforcer effectiveness may modulate operant responding for sensory reinforcers and may play a role in the effects of stimulant drugs on operant behavior.

Title: Adolescent methylphenidate exposure increases the reinforcement enhancing effects of nicotine

Authors: *D. PETERSON, A. B. SHEPPARD, M. I. PALMATIER, R. BROWN;
East Tennessee State Univ., Johnson City, TN

Abstract: Methylphenidate (MPH) is widely prescribed during childhood and adolescence for treatment of attention deficit and hyperactivity disorder. MPH is also one of the most commonly abused prescription drugs. However, the effects of MPH exposure and MPH abuse on incentive motivation are not well known. Moreover, MPH abuse during adolescence could increase sensitivity to the incentive motivational effects of other abused drugs such as nicotine in adulthood. Thus, the goals of this experiment were to investigate the effects of MPH exposure on the motivation to obtain sucrose during adolescence and to examine whether adolescent

methylphenidate exposure altered the incentive motivational effects of nicotine (NIC) in adulthood. Incentive motivation was measured using an operant conditioning paradigm with sucrose available under a progressive ratio schedule of reinforcement (PR). Adolescent female rats were used because our previous studies have shown stronger sensitization to the locomotor stimulant effects of MPH. Rats arrived at post-natal day 21 (P21) and were shaped to respond for sucrose (20% w/v) on the PR schedule beginning on P24. After stable operant responding was established, rats were randomly assigned to receive either MPH (n=7) or SAL (n=6) injections (intraperitoneal) 30 min prior to test sessions, with the constraint that sucrose rewards earned did not differ between groups. Injection tests began on P36 and were carried out on alternating days for 10 total tests (P36-54). Although there was a trend for increased motivation for sucrose in the MPH group, it did not reach statistical significance. No further testing occurred until the rats reached adulthood (P55-P78). Over the next 5 days (P79-P84), all rats were pretreated with subcutaneous NIC injections (0.4 mg/kg base) 15 min before testing sessions. Following this initial 'sensitization' period, rats were tested with different NIC doses (0-1 mg/kg base) from P85-P92. During the sensitization period, NIC increased responding equally in both groups. However, during the dose-response testing, rats in the MPH group were more sensitive to the incentive motivational effects of NIC - the median effective dose was significantly lower for rats exposed to MPH in adolescence. The findings suggest that MPH may have limited reinforcement enhancing effects in adolescents. However, exposure to MPH during adolescents may increase the incentive motivational effects of NIC in adulthood.

Title: Nicotine exposure during acquisition increases the motivational valence of non-drug reinforcers

Authors: A. B. SHEPPARD[1], R. M. FLOYD[2], Z. DIETZ[2], *M. I. PALMATIER[1];
[1]East Tennessee State Univ., Johnson City, TN; [2]Psychology, Kansas State Univ., Manhattan, KS

Abstract: Nicotine (NIC) has dual effects on reinforcement - both increasing responding for NIC as well as increasing motivation to approach and engage reward-associated cues. We have hypothesized that NIC alters incentive learning increasing the value of non-drug stimuli associated with rewards. We examined whether NIC given during acquisition of responding for a visual stimulus (VS; extinction of all lights in chamber for 30 s) increased the motivation to obtain the VS and whether the VS acquired more motivation value when responding for the VS was acquired under the influence of NIC. To do so, we determined if changes in responding during acquisition would persist beyond the pharmacological effects of NIC. In Experiment 1, rats were randomly assigned to receive either NIC (Acq-NIC group) or saline (Acq-SAL group) injections prior to acquisition of responding for the VS. Rats received designated injections 15 minutes prior to responding for the VS on fixed ratio 1 (FR1) and FR3 schedules of reinforcement. During the final tests, all rats receive SAL injections prior to responding under an FR3 and were subsequently shifted to a progressive ratio (PR) reinforcement schedule - a more sensitive measure of motivation. Under the PR schedule, rats in the Acq-NIC group had higher breaking points than the Acq-SAL group, even though both groups were pretreated with SAL. Experiment 2 used similar procedures but instead of a SAL group, rats were assigned to a Post-NIC group to equate total drug exposure. This group received NIC injections in the home cage 3 hrs after test sessions were completed. The Pre-NIC group received NIC injections 15 min before all acquisition sessions. During acquisition, rats were shifted from an FR3 to a PR schedule. Once stability criteria were met on the PR, all rats received placebo injections 15 min before test sessions. Even though both groups were pretreated with SAL during these tests, the Pre-NIC group had significantly higher breaking points than the Post-NIC group. Follow-up studies used a more potent reinforcer (sucrose) in order to increase the value of incentives in the test chamber. The findings suggest that NIC can potently increase incentive learning.

Title: Nicotine enhances the rewarding properties of sucrose

Authors: *R. SCHASSBURGER[1,2], L. E. RUPPRECHT[1,2], T. T. SMITH[3], D. M. BUFFALARI[1,2], E. THIELS[4,2,5], E. C. DONNY[3], A. F. SVED[1,3,2];
[1]Neurosci., [2]Ctr. for Neurosci., [3]Psychology, [4]Neurobio., [5]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Nicotine serves not only as a primary reinforcer but also acts to enhance the reinforcing properties of environmental and non-pharmacological stimuli. Nicotine has been shown to enhance the reinforcing properties of a mildly-reinforcing visual stimulus and to promote operant responding. Reinforcement-enhancement occurs irrespective of whether nicotine delivery is contingent or non-contingent on behavior and experimenter- or self-administered. The present study sought to evaluate the nicotine reinforcement-enhancement effect on a natural reward. Adult male rats (n = 32) were allowed to nosepoke for sucrose (45 mg pellets) on a progressive ratio (PR) schedule of reinforcement. Sucrose maintained a high level of responding at the active nosepoke port. Nicotine (0.5 mg/kg; s.c.) administered 10 min prior to the operant session significantly increased sucrose pellets earned by 22% ($p<0.01$) and active responses by 99% ($p<0.01$), without increasing responding into the inactive nosepoke ($p>0.05$). This selective effect of nicotine on responding for sucrose was observed on the first day of nicotine treatment, and was maintained over six sessions of daily nicotine treatment. Blockade of nicotinic acetylcholine receptors (nAChR) by systemic administration of mecamylamine (3.0 mg/kg; s.c.) immediately prior to the daily nicotine treatment reduced responding for sucrose to the same level of responding as observed in the absence of nicotine. Systemic administration of dopamine antagonists (1, 3, 10, or 30 μg/kg SCH23390; 1, 3, 10, or 30 μg/kg eticlopride; s.c.) also reduced the number of sucrose pellets earned; ongoing studies are investigating the specific involvement of dopamine receptors in the nucleus accumbens in nicotine reinforcement-enhancement. These results demonstrate that the robust enhancement of environmental stimuli by nicotine in the maintenance of operant behavior extends to natural rewards. Moreover, this effect may in part be mediated by nicotinic acetylcholine receptors and dopamine receptors. Our finding that nicotine enhances responding for a food reward is particularly interesting in light of the anorexigenic effects of nicotine. It underscores the robustness of the reinforcement-enhancement effect of nicotine, and suggests that nicotine's reinforcement-enhancement can overcome competing consequences of nicotine.

Title: Preferences for cocaine and food rewards: Neurochemical profiles in the nucleus accumbens distinguish cocaine and pellet preferring rats

Authors: *A. N. PERRY[1], C. WESTENBROEK[1], L. JAGANNATHAN[1], J. B. BECKER[1,2,3,4]; [1]The Mol. & Behavioral Neurosci. Inst., [2]Dept. of Psychology, [3]Dept. of Psychiatry, [4]Neurosci. Program, Univ. of Michigan, Ann Arbor, MI

Abstract: Given the opportunity to self-administer either palatable food pellets or cocaine, most rats choose pellets. We have previously shown that cocaine-preferring (CP) rats display increased drug intake at the expense of earning pellets, have enhanced motivation for cocaine and reduced motivation for pellets and show greater reinstatement of drug seeking following cocaine priming and exposure to a drug-paired cue. We propose that CP rats represent an addictive phenotype that distinguishes them from the majority of rats that are able to regulate their drug intake and maintain a pellet preference (PP). The objective of the current study was to characterize the cocaine-induced dopamine (DA) and norepinephrine (NE) responses in the nucleus accumbens (NAc) of PP and CP rats. Male and female Sprague-Dawley rats were fitted with jugular catheters and microdialysis guide cannulae targeting the NAc. Rats self-administered cocaine (0.4 mg/kg/inf) and pellets (45 mg, BioServ) on a fixed ratio 5 schedule 4 days a week for 7 weeks to identify PP and CP individuals. Motivation for cocaine and pellets was assessed once each week on a progressive ratio schedule. The DA and NE responses to an acute cocaine infusion (1.2 mg/kg, i.v.) were investigated both early and late during self-administration. When response preferences were stable late during self-administration, rats were treated with each of the following: the beta adrenergic receptor antagonist S-(-)-propranolol (10 mg/kg, i.v.), the alpha 1 adrenergic receptor antagonist terazosin (2 mg/kg, i.v.) or the saline vehicle (1 ml/kg, i.v.) 15 minutes before self-administration in a counter-balanced order to examine the roles of noradrenergic receptors in preference behavior. PP and CP rats had similarly robust DA and NE responses in the NAc early in self-administration. Preliminary results indicate that CP rats displayed attenuated DA and NE responses late in self-administration when preferences were stable, whereas PP rats maintained a normal DA response and an attenuated NE response. Propranolol reduced both cocaine and pellet intake in CP rats, with less pronounced effects in PP rats. Terazosin's effects were mixed. In conclusion, the expression of a preference for cocaine is associated with a specific neurochemical profile distinct from animals that do not prefer cocaine. The results of pharmacological manipulations indicate the potential for interaction between the DA and NE systems in the display of preference behavior.

Title: Cocaine affects acoustic startle in concert with estrus cycle stages

Authors: *L. B. MALAVE[1,2,3], P. A. BRODERICK[1,2,3,4];
[1]Dept. of Physiology, Pharmacol. and Neurosci., Sophie Davis Sch. CCNY, New York, NY; [2]Biol., CUNY Grad. Ctr., New York, NY; [3]Ctr. for Advanced Technol. (CAT) CUNY, New York, NY; [4]Neurol., NYU Langone Med. Ctr., New York, NY

Abstract: Startle response to auditory stimuli via prepulse inhibition (PPI) examines the ability to neuronally gate the sensory/motor network to heed warning signals. PPI refers to the process in which a weaker prestimulus (prepulse) impedes the reaction of a subject to a subsequent strong startling stimulus (pulse). PPI is significantly decreased in cocaine-administered human subjects (Geyer; Braff, 1987). Moreover, we reported sex differences to acoustic startle response during cocaine-administration (Broderick and Rosenbaum, 2013). There are many studies showing that sensitivity to cocaine reward varies during the estrous cycle (Zakharova et al., 2009; Kippin et al., 2005; Feltenstein et al., 2009). Furthermore, we have published a body of evidence on cocaine induced estrus cycle changes. Thus, these changes in estrus cycle may be the underlying cause of the sex differences in acoustic startle response for cocaine-administered animals. In addition, caffeine did not affect estrus cycle nor does the combination of cocaine and caffeine. We observed that caffeine blocks the cocaine induced estrus cycle changes and may neuro-protect against the decrease in PPI when administered in concert with cocaine (Broderick et al., 2012). In the present study we set out to correlate estrus cycle stages with acoustic startle responses on varying doses of cocaine, caffeine and combination of both.

Title: SIRT1 and MAOA regulation in cocaine excited delirium

Authors: *S. GARAMSZEGI, L. DUQUE, X. XIE, N. ADI, D. C. MASH;
Neurol., Univ. of Miami, Miami, FL

Abstract: Excited delirium syndrome (ExDS) is a condition associated with cocaine abuse that manifests as a combination of psychomotor agitation, violent and bizarre behavior, extraordinary strength, and hyperthermia. ExDS subjects often die in police custody, with heighted reactivity to restraint stress. SIRT1, a NAD^+-dependent protein deacetylase regulates anxiety and exploratory drive by monoamine oxidase A (MAOA) activation (Libert, S. et al., Cell 147: 1459-72, 2011). Knockout mice lacking functional SIRT1 have lower levels of MAOA and are less susceptible to depression and anhedonia following social defeat. In contrast, SIRT1 overexpressors have higher levels of MAOA. SIRT1 deacetylates transcription factor NHLH2 to increase the activation of the MAOA promoter, resulting in a reduction in serotonin. Gene expression differences in the substantia nigra (SN) were analyzed in cases of cocaine-related ExDS (n=43) and compared to cocaine intoxication deaths (n=108) and age-matched drug-free controls (n=107). In ExDS cases, SIRT1 (1.5-fold; p= 0.0001) and MAOA (2.1-fold; p=0.0147) were upregulated compared to cocaine abusers and control subjects. SIRT1 deacetylates heat shock transcription factor (HSF1) which activates its binding to the HSP70 promoter and increases its transcription under conditions of elevated core body temperature. In ExDS, HSPA1B gene is significantly upregulated (2.5-fold; p <0.0001) in the SN. Genetic variation in SIRT1 has been associated with body mass index (BMI) and risk of obesity. ExDS disproportionately affects male cocaine abusers with high BMI values (OR = 2.8; C.I. 1.2 - 6.4), suggesting an association between food intake patterns and obesity in these subjects. SIRT1 has been suggested to link the nutritional status of animals to behavior. Cocaine abusers decrease food intake during a period of binge use, following by hyperphagia during states of withdrawal. A genetic study of SIRT1 polymorphisms may suggest a role of this sirtuin in the heightened anxiety-like state associated with terminal delirium and hyperthermia in ExDS.

Title: Glia-derived glutamate differentially modulates cocaine-taking and cocaine-seeking behavior in rats

Authors: *Z. XI, H.-J. YANG, X. LI, G.-H. BI, H.-Y. ZHANG;
NIDA, IRP, BALTIMORE, MD

Abstract: It is well documented that neuronal glutamate release plays a critical role in cocaine- or cue-induced reinstatement of drug-seeking behavior. However, it remains unclear whether glia-derived glutamate similarly regulates cocaine-taking and cocaine-seeking behavior. In the present study, we evaluated the effects of TBOA, a selective glial glutamate transporter (GLT-1) inhibitor, and NPPB, a glial anion channel blocker, on cocaine self-administration and reinstatement of drug-seeking behavior. We found that: 1) local perfusion of TBOA into the NAc significantly elevated, while NPPB lowered extracellular glutamate in a dose-dependent manner; 2) microinjections of TBOA into the NAc, but not the dorsal striatum, inhibited cocaine self-administration under both fixed-ratio (FR2) and progressive-ratio (PR) reinforcement, while microinjections of NPPB into the NAc had no effect on cocaine self-administration; 3) this effect on cocaine self-administration was blocked by co-administration of TBOA and AP-5 (a NMDA receptor antagonist), ifenprodil or Ro25-6981 (selective NMDA-NR_{2B} receptor inhibitors), but not by DNQX (an AMPA receptor blocker) or NVP-AAM007 (a NMDA-NR_{2A} receptor antagonist), suggesting a NMDA-NR_{2B}-mediated effect; 4) conditioned knockdown of GLT-1 in the NAc by antisense oligonucleotides also decreased cocaine self-administration in rats in a dose-dependent manner; 5) microinjections of TBOA, but not NPPB, into the NAc, but not the dorsal striatum, reinstated drug-seeking behavior in rats extinguished from cocaine self-administration. Taken together, the present findings suggest that elevation of extracellular glutamate in the NAc by inhibiting glial GLT-1 inhibits cocaine-taking behavior in rats during self-administration, and reinstates cocaine-seeking behavior in rats during reinstatement testing.

In contrast, attenuation of glial glutamate release via anion channels has no effect on cocaine-taking and cocaine-seeking behavior. *Supported by NIDA-IRP*.

Title: Thalamic connectivity with independent functional components of cognitive control distinguishes cocaine addicts from healthy controls

Authors: *C.-S. R. LI, S. ZHANG, S. HU;
Dept Psychiatry, Yale Univ., NEW HAVEN, CT

Abstract: BackgroundOur recent work combining brain imaging and longitudinal follow-up described deficits in thalamic cortical processes of cognitive control that predicted relapse in cocaine addicts (Luo et al., 2003, Brain). Here, we examined how thalamic connectivity with components of cognitive control, as identified by independent component analysis (ICA), distinguished cocaine addicts from healthy individuals.
MethodsFunctional MRI data were collected on the stop signal task from individuals with cocaine dependence (CD, n = 100) and demographics-matched health controls (HC, n = 100). Preprocessed time series were analyzed with group ICA (GIFT, http://icatb.sourceforge.net/, version 1.3i) to identify spatially independent and temporally coherent networks. After back-reconstruction, z values of each component for each voxel of the whole thalamus were computed as a feature vector for all subjects. Two-sample t tests identified feature vectors that were significantly different between CD and HC. A threshold was applied to this difference to identify final feature sets for classification with a multivariate pattern classifier.
ResultsLeave-one-out cross-validation with a total of 2,285 feature vectors ($p<0.05$, CD vs. HC) distinguishes CD and HC at 95% accuracy. Notably, the thalamus voxels aggregated in specific nuclei such that their functional connectivity with specific IC distinguished CD from HC. For instance, voxels clustered in the medial nucleus for medial prefrontal cortex, motor cortex, and regions of the default mode network as well as in the lateral nucleus for cuneus/precuneus and

subcortical areas to achieve successful classification.
ConclusionsThese findings suggested that, by connecting to distinct cerebral networks and potentially serving different functions in cognitive control, subnuclei of the thalamus played different roles in distinguishing CD from HC. These new findings shed further light on deficits of cognitive control in cocaine dependence and suggest a useful approach to unraveling the neural endophenotypes of complex mental disorders.

Title: Tracking changes of medium spiny projection neurons in the dorsolateral striatum during chronic cocaine self-administration

Authors: *K. COFFEY, D. J. BARKER, S. MA, J. KULIK, M. O. WEST;
Psychology, Rutgers Univ., Piscataway, NJ

Abstract: It has been posited that the transition from drug use to addiction, involves a shift from goal-directed drug seeking to habitual drug taking. It is thought that one neural substrate for this shift may be the Dorsal Striatum. It is hypothesized that early in training Dorsomedial Striatum (DMS) processes a (response - outcome) relationship and produces a goal-directed behavior. After extended training, the behavior becomes skilled and the Dorsolateral Striatum (DLS) is thought to produce the skill habitually. However, this model of DLS involvement in addiction is woefully oversimplified. DLS consists of at least 3 cell types, all of which serve different functions. First are the interneurons, Fast-Spiking Interneurons (FSIs - Gabbaergic ~10%) and Tonically Active Neurons (TANs - Cholinergic ~1%), which play critical roles in modulating the activity of projection neurons. Based on their sensory input, and direct connection to projection neurons, it has been suggested that the interneurons are encoding the habitual stimulus response relationship. However, the remaining medium spiny projection neurons (MSNs ~89%) are the most frequently studied in their relationship to habitual behavior. These neurons are somatotopic in nature, similar to motor cortex. They respond in unconditioned phasic bursts during movement of discrete body parts. Often, labs that study these neurons do not account for this specificity, confounding their habit learning results with simple movement differences. To control for motor

differences, this study tracked a single MSN population (head movement neurons) during chronic cocaine self-administration (SA), using a movement operant. By ensuring that cocaine taking responses could be matched and identical across days, we are able to draw conclusions about learning related changes in DLS activity across chronic cocaine self-administration. MSNs in the DLS process discrete motion characteristics (i.e. velocity), and undergo motor-training related changes in activity, that correlate to changes in animal behavior. This evidence indicates that MSNs in DLS serve as an important training signal during the learning of skilled behavior, but they do not undergo the population level increase in activity proposed by the habit hypothesis.

Title: Distinct roles of PKC signaling at direct and indirect pathway medium spiny neurons during reinstatement of cocaine-seeking

Authors: *P. I. ORTINSKI, L. A. BRIAND, C. PIERCE, H. D. SCHMIDT;
Univ. of Pennsylvania, PHILADELPHIA, PA

Abstract: Cocaine abuse in humans is frequently characterized by withdrawal from and relapse to chronic drug use. The relapse to cocaine seeking in rodents can be modeled as enhanced behavioral responding following exposure to a pharmacological trigger. In particular, reinstatement of cocaine seeking can be triggered by stimulation of dopamine receptors in the nucleus accumbens, a component of the mesolimbic dopamine reward pathway. Here, we show that microinjection of either D1-like or D2-like dopamine receptor agonists into the rat nucleus accumbens shell leads to reinstatement of cocaine-seeking behavior. Administration of the protein kinase C antagonist, chelerythrine, attenuates reinstatement induced by the D2-like, but not the D1-like dopamine receptor agonists. We explore the possible neuronal mechanisms for this phenomenon by evaluating the effects of chelerythrine at medium spiny neurons of the direct

(D1-expressing) and indirect (D2-expressing) pathways. We find that exposure of brain slices to chelerythrine modulates excitatory and inhibitory synaptic signaling differently at D1- and D2-expressing neurons. Furthermore, sensitivity of evoked synaptic activity to chelerythrine is dependent upon the frequency of stimulation of synaptic afferents. These results suggest the possibility that distinct signaling patterns at neurons of the direct and indirect pathways in the nucleus accumbens shell underlie distinct roles of protein kinase C during reinstatement of cocaine seeking by agonists at D1-like and D2-like dopamine receptors.

Title: Corticostriatal regulation of glutamate homeostasis by astrocytes in the nucleus accumbens: Effects of pacap on cystine-glutamate exchange by system x_c- in the nucleus accumbens

Authors: *L. KONG[1], A. MADAYAG[3], J. M. RESCH[2], S. CHOI[2], J. R. MANTSCH[2], D. A. BAKER[2];
[2]Biomed. Sci., [1]Marquette Univ., Milwaukee, WI; [3]Univ. of North Carolina Sch. of Med., Chapel Hill, NC

Abstract: Repeated cocaine administration is associated with a persistent disruption of glutamate homeostasis in the nucleus accumbens, and this may be due to altered release and/or clearance by astrocytes. Previous work has shown decreased activity of glutamate release from system x_c- and glutamate clearance by GLT-1, and both mechanisms are expressed on astrocytes. The importance of these findings is evident from studies demonstrating that normalizing the function of either mechanism reduces the magnitude of cocaine-primed reinstatement. The purpose of these studies was to explore the potential involvement of the pituitary adenylyl

cyclase activating polypeptide (PACAP) in cocaine-induced blunting of system xc- activity. Our interest in this peptide stems from earlier observations that it likely originates from corticostriatal projection neurons since PACAP is co-localized with VGLUT in the prefrontal cortex. This is important because cocaine appears to reduce the activity of corticostriatal projections. In addition, PAC1R, the primary receptor for PACAP is expressed on astrocytes. Lastly, PAC1R signaling has been shown to regulate glutamate clearance by astrocytes. To examine the potential for PACAP to regulate system xc-, we first examined the impact of PAC1R signaling on cystine uptake in rat cortical and striatal cultures. We found that 24 hr PACAP treatment produced a concentration-dependent increase in ^{14}C-cystine uptake in cortical and striatal astrocytes. To examine the impact of repeated cocaine administration on this effect, we then examined the impact of PACAP treatment on ^{14}C-cystine uptake in ex vivo nucleus accumbens tissue punches obtained from rats withdrawn for at least three weeks from daily saline or cocaine self-administration. Interestingly, PACAP-induced enhancement of ^{14}C-cystine uptake in nucleus accumbens tissue punches was not observed in tissue punches obtained from rats withdrawn from repeated cocaine. To determine the behavioral significance of these observations, we microinjected PACAP into the nucleus accumbens and found that this significantly reduced cocaine-primed reinstatement. Collectively, these data are consistent with the possibility that reduced PACAP signaling, possibly as a result of corticostriatal hypofunction, lead to altered glutamate release and clearance by astrocytes in a manner that influences the magnitude of cocaine-primed reinstatement.

Title: Chronic non-contingent cocaine alters behavioral measures of urgency in a frustrative reward-omission test

Authors: *A. BARKER, G. V. REBEC;
Program Neurosci & Dept. Psychological & Brain Sci., Indiana Univ., Bloomington, IN

Abstract: BACKGROUND: Urgency is a personality sub-trait of impulsivity that serves as a stronger predictor for substance abuse over other forms of impulsivity such as disinhibition or sensation-seeking. It is unknown whether high urgency individuals are intrinsically more susceptible to substance abuse, or if substance abuse itself exacerbates urgency the way psychostimulants are known to enhance other forms of impulsivity. A second unknown is the role of the dopaminergic system in altering the expression of urgency. In this study, rats, previously exposed to cocaine or vehicle, were assessed for urgency in a frustrative reward-omission test. Some rats were treated instead with RTI-113, a selective dopamine transport (DAT) inhibitor. Methods: Adult, male rats received cocaine (ip) in linearly escalating doses beginning at either 10 mg/kg or 20 mg/kg. By the tenth day the doses were twice the initial starting dose, ending at 20 mg/kg or 40 mg/kg. RTI-113 was given (ip) once daily at a constant dose of 5.0 mg/kg, and control subjects received an equal volume of saline on the same schedule. The animals were returned to their home cages following each injection. After the final day of injections, subjects remained in their home cages for 14 days of abstinence prior to beginning of training. Animals were trained on a frustrative reward-omission test (32 trials/day) composed of a classical and operant conditioning portion. A cue predicted receipt of a food-pellet followed by presentation of active and inactive levers for 45 s during which time rats earned as many rewards as possible on an FR10 schedule. On the 4 data collection days there was a 33% chance of free pellet omission, and each day of data was separated by 3 days of extinction where no omission occurred. RESULTS: All treatments showed an urgency effect within groups, validating the test. Cocaine produced a dose-dependent alteration of behavior on omission trials. The high dose cocaine group showed a shorter latency to lever-press and a greater rate of lever-pressing. Neither dose of cocaine resulted in a greater number of presses, however. Interestingly, the RTI-113 group showed a greater number of lever presses on omission trials over all other groups, but did not show any effect on rate or latency to press. CONCLUSION: Cocaine augments responding in a frustrative reward-omission task, a measure of urgency, but our RTI-113 data suggest that the effect of cocaine may not involve the dopaminergic system. Thus, although dopamine may play a role in urgency, other transmitter systems are likely to modulate this response.

Abstract: The development and maintenance of cocaine addiction and relapse after abstinence have been shown to depend heavily on learned associations between environmental stimuli and the rewarding properties of the drug. However, not much is known about the molecular mechanisms that lead to the formation of these environmentally cued drug associations. The conditioned place preference (CPP) paradigm exploits the neural circuitry underlying the reward, learning, and memory processes of the brain, allowing us to explore the maladaptive neural and molecular changes that occur during the formation of these associations. The present study investigated the molecular mechanisms underlying cocaine-induced CPP in response to two doses of cocaine (5mg/kg, i.p. or 20mg/kg, i.p.). In addition, we attempted to block the acquisition of cocaine CPP using the NMDA receptor antagonist MK-801. We found that CPP behavior was expressed only in response to the higher dose of cocaine and was associated with an increase in Nucleus accumbens (NAc) ERK phosphorylation (pERK) and Caudate Putamen (CPu) deltaFosB protein levels during CPP testing. Pretreatment of MK-801 (0.025 mg/kg. i.p.)30 minutes prior to cocaine administration during conditioning, blocked the acquisition and expression of cocaine CPP and reduced NAc pERK and CPu deltaFosB levels. This study provides novel evidence for the role of the NMDA receptor and ERK signaling in the expression of cocaine induced CPP.

Title: The role of N-methyl-D-aspartate receptor co-agonists in cocaine-induced conditioned place preference and locomotor sensitization: Implications for comorbid schizophrenia and substance abuse

Authors: *M. D. PUHL, A. J. BECHTHOLT, J. T. COYLE;
Psychiatry, Harvard Med. School, McLean Hosp, Belmont, MA

Abstract: Schizophrenia is associated with a high susceptibility to substance abuse. Recent research suggests that dysregulation of *N*-methyl-D-aspartate receptor (NMDAR) function may play a role in the pathopyhsiology of both schizophrenia and drug addiction. NMDARs play a critical role in the neuroplasticity that mediates adaptive changes to abused drugs. In addition, hypofunction of NMDARs has been implicated in schizophrenia. This hypofunction may be due to decreased availability of D-serine, an NMDAR co-agonist. Our laboratory has developed two transgenic mouse lines to test the validity of this hypothesis. The first line is a constitutive knockout of the synthetic enzyme that produces D-serine, serine racemase (SR). Null mutants (SR-/-) exhibit NMDAR *hypo*function. The second line is a constitutive knockdown of glycine transporter 1 (GlyT1), which regulates synaptic glycine, another NMDAR co-agonist. Heterozygous mutants (GlyT1+/-) exhibit NMDAR *hyper*function. Previously, we characterized the behavior of these lines in a cocaine-induced (20 mg/kg) conditioned place preference (CPP) and locomotor sensitization paradigm. Briefly, GlyT1+/- mice displayed hastened extinction of cocaine-induced CPP, accompanied by robust cocaine-induced reinstatement, as well as enhanced locomotor sensitization to cocaine. Interestingly, SR-/- mice appeared to immediately forget the learned preference, did not exhibit cocaine-induced reinstatement, and displayed attenuated locomotor sensitization to cocaine. In the current study, both GlyT1+/- and SR-/- mice were tested in the cocaine-induced CPP paradigm used previously, however, GlyT1+/- mice were either treated chronically (17 days) with gavestinel (10 mg/kg on Day 1, 5 mg/kg on Days 2-17), a GMS antagonist, or vehicle, and SR-/- mice were either treated chronically (17 days) with D-serine (300 mg/kg on Day 1, 150 mg/kg on Days 2-17) or vehicle, with the hypotheses that these treatments would normalize the behaviors of GlyT1+/- and SR-/- mice, respectively. Gavestinel caused the GlyT1+/- mice to immediately forget the learned preference and prevented cocaine-induced reinstatement, but had no effect on locomotor sensitization to cocaine. D-serine appeared to have no effect on extinction or reinstatement of cocaine-induced CPP, but completely reversed the deficit in locomotor sensitization to cocaine. These results further elucidate the role of NMDAR co-agonists in cocaine-induced CPP and locomotor sensitization and may shed light on the neural mechanisms underlying co-morbid schizophrenia and substance abuse. This research was supported by DA015036 and MH51290.

Title: Activity-regulated cytoskeletal protein expression is decreased in the dorsomedial striatum of relapse vulnerable animals: Association with miR-221 and miR-431 expression

Authors: *R. K. QUINN, A. L. BROWN, E. M. LEVI, B. J. GOLDIE, D. W. SMITH, M. J. CAIRNS, C. V. DAYAS;
Sch. of Biomed. Sci. and Pharm., Univ. of Newcastle, Callaghan, Australia

Abstract: Compulsive drug-taking has been linked with impairments in synaptic plasticity and dysregulated microRNA (miRNA) expression in the ventral and dorsal striatum respectively. We found that animals characterized as ‘relapse’-vulnerable exhibited deficits in gene expression for synaptic plasticity associated-proteins in the dorsal striatum (DS), most notably, activity-regulated cytoskeletal protein (ARC) and dopamine receptors 1 (Drd1a) and 2 (Drd2). Given the important role of miRNA in negatively regulating mRNA expression and fine tuning synaptic plasticity, we examined the possible contribution of miRNA to the specific changes in mRNA we observed in DS subregions of ‘relapse’-vulnerable animals.
Animals were trained to self-administer cocaine, and subsequently assessed for motivation to take drug, ability to refrain from drug seeking and propensity to relapse to drug seeking. These indices were used to phenotype animals in ‘relapse’-vulnerable or resistant groups animals. Within the DS, miRNA expression profiles were analysed for both ‘relapse’-vulnerable and resilient animals using microarray analysis. Agilent GeneSpring software was used to identify differentially expressed miRNA, with changes confirmed using qPCR Luciferase assays were

used to confirm miRNA regulation of synaptic plasticity genes in vitro.
ARC mRNA expression and protein levels were significantly reduced in the DMS but not DLS of vulnerable animals. Of note two microRNA predicted to regulate, miR-431 and miR-221, were significantly increased in both the DMS and DLS of addiction vulnerable animals. miR-221 has previously been shown to regulate ARC expression in vitro. To determine if miR-431 regulates ARC we used luciferase assays and found that antisense miR-431 increased luciferase expression, indicating miR-431 regulates ARC expression in vitro. Interestingly, we also found that the expression of miR-212 previously linked with compulsive cocaine-seeking, was decreased in the DMS but increased in the DLS of vulnerable rats..
These results support the accumulating evidence that dysregulated miRNA expression can lead to addiction/relapse vulnerability. Specifically our data suggest that negative regulation of ARC by miR-221/mir-431 may be an underlying neurobiological mechanism contributing to the long lasting drug relapse risk. Furthermore, the opposing pattern of miR-212 expression in the DMS and DLS is consistent with distinct roles for these subregions in regulating addiction processes. Future studies are planned to characterize the pattern of miRNA expression changes in DMS and DLS across the addiction cycle.

Title: How does the brain “put on the brakes” in addiction? Modeling inhibition of a pre-potent response to affect-positive stimuli

Authors: *A. R. CHILDRESS[1], Y. LI[1], M. GOLDMAN[1], J. SUH[1,2], Z. SINGER[1], R. EHRMAN[1,3], T. FRANKLIN[1], D. LANGLEBEN[1,4], K. YOUNG[1], R. WETHERILL[1], M.

GAWRYSIAK[4], C. O'BRIEN[1];
[1]Dept Psychiat, Univ. PENN Perelman Sch. Med., Philadelphia, PA; [2]Psychiatry, [3]Behavioral Healthy, [4]Behavioral Hlth., Philadelphia Dept. of Veteran's Affairs Med. Ctr., Philadelphia, PA

Abstract: Aims: Some individuals are able to manage the pull of rewards – e.g., food, sex, or drugs of abuse – while others struggle. This struggle is prominent in the addictions: addicted individuals fail to inhibit their "approach response" to rewarding drugs of abuse, despite the clear negative consequences (e.g., loss of family, friends, jobs, health) of this pursuit. Learning how the brain succeeds, or fails, to "put on the brakes" in response to positive stimuli – even in the presence of a negative danger signal – is critical to developing therapeutics to improve inhibitory function in addictions. Toward this goal, we have developed a novel Go-NoGo task that uses valenced (positive or negative) pictures as Go and NoGo stimuli. We are using this novel task to reveal the brain regions involved in "putting on the brakes" to danger signals occurring during a stream of positive stimuli.
Methods: Fast event-related BOLD fMRI at 3T (SPM8) was used to measure brain responses in a cohort of 57 addicted (cocaine, marijuana or prescription opioids; ongoing) adults during performance of a novel Affect Congruent Go-NoGo task with pleasant images (e.g., baby animals) that encouraged approach as Go stimuli (87.5% of trials), and dangerous images that discouraged approach (e.g., scorpions) as NoGo stimuli (12.5% of trials). Pre-planned contrasts compared the brain response during trials for successful (STOPS) vs. failed (ERROR) inhibition.
Results: Successful inhibition trials (STOPS), as compared with failed inhibition trials (ERRORS), were associated with activation of circuitry common to "motor only" Go-NoGo tasks (e.g., d. cingulate, d.l. prefrontal cortex, and d. striatum/putamen; peak $t = 10.16$, $p < 0.0000$ FWE). Brain regions important in the processing of motivational, valenced stimuli (v. pallidum / d. amygdala, and the caudal orbitofrontal cortex) were also activated during successful inhibition in the novel task.
Conclusion: Successful inhibition in the novel Affect-congruent Go-NoGo was linked to classic "brain brakes" circuitry (d. cingulate, d.l. prefrontal cortex, and d. striatum). Successful inhibition in this novel task was also reflected in the activation of motivational circuitry – a feature that is not captured by standard Go-NoGo tasks with unvalenced, arbitrary stimuli (e.g., letters, numbers or shapes). The novel task may thus provide a closer model to the clinical deficits in addiction – e.g., failure to inhibit approach to drug reward, despite potential dangers. In ongoing work, we are testing the ability of this new task to identify individuals at risk for relapse, and to screen candidate medications for their ability to boost the "brain brakes".

Title: An escalating dose regimen of cocaine leads to site-specific changes in neuropeptide Y immunoreactivity in the rat brain

Authors: *M. SUAREZ[1], C. P. KING[2], D. DANIELS[2], A. C. THOMPSON[3];
[1]Psychology, Univ. At Buffalo, BUFFALO, NY; [2]Psychology, [3]Res. Inst. on Addictions, Univ. at Buffalo, Buffalo, NY

Abstract: Emerging evidence suggests that neuropeptide Y (NPY) acts on neural substrates that underlie drug use and dependence. Psychostimulants and other drugs of abuse regulate synthesis and release of NPY in the brain and increasing evidence suggests that repeated exposure to these compounds result in neural adaptations that persist through the first few months of abstinence from chronic cocaine exposure. Our laboratory has been investigating the effect of acute manipulation of NPY in the brain on the reinstatement of cocaine seeking behavior during periods of abstinence and we have found that increasing NPY attenuates reinstatement of cocaine-mediated behaviors. The current study was designed to determine if our model of cocaine exposure, an escalating dose regimen in rats, alters NPY after short and long periods of abstinence. To this end, we used immunohistochemistry, which has better anatomical resolution than the techniques used in earlier reports. Male Long-Evans (hooded) rats were given daily injections of cocaine (COC) using an escalating cocaine dose regimen (5-30 mg/kg IP), or vehicle (VEH) for 21 days. Either 1 or 22 days after the final cocaine injection, brains were harvested, cut into 40 µm sections, and every tenth section was processed for NPY-immunoreactivity A significant interaction between cocaine treatment and length of abstinence was found in most forebrain areas. This interaction was due to (1) a decrease in NPY density in the COC-22 d group, with the greatest effect occurring in subregions of the medial prefrontal cortex (i.e. cingulate cortex), and (2) an increase in NPY density the COC-1 d group in a limited number of areas (i.e. infralimbic cortex and prelimbic cortex). The possibility of an effect of age difference on NPY density between rats killed 1 d or 22 d after the last injection was controlled by the experimental design and also evaluated; no effect of age on the interaction between cocaine treatment and length of abstinence was found in preliminary analysis. These results add to a growing body of literature showing that repeated cocaine exposure with abstinence decreases multiple cellular and molecular measures of NPY in forebrain structures and supports the idea that the behavioral sequelae, consequent to cocaine dependence and manifest during abstinences, may be mediated by changes in NPY activity.

Title: Mutating Slc7A11 to create a system xc- knockout rat

Authors: *S. CHOI[1], A. GEURTS[2], J. RESCH[1], N. RADDATZ[1], L. KONG[1], J. CLELAND[1], J. MANTSCH[1], D. BAKER[1];

Abstract: Glutamate is often described as the primary excitatory neurotransmitter in the brain yet we are only now unmasking how the many components of this complex network of receptors, membrane-expressed enzymes, transporters, and release mechanisms function in an integrated manner to regulate the neurotransmitter actions of this amino acid. System x_c^-, which is highly expressed by astrocytes, is an example of a poorly understood source of glutamate release that functions as a cystine-glutamate antiporter that couples the uptake of one molecule of cystine to the release of one molecule of glutamate. As a result, system x_c^- is at the interface between excitatory signaling and oxidative stress making it an intriguing target in attempts to understand the pathological states of the central nervous system, especially as it relates to astrocytic control of the primary excitatory neurotransmitter in the brain. To better understand the contribution of system x_c^- to multiple aspects of brain functioning, we developed transgenic rats by mutating the Slc7A11 gene using Zinc-Finger Nucleases (ZFN). Genotyping data revealed that efforts to mutate Slc7A11 were successful in two lines of Sprague Dawley rats. The first line (M1) contains a 39 base pair deletion in exon 2 leading to a frameshift and anticipated truncation of the xCT protein. The second line (M2) has a deletion of 13 amino acids corresponding to the majority of the 3rd transmembrane domain. We have confirmed that the M1 mutation results in a complete elimination of system x_c^- activity by demonstrating a lack of system x_c^- dependent uptake of ^{14}C-cystine in striatal tissue punches. We will use these rats to determine the role of

system x_c^- in multiple behaviors used to model aspects of drug addiction and schizophrenia.

Title: Contingent cocaine exposure regulates inhibitory synaptic transmission in the nucleus accumbens

Authors: *M. OTAKA[1], M. ISHIKAWA[1], B. R. LEE[3], L. LIU[1], P. A. NEUMANN[1], Y. H. HUANG[2], O. M. SCHLÜTER[4], Y. DONG[1];

Abstract: Addiction is known as a relapsing chronic psychiatric disorder. The high possibility of relapse significantly interrupts the treatment of addiction. It has been well characterized that drug addiction causes dynamical cellular adaptations in medium spiny neurons (MSNs) within the nucleus accumbens shell (NAc). The neuronal output NAc MSNs is mainly determined by the integration of membrane excitability and excitatory/inhibitory synaptic inputs. Cocaine-induced alterations at excitatory synapses and membrane excitability have been extensively examined. However, the overall functional output of NAc MSNs following cocaine exposure is still poorly defined because little is known whether inhibitory synaptic input to MSNs is also affected by cocaine. Our results showed alterations at inhibitory synapses in MSNs at NAc shell following cocaine self-administration in rats. Specifically, the amplitude of miniature IPSCs (mIPSCs) was

decreased after 3 weeks WD from 5 d cocaine self-administration. Upon re-exposure to cocaine after 3 weeks WD, the frequency of mIPSCs became significantly higher. Furthermore, the reversal potential of IPSCs, which was not significantly altered during WD, became more hyperpolarized upon cocaine re-exposure. Moreover, the relative weight of excitatory and inhibitory inputs to NAc MSNs was significantly decreased after 1 d cocaine WD, increased after 3 weeks WD, and returned to the basal level upon cocaine re-exposure after 3 weeks WD. Taken together with previous results showing cocaine-induced adaptations at excitatory synapses and intrinsic membrane excitability of NAc MSNs, our present results may provide overall picture of the functional state of NAc MSNs following cocaine exposure and possible therapeutic approaches for cocaine addiction.

Title: An adaptive role for TNFα mediated plasticity in response to cocaine

Authors: *G. M. LEWITUS, S. KONEFAL, D. STELLWAGEN;
Neurol. and Neurosurg., McGill Univ. Hlth. Ctr., Montreal, QC, Canada

Abstract: Repeated cocaine administration produces enduring molecular, cellular and behavioral plasticity associated with changes in striatal glutamatergic synapses. The mechanism underlying this type of plasticity, however, is not well understood. In addition to its role in the inflammatory response, the cytokine TNFα is elevated by drugs of abuse and has been shown to regulate AMPA receptor (AMPAR) trafficking. On hippocampal and cortical pyramidal cells, exogenous application of TNFα leads to a dramatic and rapid exocytosis of AMPA receptors. In contrast, medium spiny neurons (MSNs) in the striatum respond to TNFα by endocytosing AMPA receptors. The aim of the present study is to investigate the role of TNFα in the striatal plasticity

induced by cocaine. We use patch-clamp recordings to investigate the contribution of TNFα to the regulation of AMPAR trafficking on MSNs in the nucleus accumbens and its relevance to behavioral sensitization to cocaine. We find that the TNFα -/- mice display an increased locomotor response as compared to wildtype mice following a behavioral sensitization protocol. Further, we find that pharmacologically blocking TNFα signaling during sensitization, but not during the withdrawal period is sufficient to increase behavioral responses. Moreover, the increased behavioral sensitization in TNFα -/- is associated with altered glutamatergic synaptic strength in the nucleus accumbens. These results suggest that TNFα-mediated striatal plasticity is a homeostatic response to cocaine administration.

Title: Role of HDAC3 in modulating acquisition/consolidation and extinction of cocaine-induced conditioned place preference

Authors: *A. WHITE;
Neurobio. and Behavior, UC Irvine, Irvine, CA

Abstract: Histone acetylation is a key mechanism of gene expression control involved in several aspects of drug-seeking behavior. Histone acetylation is regulated by histone acetyltransferases (HATs) and histone deacetylases (HDACs), which facilitate and repress transcription, in general. In this study, we specifically examined the role of HDAC3, the most prominently expressed HDAC in the brain, in the acquisition/consolidation and extinction of cocaine-induced conditioned place preference (CPP). We have previously demonstrated that HDAC3 is a critical

negative regulator of long-term memory formation. As cocaine-induced CPP is an associative memory task, we predicted that genetic deletion and/or pharmacologic inhibition of HDAC3 would facilitate acquisition/consolidation and also facilitate extinction. Indeed, Hdac3-FLOX mice with a focal deletion in the nucleus accumbens showed significantly enhanced CPP, which correlated with increased histone acetylation at H4K8 and increased expression of immediate early genes c-Fos and Nr4a2. Chromatin immunoprecipitation demonstrated that increased gene expression of these genes is associated with the loss of HDAC3 at their promoters. These results show that HDAC3 negatively regulates cocaine-induced CPP. To examine extinction, we turned to a pharmacological approach in which an HDAC3 specific inhibitor was used to block HDAC3 activity during the consolidation phase of extinction memory formation. HDAC3 inhibition significantly enhanced extinction of cocaine-induced CPP. Similar to our previously published memory findings, HDAC3 inhibition not only facilitated extinction, but generated a form of extinction that is persistent and that blocks reinstatement. Additionally, HDAC3 inhibition during extinction promoted a distinct pattern of histone acetylation linked to gene expression within the infralimbic cortex, hippocampus, and nucleus accumbens. Together, these results demonstrate that HDAC3 is a key enzyme involved in the acquisition/consolidation and extinction of drug-seeking behavior.

Title: Manipulation of moesin protein levels in the nucleus accumbens core regulates cocaine-induced locomotor activity

Authors: W. KIM[1], J. JANG[1], B. CHO[1], J. LEE[1], W. CAI[1], S. JEON[2], *J.-H. KIM[1];
[1]Dept of Physiol., Yonsei Univ. Coll Med., Seoul, Korea, Republic of; [2]Res. Inst. of Biotech., Dongguk Univ., Seoul, Korea, Republic of

Abstract: The ezrin-radixin-moesin (ERM) proteins have been implicated not only in cell-shape determination but also in cellular signaling pathway. Previously, we showed that cocaine

decreases the phosphoryaltion levels of ERM in the NAcc in a time- and dose-dependent manner. However, it has not been determined yet what functional role ERM proteins play in the nucleus accumbens (NAcc) in relation with drugs of abuse. Here we microinjected lenti viral vectors, which contains either wild-type or mutant moesin gene, into the NAcc core and measured locomotor activity following either saline or cocaine (15 mg/kg, IP) injections. Interestingly, over-expression of wild-type mosein in this site inhibited cocaine-induced hyper-locomotor activity, while mutant gene further enhances it, compared vehicle microinjection groups. In saline treated rats, both viral vectors produced locomotor activity not different from vehicle microinjection groups. These results first time indicate that moesin-mediated signaling pathways in the NAcc core contribute to cocaine-induced locomotor activity. Considering the fact that there is very little known about the functional role of ERM proteins in the brain in the literature, our present findings will open a new venue especially bringing ERM proteins to our attention in terms of psychomotor stimulants-related signaling pathways.

Title: Beta-arrestin 1 dependent regulation of cocaine self-administration in mice

Authors: *N. MITTAL[1], Z. ABDULLA[2], A. M. JAMES[3], D. JENTSCH[3], C. CRAWFORD[2], C. EVANS[3], W. WALWYN[3];
[1]Univ. of Texas At Austin, Austin, TX; [2]California State Univ. San Bernardino, San Bernardino, CA; [3]Univ. of California Los Angeles, Los Angeles, CA

Abstract: AMPARs (2-amino-3-(3-hydroxy-5-methyl-isoxazol-4-yl)propanoic acid receptors) rely on the 3-dimensional structure of the postsynaptic density to be trafficked into and removed from the synapse as necessary. This is mediated by the rapid rearrangement of actin filaments, which is orchestrated by a series of proteins, including the actin severing protein, cofilin, Lim domain kinase (LIMK), the upstream kinase, and Slingshot, a phosphatase. These proteins are in

turn associated with one of the two non-visual arrestins, thereby providing spatiotemporal regulation of actin turnover. These protein interactions predict that mice lacking one of the arrestin isoforms, β-arrestin 1, may demonstrate altered AMPAR function. As changes in AMPAR subunit composition and function are a well-recognized hallmark of single and repeated exposure to psychostimulants such as cocaine, we examined whether mice lacking B-arrestin1 show an altered profile of cocaine self-administration and of AMPAR function. We first defined the profile of intravenous self-administration of cocaine in β-arrestin 1 knockout (βarr1-/-) and wildtype (WT, βarr1+/+) mice. Mice were trained to self-administer cocaine (1 mg/kg/infusion) on schedules of reinforcement that progressively advanced: fixed ratio (FR) 1, FR2, and FR5. Sessions were conducted on sequential days and each lasted 2 hours. Relative to their WT littermates, βarr1-/- mice earned fewer cocaine infusions during the early stages of acquisition (at FR1; p=0.016), but not thereafter (at FR2 or FR5). After stable responding at FR5 was achieved, 5 days of extinction followed, in which the mice were placed in the operant boxes but no drug delivered when the active lever was pressed. During early extinction learning WT mice showed a faster decline in the number of lever presses as compared to βarr1-/- mice (p=0.015). Thereafter, both genotypes showed equivalent cue-induced reinstatement behaviors. At the end of either the acquisition or reinstatement phases, mice were removed from the study to assess the AMPA/NMDA (A/N) ratio from evoked excitatory post-synaptic currents (eEPSCs) in medium spiny neurons in the nucleus accumbens shell. We found that the A/N ratio from naive WT mice was lower than that of naïve βarr1-/- mice (p=0.047). Acquisition and reinstatement of cocaine self-administration was associated with a progressive increase in the A/N ratio in WT mice. In contrast, the A/N ratio from βarr1-/- was not altered at any stage. These data suggest that β-arrestin 1 plays an important role in the acquisition and extinction of cocaine self-administration, and in the adaptations of AMPAR function that may underlie these behaviors.

Title: Expression of the HIV-1 glycoprotein, gp120, increases ROS production and glutamate NMDA receptor density in the dorsal striatum following repeated systemic cocaine administration

Authors: *D. A. LANE, M.-K. LYNCH, G. WANG, C. IADECOLA, V. M. PICKEL;
Brain and Mind Res. Inst., Weill Med. Col. of Cornell Univ., NEW YORK, NY

Abstract: Human immunodeficiency virus (HIV) infection is associated with increased susceptibility for drug addiction, which may be indicative of convergent intracellular signaling in targeted brain regions. The production of reactive oxygen species (ROS) in response to glutamate activation of NMDA receptors plays an important role in both neurodegenerative and addictive diseases suggesting that this pathway may be a key mechanism involved in this convergent signaling. We tested this hypothesis using a cocaine model and examining changes in the mouse dorsal striatum, which is one of the regions most notably involved in HIV associated motor dysfunctions and in the emergence of drug-seeking motor habits that are dependent on both dopamine and NMDA receptor mediated glutamatergic transmission. Cocaine (15 mg/kg/day) was administered for 14 consecutive days in wild-type (WT) and transgenic male mice that over express GFAP-gp120 (gp120+), followed by behavioral testing. Isolated striatal cells from each treatment group were processed for ROS detection using dihydroethidine fluorescence imaging. Tissue sections through the striatum of the same experimental groups were processed for dual immunogold labeling of NMDA NR1 subunit and peroxidase identification of the dopamine D1 receptor, a receptor that is often co-mobilized with NR1 in striatal neurons. Both gp120+ and WT control mice showed sensitization to the stimulant effects of cocaine (3 fold increase in distance traveled) and conditioned place preference to cocaine-paired environments as compared to saline controls. Whereas, chronic cocaine attenuated the production of NMDA-elicited (100 μM) ROS in WT mice, it significantly increased ROS in gp120+ mice (1.04 vs. 1.20 ± 0.03 standard ROS units, $p < 0.01$). Further, the change ROS production was associated with increased NMDA receptor density, both at the plasma membrane and in the cytoplasm, of dopamine D1-receptor containing dendrites within the dorsal striatum of gp120+ mice. Taken together, the data suggest that the presence of gp120 augments cocaine-induced activation of dopamine receptive striatal neurons, which can increase cocaine craving and seeking through mechanisms that involve NMDA receptor-mediated ROS production.

Title: Cellular mechanisms of enhanced cocaine self-administration in mhc class I deficient mice

Authors: *G. MURAKAMI, H. MENG, M. EDAMURA, D. NAKAHARA;
Dept. of Psychology, Hmamatsu Univ. Sch., Shizuoka, Japan

Abstract: Brain was thought to be an immune privilege region, however, it has been recently discovered that various immune proteins have important roles even in the brain. Particularly major histocompatibility complex class I (MHCI) is critically involved in the organization of neural circuits in development and learning and memory in adults. Given that cocaine abuse activates the immune system in peripheral organs, it is reasonable to hypothesize that cocaine modulates the expression of MHCI and changes the synaptic plasticity in brain regions contributing to cocaine addiction. Our previous experiment showed that mice with functionally deficient MHCI exhibited enhanced locomotor sensitization induced by repeated cocaine injection in comparison with their wild type. In self-administration paradigm, functional MHCI deficient mice showed much more addictive behavior such as enhanced locomotor activity and nose-poking than wild type mice after 10 days of cocaine administration and 10 days of abstinence followed by a 3-day reinstatement. This result showed a critical involvement of MHCI in cocaine addiction.
To assess whether cocaine modified expression of MHCI in the brain, we compared the mRNAs of H2D and H2K by qPCR in brain regions such as the ventral tegmental area (VTA), accumbens (Acb), prefrontal cortex (PFC), amygdala (Amy) and hippocampus (Hip). Cocaine decreased H2D expression only in the VTA after the injection for 7 days followed by 10 days of abstinence. The decrease of H2D expression in the VTA was also observed in the mice exposed to self-administration paradigm. We also confirmed that H2D was expressed in dopaminergic neurons in the VTA by immunohistochemistry with membrane-nonpermeabilization method using several antibodys. Now we are investigating the role of MHCI in the cocaine addiction at a level of electrophysiological properties of dopaminergic neurons in the VTA. To confirm the reduction of H2D particularly in the VTA contributing to the process of cocaine addiction, we are also trying to manipulate the expression of H2D in the VTA using adeno-associated virus vector.

Title: Cocaine exposure alters pathway-specific synaptic connectivity in the Nucleus Accumbens

Authors: *A. MACASKILL, J. M. CASSEL, A. G. CARTER;
New York Univ., New York, NY

Abstract: Alterations in the synaptic properties of medium spiny neurons (MSNs) in the Nucleus Accumbens (NAc) are thought to play a key role in the transition to addiction. MSNs in the NAc are segregated into the direct and indirect pathways, which have opposing effects on reward-related behaviors. Drug induced changes in synaptic properties are thought to change the balance of the two pathways, resulting in altered basal ganglia output. However, MSNs process diverse long-range excitatory synaptic inputs from multiple brain regions, each with distinct properties and functions. Here we use a combination of electrophysiology, two-photon microscopy and optogenetics to study the impact of drug exposure on NAc circuitry. We find alterations in the synaptic organization of the NAc circuit at the subcellular level of spines and dendrites. These changes are input specific, with inputs from the ventral hippocampus and basal amygdala each displaying unique functional alterations. Thus, drug induced alterations in NAc circuitry are not homogenous, but depend upon the presynaptic origin of the synaptic contact.

Title: Sex differences in girk signaling in layer 5/6 pyramidal neurons of the mouse prefrontal cortex

Authors: *E. MARRON, M. HEARING, K. WICKMAN;
Pharmacol., Univ. of Minnesota, Minneapolis, MN

Abstract: Glutamatergic pyramidal neurons in the deepest layers (Layers 5/6) of the medial prefrontal cortex (mPFC) are the primary output neurons of the mPFC and as such, play a key role in modulating neurotransmission in the mesocorticolimbic system. Studies in both humans and rodents have demonstrated sexually-dimorphic behavioral responses to cocaine and cocaine-related cues including increased behavioral activation, place preference, and reinstatement of drug-seeking. This sex disparity has been linked to intrinsic differences in inhibitory G protein-coupled receptor (GPCR) function in the mesocorticolimbic system, including differential D_2R activation in the mPFC. $GABA_B$ receptor-dependent signaling also plays a key role in regulating mPFC glutamatergic output. The postsynaptic inhibitory influence of $GABA_B$ and D_2R is mediated in many neurons by G protein-gated inwardly-rectifying K^+ (Girk/$K_{IR}3$) channels. Thus, we investigated whether sex differences exist in mPFC Layer 5/6 pyramidal neuron $GABA_BR$-Girk signaling. Somatodendritic currents induced by the $GABA_BR$ agonist baclofen were measured using the whole-cell voltage-clamp technique in Layer 5/6 pyramidal neurons in acutely-isolated coronal slices from adolescent male and female C57BL/6 mice. Baclofen triggered robust outward currents ($I_{Baclofen}$; V_{hold}= -60 mV) in both male and female mice that reversed near E_K (-92 mV) and correlated with decreased input resistance, features consistent with the activation of a K^+ channel. $I_{Baclofen}$ was significantly larger in wild-type male mice compared to age-matched female counterparts. While $I_{Baclofen}$ was markedly reduced in male mice lacking either Girk1 or Girk2 subunits, no significant differences in $I_{Baclofen}$ were seen in female wild-type and *Girk*$^{-/-}$ mice. Importantly, Layer 5/6 pyramidal neurons in wild-type females also displayed a reduction in the current needed to evoke an action potential and enhanced current-evoked action potential firing compared to wild-type males. Taken together, these data suggest that female mice display intrinsically lower Girk-dependent signaling in Layer 5/6 mPFC pyramidal neurons, which promotes enhanced excitability of these neurons. Since increased excitability of Layer 5/6 mPFC pyramidal neuron excitability and neurotransmission are critical for the expression of cocaine-related behavior, intrinsic differences mPFC Girk-related signaling may contribute to differences between males and females in their response to cocaine.

Title: Antioxidant compounds modulate cocaine-conditioned effects on locomotion

Authors: *J. D. NGUYEN, M. J. FORSTER;
Univ. of North Texas Hlth. Sci. Ctr., Fort Worth, TX

Abstract: It was hypothesized that an acutely reducing cellular redox state could attenuate redox signals involved in neural plasticity events mediating associations of context with psychostimulant exposure. To test this hypothesis, three compounds with different antioxidant actions were evaluated for their ability to affect the acquisition and expression of context-dependent increases in locomotion produced by a single exposure to cocaine. Cocaine (40 mg/kg) was administered to different groups of Swiss-Webster mice via intraperitoneal injection (i.p.), in either a locomotor activity testing apparatus or the home cage, 2 hours following an activity test under saline. Mice placed in the testing chambers were given 30 minutes to explore freely and locomotion was monitored using a Digiscan photocell apparatus. A conditioned effect of cocaine was inferred by an increase in horizontal activity counts relative to home cage cocaine controls during a test in the same apparatus on the following day. For testing of effects on expression of the conditioned cocaine effect, N-acetylcysteine (25, 50, 100 mg/kg), dimethylthiourea (5, 10, 25, 50 mg/kg), L-ascorbic acid (25-500 mg/kg), or vehicle was administered prior to placement into the activity chambers on the test day. The same compounds were administered prior to the acquisition day in a separate set of studies. N-acetylcysteine (100 mg/kg) and dimethylthiourea (25 and 50 mg/kg) inhibited the expression and the acquisition of cocaine-conditioned locomotion, though L-ascorbic acid (100 mg/kg) increased the acquisition of the conditioned locomotor effect and did not affect its expression. Additionally, L-ascorbic acid was found to facilitate the acute motor stimulant effect of cocaine, whereas N-acetylcysteine and dimethylthiourea did not affect the locomotor response to cocaine. The ability of these compounds to inhibit or exacerbate the conditioned behavior suggests that alteration of redox state may indeed influence neural plasticity dependent alterations in brain mediating addiction and relapse. Therefore, compounds producing alterations in cellular redox state may be viable targets for addiction treatment medications.

Title: The effect of acupuncture on the cocaine-induced anhedonia

Authors: *S. IN[1], B. LEE[1], H. HAN[1], H. KIM[2], S. YOON[2], C. YANG[2], S. LEE[3], R. ZHAO[5], S. LIM[1], J. KIM[1], Y. LEE[1], H. LEE[1], T. JUNG[4], S. IN[1];
[1]Acupuncture, Moxibustion & Acupoint, [2]Physiology, Col. of Oriental Med., [3]Gigong, Col. of Oriental Med., [4]Diagnostics, Daegu Haany Univ., Daegu, Korea, Republic of; [5]Pharmacol., Mudanjiang Med. Univ., Mudanjiang, China

Abstract: Objectives: Anhedonia often appears in the psychiatric disorders such as schizphrenia and depression. It is a kind of side effect of antidopaminergic drugs and easily caused by withdrawal from the abused drugs like cocaine or amphetamine that enhances dopaminergic neurotransmission. The purpose of this study was to examine the effects of acupuncture on the anhedonia induced by cocaine and to investigate possible neuronal involvement.
Material & Methods: Male Wister rats were trained to self-administer 4% sucrose solution under a fixed ratio (FR) schedule using 2 h session for 10 days (Day 1-3: FR 1, Day 4-6: FR 3, Day 7-10: FR 10, 0.1ml per infusion) and rats who had established stable response were trained with progressive ratio (PR) schedule. When animals had taken no more sucrose solution for 1 h, the number of infusions was defined as break point. After 10 days of PR training, animals that established stable baseline (variation less than 10% of the average for three consecutive days) on the break point received cocaine 24 h after the establishment of baseline. Cocaine (15 mg/kg) or saline was given total 8 times intraperitoneally with an interval of 90 min with the exception of the first interval of 30 min. Thereafter, animals were re-exposed to the sucrose self-administration 12 h, 36 h, and 60 h after the finish of cocaine injection. Acupuncture was applied at each acupoint immediately before the start of re-exposure to sucrose. GABAA receptor antagonist, bicuculline (1.0 mg/kg), and GABAB receptor antagonist, SCH 50911 (2.0 mg/kg), were given 20 min prior to the acupuncture.
Results: It has been shown that animals that had been exposed to cocaine exhibited decreased sucrose-seeking behavior and that acupuncture at SI5, but not at the control acupoint LI5, significantly increased the sucrose self-administration. And this effect of acupuncture was blocked by the treatments of GABA receptor antagonists (GABAA and GABAB).
Conclusions: The results of this study demonstrate that acupuncture at SI5 may be effective in the treatment of anhedonia caused by exposure to cocaine and that this effect is mediated by, at least in part, GABA receptor system.

Title: Acceleration of habit learning following cocaine sensitization and reversal by N-acetylcysteine

Authors: *L. H. CORBIT[1], B. C. CHIENG[2], B. W. BALLEINE[2];
[1]Univ. of Sydney, Sydney, Australia; [2]The Univ. of Sydney, Brain and Mind Res. Inst., Sydney, Australia

Abstract: Drug addiction is defined primarily by behavioural characteristics related to loss of control over drug use. Despite an increasing number of studies examining the effects of stimulant exposure on drug seeking and taking, there has been little systematic research into how these drugs influence normal decision-making.
Repeated exposure to drugs of abuse causes a wide range of long-lasting neural adaptations, however, to date, this work has not established whether these changes are sufficient to lead to executive dysfunction. Of note, several recent reports show that repeated amphetamine exposure, sufficient to induce sensitization, accelerates the loss of volitional control over reward seeking, causing abnormally rapid development of habitual reward seeking.
Chronic drug exposure has been demonstrated to impair glutamate homeostasis by altering the balance between synaptic and extra-synaptic glutamate release and elimination (see Kalivas, 2009). Drugs that restore this balance have been shown to reduce drug-seeking behaviours. For example, treatment with N-acetlycysteine (NAC), prevents behavioural sensitization and reinstatement of cocaine self-administration. These findings raise the intriguing hypothesis that NAC may also prevent the abnormally rapid formation of habits after stimulant exposure and help to restore normal decision-making processes.
The following experiments examined whether pre-training exposure to cocaine accelerates habit learning (defined as loss of sensitivity to outcome devaluation) and whether co-treatment with NAC could prevent the effects of cocaine on subsequent learning. Ex-vivo electrophysiological

experiments examined changes in glutamatergic signaling following cocaine pre-treatment in the dorsomedial (DMS) and dorsolateral (DLS) regions of the dorsal striatum previously shown to underlie goal-directed and habit learning, respectively. We find that cocaine exposure accelerates habit learning and this effect is prevented by co-treatment with NAC suggesting that dyregulation of glutamate homeostasis contributes to accelerated habit learning following drug exposure. Furthermore, spontaneous glutamate release was found to be elevated in the DMS following cocaine exposure suggesting that the rapid shift from goal-directed to habitual control following drug exposure relates to dysregulation of the goal-directed system permitting early dominance by the habit system rather than direct effects on plasticity in structures controlling habit learning.

Title: Local field potentials in the ventral tegmental area correlate with cocaine-induced locomotor activation: Measurements in freely moving rats

Authors: *A. HARRIS[1], A. LI[2], J. E. SIBI[2], S. A. MORRIS-BOBZEAN[2], Y. PENG[2], L. I. PERROTTI*[2];
[1]The Univ. of Texas At Arlington, Arlington, TX; [2]The Univ. of Texas at Arlington, Arlington, TX

Abstract: It is well established that the ventral tegmental area (VTA) is a critical nucleus for the development of drug-related changes in behavior. For example, when administered acutely, the psychostimulant cocaine activates neurons in the VTA (and other regions of the mesocorticolimbic reward pathway) and results in an increase in locomotor behavior. However, our current knowledge of how acute drug-induced changes in the firing rate of local field potentials in reward related circuitry correlate with drug-induced behaviors in real-time are limited. The use of our custom-designed wireless recording module presents a unique opportunity to assess changes in neuronal activity within the VTA of freely moving rats during

cocaine-induced locomotor activation. The overall goal of this study was to test the hypothesis that changes in field potential activity in the VTA would increase with increases in locomotor behaviors after the administration of a single cocaine injection. Adult female rats received a unilateral implant of an electrode in the VTA (5.8 posterior to bregma, 2.0mm lateral to the right, and 8.3 mm from dura at an angle of 10 degrees). Field potentials and locomotor behaviors were simultaneously recorded in freely-moving rats for a 30 minute baseline period; again for 30 minutes following an injection of NaCl (0.9% NaCl at 0.1 ml/kg, i.p.), and a third time for 60 minutes following an injection of cocaine hydrochloride (10mg/kg, i.p.). Field potentials were analyzed by power spectrum in Spike 2 (CED). Different frequency bands (Delta,>4 Hz; Theta, 4-8 Hz; Alpha,8-13 Hz; Beta,>13-30 Hz; and Gamma, 30-100+ Hz) were processed using an ANOVA, followed by posthoc LSD tests. Results showed significant increases in locomotor behaviors after cocaine administration when compared to baseline and saline time points, ($p<.05$). More specifically, we observed significant increases in field potential activity ($p<.05$) at all frequency bands at 30 min and 60 min following cocaine administration. Further analyses revealed substantial increases in delta and theta waves within these field potentials. Our study has provided data to support the use of our custom-designed wireless recording module to further explore the neural activity during drug-induced behavioral activation.

Title: Effects of a positive allosteric modulator of the metabotropic glutamate receptor 5 within the Nucleus Accumbens shell during environmental elicited cocaine conditioning

Authors: *K. TORRES, A. MARTÍNEZ-RIVERA, L. GONZÁLEZ, C. S. MALDONADO-VLAAR;
Biol., Univ. De Puerto Rico, Rio Piedras, San Juan, PR

Abstract: Recent data from our laboratory suggest that the associative learning required for cocaine conditioning is disrupted by mGluR5 antagonist treatment within the NAc. Specifically, we demonstrate that mGluR5 blockade decreased environmental-elicited cocaine conditioning response. This significant reduction was not found in the control or the cocaine-unpaired subjects. Our results imply that mGluR5 could be modulating the memory processes regulated within the NAc essential for the association of environmental cues with cocaine effects. In contrast, previous results report that mGluR5 positive allosteric modulators (PAMs) enhance synaptic plasticity, improve spatial learning and its a beneficial effects in the treatment of cognitive impairment associated with schizophrenia. Moreover, limited numbers of studies have examined the effects of mGluR5 PAMs on cocaine addiction. However, no study to date has investigated the therapeutic potential of other mGluR5 PAM novel compounds on specific aspects of cocaine addiction such as conditioned locomotor response. Therefore, this research seeks to unveil the role that a selective PAM of mGluR5 within NAc shell has on cocaine conditioning. Our hypothesis is that the mGluR5 selective agonist CHPG (RS)-2-chloro-3-hydroxyphenylglycine will promote and enhance the expression of the cocaine conditioned response. Rats were implanted with cannulas within NAc shell, and separate groups were exposed to a multimodal environment within activity chambers that signaled cocaine (paired) or saline (controls, unpaired). Prior to placing the animals in the chambers, rats received systemic injections of saline or cocaine for 10 consecutive sessions. On the day of the conditioned response expression, different groups of rats were microinjected with vehicle or the agonist CHPG into the NAc shell and then they were placed in the activity chambers. Interestingly, results show no change in the expression of the conditioned response in cocaine paired experimentally treated animals. Future studies are needed to further characterize these effects.

Title: Targeting serotonin uptake to ameliorate social behavior deficiencies in pre-clinical models

Authors: *G. G. GOULD;
Physiol., UT Hlth. Sci. Ctr, SA, San Antonio, TX

Abstract: Impaired social behavior is a symptom that occurs in several psychiatric disorders including autism, schizophrenia and depression. Sociability impairments manifest in several forms, including indifference to social engagement, anxiety and/or empathy deficits. These dimensions, especially indifference to engagement, have proven difficult to treat with available pharmaceuticals. Based on clinical findings and experiments in rodents, serotonin (5-HT) neurotransmission is often disrupted in the socially-impaired brain, and the frontal cortex may be the main brain region involved. Two drugs are commonly used to treat autism; risperidone curbs aggression but blunts other forms of social interaction, and fluoxetine improves social behavior somewhat but is uneffective in individuals with reduced 5-HT transporter (SERT) function (due to common or rare gene polymorphisms). We have utilized two mouse models of impaired social behavior, inbred BTBR mice and SERT knock-out mice on a C57BL/6 background, to examine the effects of blocking SERT and novel drug targets on social behavior. In three-chambered sociability tests, social behavior of adult male BTBR mice worsened with 24h dietary tryptophan depletion, but improved significantly with 24h 5% dietary tryptophan supplementation ($p < 0.05$). BTBR sociability also improved with acute fluoxetine ($p < 0.05$), but not with citalopram treatment at doses ranging from (0.5 - 50 mg/kg). These findings indicate that 5-HT neurotransmission may be relatively low in BTBR mice. Our goal is to characterize the effects of blocking ancillary transporters of serotonin, with lower affinity but greater capacity than the SERT to remove 5-HT from extracellular fluid. These auxillary transporters, collectively known as 'uptake 2' include dopamine and norepinephrine transporters, as well as organic cation transporters and plasma membrane monoamine transporters found throughout the brain. The pseudoisocyanine decinium-22 (D-22) blocked 5-HT uptake in vitro (Km = 92 +/- 12 nM) but had negligible affinity for the SERT (Ki > 3000 nM) in hippocampal synaptosomes. In SERT -/- and BTBR mice, social behavior improved with acute D-22 treatment at doses of 0.01 - 0.1 mg/kg. This indicates that uptake 2 blockade may be an effective treatment for inpaired social behavior, and warrants further study. Our findings also support the idea that insufficient 5-HT neurotransmission may underlie impaired social behavior in autism and other psychiatric disorders.

Title: Serotonin regulates hippocampal synaptic plasticity and object memory in mice

Authors: *S. P. FERNANDEZ[1], A. GRUART[2], J. DELGADO[2], P. GASPAR[1];
[1]INSTITUT DU FER A MOULIN Inserm-U839, PARIS, France; [2]Neurosci. Div., Pablo Olavide Univ., Seville, Spain

Abstract: Low levels of serotonin (5-HT) have been associated with the learning and memory deficits seen in Alzheimer's disease, autism and major depression. Studies performed in healthy volunteers have shown that 5-HT depletion disrupts consolidation of new information, specifically in tasks involving delayed recall and/or recognition of visually-presented words, spoken words, pictures or abstract figures. Despite this evidence, the mechanism by which 5-HT regulates learning and memory function is not clear.
We used a genetic model of 5-HT depletion, Pet1 knock-out mice (Pet1 KO), to understand the role that 5-HT serves in modulating learning and memory function. In Pet1 KO mice, the levels of 5-HT are highly decreased, specifically associative cortical areas and the hippocampal formation are completely depleted of 5-HT axons. Our results showed that Pet1 KO mice are capable of acquiring associative fear conditioning, reward reinforced associative learning and motor learning; however, they do not recall familiarization with objects. The novel object recognition test was used to measure hippocampal-dependent declarative memory. The animals are trained to familiarize with two identical objects, and then subjected to a test session where one object is replaced by a novel one. This observation strongly linked object recognition deficit with 5-HT depletion; however does not specify the underlying mechanism. Previously it was shown that the consolidation of object memory involves the enhancement of synaptic strength across the CA3-CA1 hippocampal connexion; a phenomenon called as long-term potentiation (LTP). To test the hypothesis that LTP deficit is responsible for the memory impairment observed in Pet1KO mice, we performed in vivo recordings of field potentials in the CA1 region of the hippocampus of mice while performing the object memory task. We found that in Pet1 KO, experience-dependent LTP is exaggerated compared to wild-type mice, possibly explaining the aberration seen in forming correct maps of the object presented. These results established for the first time a direct link between central 5-HT depletion, memory impairment and synaptic plasticity deficits.

Title: Sub-chronic administration of MDMA leads to long term changes in murine social behavior

Authors: *D. W. CURRY[1,3], K. S. MURNANE[3], M. T. LOGUN[2], L. L. HOWELL[3,4]; [1]Neurosci. Grad. Program, [2]Emory Univ., Atlanta, GA; [3]Neuropharm. and Neurologic Dis., Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [4]Psychiatry and Behavioral Sci., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: S,R(+/-)-3,4-methylenedioxymethamphetamine (MDMA) is a ring substituted amphetamine derivative and popular recreational drug (ecstasy). It has robust prosocial effects that include increased gregariousness and empathy. Recently there has been a resurgence of interest in the drug's therapeutic potential, and several clinical trials have been undertaken to ascertain its efficacy for treating a variety of conditions including post-traumatic stress disorder and end of life anxiety. However the long term outcomes following MDMA use are decidedly mixed. While some users have reported improved social functioning and generally positive effects, others report increased depression, anxiety, and aggressive behavior. The neural changes that underpin these behavioral outcomes are not well understood. In this study, male Swiss Webster mice received a sub-chronic regimen of either racemic MDMA (7.8 mg/kg) or saline. Treatments were given via intraperitoneal injection every 48 hours for a total of 4 drug administrations. 30 minutes after each injection, mice were tested with a novel conspecific in a social interaction test. We found that mice sensitized to the prosocial effects of the drug, steadily increasing their social behavior following each subsequent drug administration. After an abstinence period of 48 hours, subjects were tested without drug, to assess any long term changes to baseline social behavior. Mirroring the human data, there was considerable variability in the long term effects of MDMA on murine behavior. There were increases in both social interaction and aggression, indicating within species variability to the drug's long term effects. Following testing, subjects were euthanized and their brains were analyzed for changes in monoamine content and serotonin receptor densities. These results were correlated with the various behavioral outcomes. The acute prosocial effects of MDMA appear to be conserved across species and our results indicate that even the long term effects on behavior can be investigated

using a mouse model. These findings will serve as the basis for future experiments that can determine the mechanisms underlying these behavioral changes. Because MDMA is both a widely used drug of abuse and a potential therapeutic, there is great impetus to better understand it's acute and long term behavioral and neurological effects. Furthermore, an understanding of these effects will provide significant insight into the neurobiological mechanisms that regulate and motivate social interaction.

Title: A predisposition toward inherent impulsivity is associated with elevated 5-HT2AR expression

Authors: *L. H. FINK[1], N. C. ANASTASIO[1], R. G. FOX[1], F. G. MOELLER[2], K. A. CUNNINGHAM[1];
[1]Dept. of Pharmacol. & Toxicology, Univ. of Texas Med. Br., Galveston, TX; [2]Dept. of Psychiatry, Virginia Commonwealth Univ., Richmond, VA

Abstract: Inherently poor response inhibition, or "action without reflection," may increase susceptibility to drug abuse and dependence. Serotonin (5-HT) systems play a nuanced role in impulsive action, perhaps mediated by 5-HT receptors in the prefrontal cortex (PFC). Selective 5-HT2A receptor (5-HT2AR) antagonists (e.g., M100907) reduce impulsive action with notable potency and efficacy, suggesting that tonic 5-HT2AR signaling supports impulsive behavior. We sought to test the hypothesis that the inherent predisposition to impulsive action is associated

with elevated 5-HT2AR expression and function in the PFC. These studies employed the one-choice serial reaction time (1-CSRT) task to identify high (HI) and low (LI) impulsive outbred rats. Rats were trained to nose-poke to receive a food reinforcer on a 5-sec inter-trial interval (ITI) schedule; responses during the ITI (premature responses) resulted in further delays of reward presentation. The upper 25% and lower 25% of animals were identified as HI or LI rats, respectively. Rats were sacrificed and the medial PFC (mPFC) was harvested, and crude synaptosomal protein extracted for western blot analysis. In separate sets of animals, the ability of M100907 (0.003, 0.01, 0.03, 0.1 mg/kg, i.p.) to suppress premature responses or the ability of the 5-HT2AR agonist DOI (1 mg/kg, s.c.) to elicit the head twitch response was evaluated in HI and LI rats. HI rats displayed higher 5-HT2AR expression in crude synaptosomal fractions of the mPFC relative to LI rats ($p<0.05$, Student's t-test). Higher doses of M100907 (0.03, 0.1 mg/kg) suppressed premature responses in all rats, but lower doses (0.003, 0.01 mg/kg) suppressed premature responses selectively in HI, but not, LI rats ($p<0.05$, Dunnett's test). DOI elicited a greater head twitch response in HI relative to LI rats ($p<0.05$, Student's t-test). These data demonstrate that high impulsive action is associated with elevated expression and enhanced function of the 5-HT2AR, suggesting that differential 5-HT2AR function in the mPFC may in part drive high and low impulsive action.

Title: Fast onset of action and neurogenesis dependency of 5HT4 receptor agonist in an animal model of anxiety/depression

Authors: *I. DAVID[1], D. J. DAVID[1], Z. EL-ALI[2], F. DARCET[1], M. WU[3], S. KERDINE[2], R. HEN[3], A. M. GARDIER[1,3];
[1]EA 3544 Pharmacologie des troubles anxio-dépressifs et Neurogenèse, [2]INSERM UMR 996, Univ. Paris Sud, Chatenay-Malabry, France; [3]Neurosci. and Psychiatry, Columbia Univ., New York City, NY

Abstract: Current antidepressants, as the selective serotonin reuptake inhibitor (SSRI) fluoxetine, have proven effective for the treatment of anxiety and depression. A relatively slow onset to therapeutic response of current antidepressants, combined with one third of patients who do not respond to first treatment makes it evident that the discovery of targets providing fast-acting antidepressant activity is desirable. It has been recently suggested that activation of 5-HT4 receptors might be a new strategy for developing faster-acting antidepressants. However, the precise mechanism through how this activation induces antidepressant response remains elusive. Here, we demonstrate using a mouse model of anxiety/depression, that a chronic treatment with the 5-HT4 receptor partial agonist RS67333 (1.5 mg/kg/d for x days), similarly to chronic fluoxetine (18mg/kg/d), induces anxiolytic/antidepressant-like activity in various behavioural tests and also stimulates adult hippocampal neurogenesis, Moreover, a chronic treatment with the 5-HT4 receptor antagonist GR125487, prevents the anxiolytic/antidepressant-like activity and the neurogenic effects of fluoxetine, pointing out the relationship between 5-HT4 receptors activation and antidepressant activity. Interestingly, in this mouse model of anxiety/depression and in contrast to fluoxetine, a fast acting anxiolytic/antidepressant activity of RS67333 is also observed up to 7-days. Furthermore, using this mouse model of anxiety/depression combined with an ablation of hippocampal neurogenesis by X-irradiation, we found that both neurogenesis-dependent and -independent mechanisms are involved in the anxiolytic/antidepressant efficacy of a 5-HT4 receptor agonist. Finally, we identified β-arrestin 1 as a putative blood biomarker in mouse leukocyte predicting fast response to antidepressants.
These results point out toward a pharmacological approach in which the activation of postsynaptic 5-HT4 receptors by its agonist provides an antidepressant like response that emerges faster than traditional SSRI antidepressants. This fast onset of action is unlikely recruiting adult hippocampus.

(BSI), Wako-shi, Saitama, Japan; [5]Lab. for Behavioral and Developmental Disorders, Brain Sci. Inst. (BSI), Wako-shi, Saitama, Japan

Abstract: Monoamine oxidase A (MAO-A), the catabolic enzyme of norepinephrine and serotonin, plays a critical role in emotional and social behavior. However, the control and impact of endogenous MAO-A levels in brain remains unknown. Here we show that the RING finger-type E3 ubiquitin ligase, Rines/RNF180 regulates brain MAO-A subset, monoamine levels and emotional behavior. Rines interacted with MAO-A and promoted its ubiquitination and degradation. Rines knockout mice displayed impaired stress responses and enhanced anxiety and affiliative behavior. Norepinephrine and serotonin levels were altered in locus ceruleus, prefrontal cortex, and amygdala in either stressed or resting condition and MAO-A enzymatic activity was enhanced in the locus ceruleus in Rines knockout mice. Treatment of Rines knockout mice with MAO inhibitors showed genotype-specific effects on some of the affective abnormal behaviors. These results indicated that the emotional behavior control by Rines is partly due to the regulation of MAO-A levels. Collectively, these findings verify that Rines is a critical regulator of the monoaminergic system and emotional behavior and identify a promising candidate drug target for treating diseases associated with emotion.

Title: Fluoxetine exposure during development affects later social behavior in the prairie vole (Microtus ochrogaster)

Authors: *R. H. LARKE, K. L. BALES;
Psychology, Univ. of California, Davis, Davis, CA

Abstract: Prenatal serotonin system manipulation is known to alter social behavior, and has been linked to the development of autism spectrum disorder. In this study, the prairie vole (Microtus ochrogaster), a rodent which forms lasting pair-bonds, was used as a model to test the effects of prenatal selective serotonin reuptake inhibitor (SSRI) exposure on social behavior and attachment formation. Twenty pregnant female prairie voles were treated with 5mg/kg subcutaneous fluoxetine or saline vehicle daily from the birth of their second litter to birth of the fourth litter. This allowed for 3 treatment groups: prenatal exposure; postnatal exposure; pre- and postnatal exposure. One male and one female from each litter were tested behaviorally during periadolescence, and another male and female were tested as adults. Animals were housed with an age, sex, and treatment matched animal prior to behavioral testing. Behavioral tests were chosen to detect social deficits and changes in anxiety-like behavior, and included open field, elevated plus maze, alloparental care, juvenile affiliation, intrasexual aggression, and partner preference tests. Preliminary analyses indicate no effect of SSRI exposure on anxiety-like behavior during periadolescence, but do indicate an effect on alloparental behavior during this period. Title: Effects of a sertraline (an SSRI antidepressant) and venlafaxine (an SNRI antidepressant) on forced swim test behavior and neurogenesis levels in female rats

Authors: *J. KOTT, S. BRUMMELTE;
Psychology, Wayne State Unviersity, Detroit, MI

Abstract: Depression is twice as prevalent in women as in men and the highest risk for women to develop a depressive episode is during her reproductive years. However, less research has been done to study the effects of antidepressants in females. In males, anti-depressants often increase neurogenesis in the dentate gyrus. This study aims to investigate the effects of two different antidepressants, sertraline (Zoloft, a selective serotonin reuptake inhibitor, SSRI) and venlafaxine (Effexor, a serotonin/norepinephrine reuptake inhibitor, SNRI) on depressive-like

behavior and hippocampal neurogenesis levels in female rats. For this, all animals are first tested in the forced swim test (FST), to determine their 'baseline' depressive-like behavior before oral administration of either sertraline (10 and 20mg/kg), venlafaxine (10 and 20mg/kg) or saline begins and continues for 14 days. On the last day of administration (d14), animals are again tested in the FST and are sacrificed via perfusion the following day (d15), to investigate neurogenesis levels in the dentate gyrus. We hypothesize that the antidepressants will be effective in altering forced swim test behavior in female rats, but will have less of an impact on neurogenesis levels compared to previous reports in males. This study will help us to further our understanding of the association between depressive-like behavior, antidepressants, and neurogenesis in females.

Abstract: Serotonin (5-hydroxytryptoamine, 5-HT) is known to act as a neurotransmitter in the adulthood and a neurotrophic factor in the brain development. We have previously reported that the oral administration of fluoxetine, selective serotonin reuptake inhibitor (SSRI) during postnatal weeks 1-3 normalized 5-HT turnover rate, dendritic spine and synapse densities, and spatial learning in prenatally stressed C57BL/6J mice (Ishiwata et al., 2005). Interestingly, the same treatment had no effect in no-prenatally stressed mice. These results suggest that adequate amount of 5-HT is important for the proper development of brain and behavior. However, the effect of SSRI depends on the animals tested and experimental paradigms, thus it is unclear. BALB/c mice is known to have less amount of brain 5-HT and be more anxious compared to other strains such as C57BL/6 and 129x/Sv. Therefore, we hypothesized that fluoxetine has some positive effects in BALB/c mice without stressing prenatally. In the present study, we examined the effects of SSRI on BALB/cCrSlc male mice by oral administration of fluoxetine (5 mg/kg BW/day) during postnatal weeks 1-3. We found that fluoxetine treatment increased the entries of

open arms significantly and the tendency to stay longer in open arms in elevated plus maze, suggesting the decrease of anxiety. In addition, fluoxetine treatment significantly improved the spatial learning in Morris water maze, and decreased depression-like behavior such as floating in forced swim test. In these mice, the 5-HT2A-receptor mRNA expression was increased and BDNF mRNA expression was the same in the frontal cortex. Thus, fluoxetine recovered the serotonergic system due to the insufficient 5-HT level in BALB/c mice. We are currently studying the roles of 5-HT receptors, which mediate the effects of 5-HT, using 5-HT1A-receptor agonist (8-OH-DPAT) and 5-HT2A-receptor antagonist (ketanserin).

Title: A backtranslational study of the selective 5-HT2C agonist lorcaserin in two rat obesity models

Authors: *G. A. HIGGINS[1,2], J. DESNOYER[1], A. VAN NIEKERK[1], L. B. SILENIEKS[1], W. LAU[1], S. THEVARKUNNEL[1], J. DELAY[3], H. DOBSON[1,3];

Abstract: The publication of multiple clinical reports detailing the clinical effects of the recently approved 5-HT2C agonist lorcaserin (LOR) in obese patients, provides opportunity to back-translate to preclinical obesity models. We have investigated the effect of LOR administered twice daily for 28 days in two rat obesity models, (1) the diet induced obesity (DIO) model, and (2) the Zucker rat model. In each study the model was first characterized based on body weight and composition using non-invasive Quantitative Magnetic Resonance (QMR) technology and plasma lipid profile, relative to controls, before drug treatment began. Primary efficacy endpoints were change in body weight, body fat composition (DIO study only), and plasma lipid profile. Secondary efficacy measures of food and water intake were also recorded. In the DIO study at the completion of the treatment phase, the effect of 28 day LOR treatment on cardiac function was assessed using echocardiography.
In the DIO study, 26 male Sprague-Dawley rats given ad-lib access to a high fat diet (Research Diets Inc., D12492, 60% kcal% fat) for 90 days had significantly greater body weight (703+12g

vs. 611+18g; P<0.01), % fat content (18.7+0.6% vs. 11.4+0.6%; P<0.01) and plasma lipid profile (e.g cholesterol: 3.21+0.12 vs. 2.36+0.11; P<0.01) compared to rats fed regular diet (LabDiet 5001, ~13% kcal% fat). Next, the DIO rats were divided into 3 groups allocated to receive either saline vehicle (SC b.i.d; N=10), LOR 1mg/kg (SC b.i.d; N=8), LOR 2mg/kg (SC b.i.d; N=8). Food and water intakes were measured daily and at the study completion both body composition and plasma lipid profile was remeasured. After 28 days treatment, LOR significantly affected each primary endpoint measure of body weight change (Veh: +11.3+0.5%; LOR 1: +7.8+0.1%; LOR 2: +5.9+0.6%; P<0.01), body fat percentage (Veh: +10.6+4.4%; LOR 1: 2.0+3.8%; LOR 2: -6.5+2.9%; P<0.01) and plasma cholesterol. Additional safety studies identified no evidence of liver or cardiac toxicity.
In the second study, 14 male Zucker rats received either saline vehicle or LOR (3mg/kg SC b.i.d) over 28 days. Food and water intakes were measured daily and plasma lipid profile was measured pre- and post-treatment. LOR reduced body weight gain (Veh: +0.9+1.4%; LOR 3: -3.4+2.6%; P<0.05) and multiple plasma lipid biomarkers, e.g cholesterol (Veh: 16.5+2.7, LOR 3: 10.3+1.4; P<0.05). Taken together the results of both studies show marked similarity to clinical findings with an approximate 5% change in body mass compared to control group, and modest yet reliable effects on lipid biomarkers and fat mass. LOR was also well tolerated at these doses, further consistent with clinical experience.

Title: Characterizing the next generation of psychoactive designer drugs: behavioral pharmacology of synthetic cathinones and substituted phenethylamines

Authors: *A. L. HALBERSTADT[1], S. B. POWELL[2], M. A. GEYER[2];
[1]UCSD, SAN DIEGO, CA; [2]Psychiatry, Univ. of California San Diego, San Diego, CA

Abstract: In recent years, a wide variety of synthetic psychoactive drugs have been sold by online vendors as "research chemicals" or "legal highs." Unfortunately, very little is known about the pharmacology and toxicology of these compounds. Examples of substances that are currently

being distributed include cathinone derivatives (components of "bath salts"), which release monoamines and have effects similar to amphetamine (AMPH) and 3,4-methylenedioxymethamphetamine (MDMA), and N-benzylphenethylamines such as N-(2-methoxybenzyl)-2,5-dimethoxy-4-iodophenethylamine (25I-NBOMe), which act as 5-HT2A agonists and produce hallucinogenic effects. We have characterized the effects of these compounds in rodents using the Behavioral Pattern Monitor (BPM) and head twitch response (HTR). The BPM quantifies locomotor and investigatory responses, and can distinguish between the effects of hallucinogens, AMPH-like stimulants, and MDMA-like drugs. Administration of the cathinone derivative methylone (3,4-methylenedioxymethcathinone; 2.5-10 mg/kg, IP) to Sprague-Dawley rats increased locomotor activity, reduced measures of investigatory behavior, and induced thiogmotaxis. A similar pattern of effects occurs with MDMA, but not with AMPH or hallucinogens. As with MDMA, the locomotor hyperactivity induced by methylone was attenuated by pretreatment with the serotonin reuptake inhibitor fluoxetine (10 mg/kg, IP). The HTR is a rhythmic paroxysmal rotational head movement that occurs in rodents in response to 5-HT2A activation. We assessed the HTR using a head-mounted magnet and a magnetometer coil, which can detect the behavior with high sensitivity. 25I-NBOMe produced a dose-dependent increase in HTR counts in C57BL/6J mice and was highly potent (ED50 = 0.078 mg/kg, SC). Additionally, the selective 5-HT2A antagonist M100907 completely blocked the HTR induced by 25I-NBOMe. Thus, methylone appears to produce an MDMA-like profile of behavioral changes by virtue of releasing presynaptic serotonin, whereas 25I-NBOMe induces the HTR via 5-HT2A receptor activation, consistent with its classification as a hallucinogen. These findings demonstrate that it is possible to characterize the behavioral effects of novel psychoactive substances using acute, unconditioned behavioral assays in rodents. Future studies will characterize the effects of a wider range of designer drugs using these behavioral paradigms.

Title: Pharmacological evaluation of novel positive allosteric modulators of serotonin 2C receptor

Authors: *G. ZHANG[1], C. DING[2,3], N. C. ANASTASIO[1,3], J. S. MONCRIEF[1], T. M. CARBONARO[1,3], R. G. FOX[1,3], S. J. STUTZ[1,3], T. D. SMITH[1,3], C. WILD[2,3], J. ZHOU[1,2,3], K. A. CUNNINGHAM[1,3];
[1]Ctr. for Addiction Res., [2]Chem. Biol. Program, Dept. of Pharmacol. and Toxicology, [3]Dept. of Pharmacol. and Toxicology, Univ. of Texas Med. Br., Galveston, TX

Abstract: The serotonin (5-HT) 5-HT_{2C} receptor (5-HT_{2C}R) is implicated in a diversity of physiological functions and neural disorders. Allosteric modulators of the 5-HT_{2C}R present a unique drug design strategy. We hypothesize that small molecule positive allosteric modulators (PAMs) of 5-HT_{2C}R will be a novel pharmacological means to selectively enhance 5-HT_{2C}R function *in vitro* and *in vivo* as potential pharmacotherapy with an acceptable side effect profile. We have successfully identified two synthetic routes for PNU-69176E, the only reported selective PAM for the 5-HT_{2C}R. We utilized PNU-69176E as the chemical lead to optimize the polar head domain, the lipophilic binding site, and the core scaffold to design and synthesize novel drug-like small molecules with high potency and selectivity for the 5-HT_{2C}R over the highly homologous 5-HT_{2A}R. Structure-activity relationships (SARs) were established through

radioligand binding as well as efficacy to modulate 5-HT_{2C}R-mediated downstream effectors in cell signaling assays upon exposure to orthosteric ligands (e.g., 5-HT, 5-HT_{2C}R agonist WAY163909) in Chinese Hamster Ovary (CHO) cells stably transfected with the 5-HT_{2C}R (5-HT_{2C}R-CHO cells) or 5-HT_{2A}R (5-HT_{2A}R-CHO cells). Several analogues (e.g., CYD-1-79 and CYD-6-16-2) potentiated 5-HT and WAY163909-evoked intracellular calcium (Ca_i^{++}) release in 5-HT_{2C}R-CHO, but not 5-HT_{2A}R-CHO, cells. These compounds also induced a leftward shift in the 5-HT concentration-response curve in 5-HT_{2C}R-CHO cells. CYD-1-79 and CYD-6-16-2 exhibited favorable *in vivo* bioavailability (39.1% and 27.6%, respectively) and half-life (~6 hrs and 1.5 hrs, respectively). CYD-1-79 dose-dependently modulated 5-HT_{2C}R-associated behaviors (e.g., spontaneous locomotor activity, self-grooming, impulsive action) in Sprague-Dawley rats. Taken together, our *in vitro* and *in vivo* data identified novel, selective 5-HT_{2C}R PAMs. These unique small molecules open new avenues for probing the chemical neurobiology of 5-HT_{2C}R allosteric modulation and developing novel pharmacotherapeutics for neural disorders characterized by deficient 5-HT_{2C}R function.

Title: Stop, put that cookie down: Impulsive action and binge intake of palatable food

Authors: *N. C. ANASTASIO, S. J. STUTZ, K. A. CUNNINGHAM;
Ctr. for Addiction Research, Dept. Pharmacol. and Toxicology, Univ. Texas Med. Br., Galveston, TX

Abstract: Food intake is essential for survival, but maladaptive patterns of intake, possibly encoded by a preexisting vulnerability coupled with the influence of environmental variables, can modify the reward value of food. Impulsivity, a predisposition toward rapid unplanned reactions to stimuli, is one of the multifaceted determinants underlying the etiology of dysregulated eating, its evolving pathogenesis, and treatment outcomes. Impulsivity and dysregulated eating converge mechanistically at the level of serotonin (5-HT) neurotransmission at the 5-HT2A receptor (5-HT2AR) and 5-HT2CR within an integrated brain network (e.g., prefrontal cortex, nucleus accumbens), that orchestrates a balance between stimulus-driven and goal-driven behaviors. Disturbances in this system may engender maladaptive eating behaviors [esp., binge eating on palatable high fat/sugar ("sweet-fat) foods] and the response to food stimuli seen in binge eating disorder. Yet, our understanding of the reciprocal relationships linking impulsivity to binge eating and/or relapse in the presence of food stimuli, and the shared neurobiological mechanisms, is very limited. We developed a rat model of binge eating behavior in which "binge" rats allowed unrestricted 2-hr access to sweet-fat chow (17% sucrose and 45% fat by kCal) at the start of the dark cycle consume significantly greater calories relative to control rats maintained on brown chow or continual sweet-fat chow. The highly-selective and efficacious 5-HT2CR agonist WAY163909 suppresses binge intake of sweet-fat chow ($p<0.05$) at doses lower than those required to suppress brown chow intake. To explore the relationship between impulsivity and binge-eating, we identified high (HI) and low impulsive (LI) rats in a novel model of impulsive action (1-choice serial reaction time task) in which a sweet-fat food pellet was the reinforcer. HI rats repeatedly exhibited significantly higher bingeing on sweet-fat chow compared to LI rats ($p<0.05$); a positive correlation was observed between levels of impulsivity and caloric intake during the binge ($r=0.457$, $p<0.05$). Elimination of the 5-HT2CR in the nucleus accumbens resulted in high binge eating, high impulsivity, and a shift in functional tone of the homologous 5-HT2AR. Thus, inherent impulsivity and binge eating reciprocally interact at the level of the 5-HT2R to control behavior. Through addressing a fundamental gap in our knowledge of how the neural and behavioral aspects of impulsive action are related to binge eating, we hope to develop pharmacological strategies to minimize binge eating and enhance clinical practice for disorders of overeating.

Title: Prenatal exposure to fluoxetine results in behavioral and anatomical deficits in offspring; Does tactile stimulation reduce the observed impairments?

Authors: *R. L. GIBB[1], A. NAKAHASHI[2], D. O. FROST[3], B. E. KOLB[2];
[1]Dept Neurosci, Univ. Lethbridge, Lethbridge, AB, Canada; [2]Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada; [3]Pharmacol., Univ. of Maryland, College Park, MD

Abstract: Fluoxetine is an antidepressant widely used in a variety of populations including women with perinatal depression. However, the effect of prenatal selective serotonin reuptake inhibitor exposure has not been fully understood. Previously, our lab showed that daily oral administration of fluoxetine on normal pregnant rats produces adverse behavioural effects on offspring. In the current study, we attempted to replicate the previous findings using a different drug administration method, and introduced a possible remediating factor. In order to better mimic human cases of fluoxetine administraion, instead of giving a daily single dose, we replaced the drinking water with drug solution and chronically exposed the dams to fluoxetine. Following the birth of pups, tactile stimulation (TS) was given in a cross-litter design, which is a well-established favourable experience. Female offspring exposed to prenatal fluoxetine exhibited de-feminized traits in anxiety- and exploratory-related behavioural tests. Prenatal fluoxetine impaired Morris Water Task performance in males, while the male offspring given the combination of prenatal fluoxetine and postnatal TS performed superiorly compared to all other groups. Anatomically, female fluoxetine offspring showed a reduction in cortical thickness and posterior thalamic size regardless of TS, while males showed a diminishing effect of prenatal fluoxetine in the increase in anterior thalamic size. Fluoxetine rats weighed less than control rats throughout the experiment, and TS did not remediate this effect. These preliminary results suggest that fluoxetine adversely affects offspring outcome even in the absence of depressive traits in the mothers and TS changes behaviour and brain.

Title: A non-invasive method of fluoxetine administration to rats

Authors: J. PAWLUSKI[1,3], E. VAN DONKELAAR[3], Z. ABRAMS[4], V. HOUBART[2], H. STEINBUSCH[3], M. FILLET[2], *T. D. CHARLIER[4];
[1]GIGA Neurosciences, [2]Univ. of Liege, Liege, Belgium; [3]Maastricht Univ., Maastricht, Netherlands; [4]Ohio Univ., Athens, OH

Abstract: Selective serotonin reuptake inhibitor (SSRI) medications are one of the most common treatments for mood disorders. In humans, these medications are taken orally, usually one time per day. Unfortunately, administration of antidepressant medications in rodent models is often through injection, oral gavage, or minipump implant, all relatively stressful procedures. Recent research in animal models investigating effects of environmental teratogens on development, has demonstrated that administration of a solution injected in a wafer cookie may be just as effective as injecting a solution into the animal, and thus would reduce the stress to the animal, particularly for long-term daily treatment (greater than 4 weeks). However, it remains to be determined whether this method of drug administration is effective for antidepressant medications and is comparable to other methods of antidepressant administration that are commonly used. Therefore, the aim of this project was to investigate how administration of the commonly used SSRI, fluoxetine, via a wafer cookie (Croustifondante, Delacre), compares to fluoxetine administration using an osmotic minipump (Alzet). For this experiment, adult female Sprague-Dawley rats were divided over the two administration methods; 1) Cookie and 2) Osmotic minipump, and three fluoxetine treatment doses; 0, 5 or 10mg/kg/day. Blood collection was taken at set time points in order to determine how these treatment methods affect drug levels and metabolism throughout the day. Results show that a fluoxetine dose of 5mg/kg/day results in comparable serum levels of fluoxetine and its active metabolite norfluoxetine between the two administration methods. However, minipump administration of 10mg/kg/day dose of fluoxetine resulted in significantly elevated levels of fluoxetine and norfluoxetine compared to the same dose administered once per day via a cookie. Hippocampal cell proliferation was also assessed in these females after 2 weeks of treatment and preliminary results show no marked difference in proliferation after 2 weeks of fluoxetine administration, regardless of administration method or fluoxetine dose. Together this data suggest that a once daily cookie administration of fluoxetine at a 5mg/kg/day dose is as effective as using an osmotic minipump with the same fluoxetine dose.

Title: Early life perturbations of 5HT2 receptor lead to disrupted anxiety related behavior in adulthood

Authors: *P. CHACHRA, A. SARKAR, V. A. VAIDYA;
Dept. of Biol. Sci., Tata Inst. of Fundamental Res., Mumbai, India

Abstract: The temporal window of postnatal life is critical for defining the trajectory of emotional development. Evidences indicate that during early life, environmental and pharmacological perturbations evoke lasting and robust effects on the development of mood-related behavior. Serotonin neurotransmission in early life has been reported to influence the development of emotionality. In early life, 5-HT2A/2C receptors contribute to 5HT mediated excitatory cortical responses and genetic knockout studies implicate the role of 5-HT2A and 5-HT2C receptors in the regulation of anxiety. In addition, recent reports demonstrate that models of psychiatric susceptibility based on adverse early life experience, including maternal separation and prenatal exposure to influenza exhibit potentiated 5-HT2A receptor mediated functional responses in adulthood. These evidences provided impetus for our study, which was aimed at examining the effects of chronic postnatal 5HT2 receptor stimulation, using the partial 5-HT2A/2C agonist l-(2,5-dimethoxy-4-iodophenyl)2-aminopropane (DOI), on adult anxiety behavior and the underlying molecular mechanisms.

Our findings reveal that postnatal stimulation of 5HT2A/2C receptors from postnatal day 2-21 is sufficient to evoke anxiogenic responses in adulthood in rats on the elevated plus maze (EPM) and open field tests (OFT). In the EPM task, postnatal DOI treatment (PNDOI) in animals, resulted in significant decrease in the percent path length in the open arms of the maze and a significant increase in percent path length in the closed arms in adulthood. In the OFT, PNDOI animals showed a significant decline in the percent path length traversed in the centre and the percent time spent in the centre of the arena. Experiments are underway to characterize the underlying molecular changes within limbic brain regions implicated in the regulation of mood, in PNDOI animals.

It is of interest that the enhanced anxiety states, observed following chronic postnatal DOI treatment differ from the anxiolytic effects reported earlier with acute adult DOI administration and no effects reported with chronic DOI administration in adulthood. Our results suggest that during this early time window, 5-HT2A/C receptors might be involved in the establishment of adult anxiety.

Title: Type II spiral ganglion neurons contribute to contralateral suppression of hearing

Authors: *K. E. FROUD[1], A. C. Y. WONG[1], M. KLUGMANN[1], J.-P. JULIEN[2], A. F. RYAN[3,4], G. D. HOUSLEY[1];
[1]Physiology/TNF, Univ. of New South Wales, Sydney, Australia; [2]Psychiatry and Neurosci., Laval Univ., Quebec, QC, Canada; [3]Surgery and Neurosciences, Univ. of California at San Diego, La Jolla, CA; [4]San Diego Veterans Adminsitration Med. Ctr., La Jolla, CA

Abstract: A major unanswered question in auditory neuroscience is how sensory input drives contralateral suppression (CS), the reduction in hearing sensitivity in one ear when sound is delivered to the opposite ear. The decline in hearing sensitivity arises from inhibition of auditory transduction in the cochlear outer hair cells (OHCs) mediated by the medial olivocochlear (MOC) efferent pathway. MOC neurons originate in the superior olivary complex in the brainstem. In response to sound in the contralateral ear, these neurons are activated, and via α9 / α10 nicotinic acetylcholine receptor synapses, the OHCs in the ipsilateral cochlea are hyperpolarized, increasing their thresholds. The MOC neurons must be activated via sensory input from the contralateral cochlea. Therefore either type I and / or type II spiral ganglion neurons (SGN) are involved. The type I SGN (95% of the cochlear sensory fibres) synapse with inner hair cells, while type II SGN (the remaining 5%) innervate the OHCs. Our experiments utilized a peripherin (Pph-/-) knockout mouse model to investigate the possibility that type II SGN contribute to CS. Pph is a type III intermediate filament expressed only by type II SGN, and loss of Pph expression affects the development of these neurons [1]. We therefore tested whether loss of Pph expression affected type II SGN innervation of OHC, and if so, whether this was associated with altered CS. OHC innervation was compared in Pph-/- versus WT control mice (C129/Bl6 strain) using CtBP2 / Ribeye immunofluorescence to identify the number and location of ribbon synapses.Cochlear mid-modiolar cryosections from adult (~ 4 months old) Pph-/- and WT mice were batch processed and imaged using confocal microscopy. The location of CtBP2-immunolabeled afferent synapses was recorded relative to the centre of the OHC nucleus. This analysis revealed apical displacement of synapses on the Pph-/- OHCs. Quadratic (f2-f1) Distortion Product Otoacoustic Emissions (DPOAEs) are decreased by CS [2]. We

therefore measured the effect of sound delivered to the contralateral ear, on the quadratic DPOAEs (in the ipsilateral ear) of Pph-/- and WT mice. These experiments showed that while the quadratic DPOAE magnitudes were the same in Pph-/- and WT mice, they were significantly less attenuated by contralateral sound in Pph-/- animals. This identifies a significant contribution of the type II SGN to the sensory signal driving the MOC pathway to the OHCs in the opposite cochlea. The experiments were conducted with University of New South Wales Animal Care and Ethics Committee approval.

Title: Zebrafish sensory hair-cell activity is facilitated by dopaminergic efferents via the D1 dopamine receptor

Authors: *C. G. PHILLIPS[1], J. G. TRAPANI[2], T. NICOLSON[1];
[1]Oregon Hlth. and Sci. Univ., Portland, OR; [2]Amherst Col., Amherst, MA

Abstract: Dopamine (DA) is an important neuromodulator throughout the nervous system. The effects of DA have been well-characterized in many regions including the retina where it is released in a tonic, paracrine fashion and regulates multiple aspects of vision. Dopaminergic neurons innervate hearing and balance organs, yet the influence of DA on auditory and vestibular sensory cells is not fully understood. Some hypothesize DA action on the postsynaptic primary afferent terminal, while others hypothesize direct action on hair cells. Here we show the influence of DA on the primary sensory hair-cells of the zebrafish lateral line organ using in vivo imaging, whole-mount immunocytochemistry and electrophysiological recordings. The lateral line is composed of neuromasts: small islands of hair cells that project cilia out from the fish to sense water movement, analogous to hair cells of the mammalian inner ear. Using an antibody against the zebrafish D1 dopamine receptor (D1R) we demonstrate that D1R is expressed by hair cells. D1Rs colocalize with vesicular glutamate transporter 3 (vGlut3, expressed on synaptic

vesicles) and ribeye, the main component of the synaptic ribbon. Using extracellular microphonics recordings, we show that DA facilitates the activity of hair cells via the D1R-pathway. We show the innervation pattern of dopaminergic efferents using transgenic zebrafish that express EGFP under the control of the DA transporter promoter (Tg[dat:EGFP]). By crossing Tg[dat:EGFP] fish with other transgenics that express fluorophores specifically in hair cells (Tg[myo6b:TdTomato]) or afferent neurons (Tg[neuroD:TdTomato]) we conclude that dopaminergic neurons are unlikely to directly synapse onto either cell-type. Additionally, using an antibody against the acetylcholine transporter (ChAT) and a marker for presynaptic terminals (synaptophysin) we show that cholinergic efferents and dopaminergic efferents do not colocalize. Overall our data suggest that lateral line efferents release DA in a tonic and paracrine fashion, and that DA binds to D1Rs on hair cells which leads to increased hair-cell activity.

Title: Presynaptic release properties show target-specific regulation at auditory nerve terminals in avian cochlear nuclei

Authors: J. AHN, *K. M. MACLEOD;
Univ. Maryland, College Park, MD

Abstract: Short-term synaptic plasticity acts as a time- and firing rate-dependent filter that mediates the transmission of information across synapses. In the auditory brain stem, short-term depression and facilitation are expressed in a target-dependent manner at the synaptic connections between auditory nerve fibers and the neurons in the two cochlear nuclei, nucleus magnocellularis (NM) and nucleus angularis (NA). This differential plasticity contributes to the divergence of acoustic timing and intensity information into parallel pathways. In NA, the beginning of the intensity pathway, the plasticity consists of a mixture of facilitation and depression, while the synaptic plasticity of inputs to NM in the timing pathway is dominated by short-term depression. We investigated how presynaptic mechanisms of transmitter release might differ in the two pathways. We characterized the pharmacological sensitivity of calcium channels underlying release and estimated the relative release probability using whole-cell voltage clamp

recordings in chick auditory brain stem slices.
Excitatory postsynaptic currents (EPSCs) evoked by extracellular stimulation of auditory nerve fibers and recorded in NA neurons were blocked >90% with bath application of ω-conotoxin, implicating N-type channels, while ω-agatoxin caused partial blockade. These results agree with published results from NM (Sivaramakrishnan & Laurent, 1999) suggesting identical calcium channel types underlie synaptic transmission in both nuclei. Next, we investigated the regulation of release probability in the two nuclei. We measured the time course of the blockade of the NMDA-receptor mediated EPSC with MK801, an activity-dependent open pore blocker, as an proxy for relative release probability. In NA, application of 20-40 μM MK801 blocked over 90% of the NMDAR-EPSC with a wide range of time courses in different neurons (8.6 ± 3.2 trials, n=24). The rate MK801 blockade was slower and more varied in NA versus NM neurons, suggesting release probability is higher on average in NM versus NA. The time course of MK801 blockade and the paired pulse ratio (PPR, 50 Hz) measured in the same NA neurons showed a strong correlation, indicating each is an independent measure related to initial release probability (n=16, r^2 = 0.56).Finally, an analysis of PPR elicited from different sets of fibers onto single NA neurons showed a high correlation across inputs. These results suggest that release probability is regulated in a target-specific manner at auditory nerve terminals: differing across target nuclei but also coordinated across different inputs onto individual target neurons.

Title: Functional topography of intrinsic and commissural pathways in the auditory midbrain

Authors: *C. C. LEE[1], Y. YANAGAWA[2], K. IMAIZUMI[1];
[1]Comparative Biomed. Sci., LSU Sch. of Vet. Med., Baton Rouge, LA; [2]Genet. and Behavioral Neurosci., Gunma Univ. Grad. Sch. of Med., Showa-machi, Japan

Abstract: The inferior colliculus (IC) is a crucial hub for auditory information processing and integrates inputs from brainstem, midbrain and cortical sources, among others. Yet, although previous anatomical and physiological studies have identified the broad origins and synaptic properties of many of these inputs, the functional topography of these inputs to the IC remains ill defined. There are proportionally high convergent inputs from intrinsic and contralateral IC sources to each of the separate IC subdivisions, the tonotopically organized central nucleus (ICc) and the non-tonotopic shell nuclei: dorsal cortex, external nucleus, and lateral nucleus. Since the IC has unique and distinct roles in auditory processing and behavior, we sought to examine the functional organization of its intrinsic and contralateral inputs. We developed an in vitro slice preparation that maintains intrinsic and commissural connectivity between both colliculi in the mouse. We then assessed the anatomical organization of projections in the slice using anterograde tracing with DiI, and further examined the functional topography of projections using flavoprotein autofluorescence imaging and whole-cell patch clamp recorded responses to laser-scanning photostimulation via uncaging of glutamate. In addition, in order to target inhibitory interneurons for recordings, we utilized a transgenic mouse line with VGAT positive interneurons expressing the Venus fluorescent protein (developed by Atsushi Miyawaki at RIKEN, Wako, Japan). We found that the intrinsic and contralateral projections form intact connections in our slice preparation and that the distribution of inhibitory neurons varies on a nuclear basis. In addition, we observed that the ICc is weakly activated by intrinsic and contralateral electrical stimulation, compared with the surrounding subdivisions. Some IC neurons receive functionally anisotropic intrinsic inputs and topographically segregated excitatory and inhibitory inputs from the contralateral IC, while others displayed opposing patterns. These distinct functional circuits may account for the varied physiological properties observed in vivo and support the diverse IC roles in audition.

Title: Immediate and residual suppression of neural firing in the inferior colliculus induced by focal electrical stimulation of auditory cortex

Authors: *C. D. MARKOVITZ[1], P. S. HOGAN[1], K. A. WESEN[1], H. H. LIM[1,2,3];
[1]Biomed. Engin., [2]Otolaryngology, [3]Inst. of Translational Neurosci., Univ. of Minnesota, Minneapolis, MN

Abstract: Cortical stimulation has been implicated as a treatment option for several neurological disorders such as stroke, Parkinson's disease, epilepsy, and tinnitus. However, the mechanism of action for cortical stimulation is currently unclear, and little is known about how stimulation can affect neural firing in subcortical structures that are influenced by the cortex. We sought to systematically determine the neurophysiological effect of focal electrical stimulation of the auditory cortex (AC) on the ascending auditory pathway. Particularly, we assessed whether stimulation of the AC could alter acoustic-driven neural firing within the central nucleus of the inferior colliculus (CNIC), the main auditory processing center in the midbrain and a major convergence point for ascending and descending auditory pathways.
We positioned penetrating multi-site electrode arrays into AC and the CNIC in 16 ketamine-anesthetized guinea pigs. After characterizing the acoustic-driven responses on each site to confirm its location (i.e., frequency region and sub-nuclei of AC or CNIC), we electrically stimulated the deeper output layers of AC and recorded the corresponding changes in acoustic-driven responses throughout the CNIC. Additionally, acoustic-driven responses were recorded after electrical stimulation had ceased to determine if residual changes could be induced.
Stimulation of AC output layers induced widespread suppression of acoustic-driven activity throughout the CNIC. The amount of suppression varied drastically depending on the cortical region being stimulated. For example, stimulation of the medial portion of primary auditory cortex induced suppression of nearly half of all the sites in the CNIC, while stimulation of the ventrorostral belt elicited minimal suppression. The suppression was widespread throughout the CNIC without any apparent topographic organization across the tonotopic axis nor along the isofrequency laminae. Furthermore, suppression of neural firing largely continued even after the electrical stimulation had ended. On the other hand, minimal excitation could be elicited anywhere in the CNIC. These results indicate that cortical stimulation can have a profound and lasting suppressive effect on subcortical processing.

Title: *In vivo* optical recording of auditory responses in mouse's inferior colliculus using a micro-endoscope

Authors: *H. YASHIRO[1], I. NAKAHARA[4,5], K. I. KOBAYASI[2,3], K. FUNABIKI[4,5], H. RIQUIMAROUX[1,2,3];
[1]Grad. Sch. of Life and Med. Sci., [2]Biomed. Information, Fac. of Life and Med. Sci., [3]Neurosensing and Bionavigation Res. Ctr., Doshisha Univ., Kyoto, Japan; [4]Grad. Sch. of Biostudies, Kyoto Univ., Kyoto, Japan; [5]Osaka Biosci. Inst., Osaka, Japan

Abstract: The inferior colliculus (IC) is the largest auditory afferent station located in the midbrain. The IC also receives efferent projections from higher brain area. It has been reported that the IC conducts complicated information processing. To understand the neuronal mechanisms underlying its processing, simultaneous recording of multiple neurons is, thus, important. We, therefore, started *in vivo* imaging of mouse's IC using a micro-endoscope. Our endoscope probe consists of thousands of optical fibers (3,000-6,000, Fujikura). The tip of the fiber bundle was beveled as pencil-like shape for brain insertion with minimum invasion. We coated the tip surrounds with Au, and further insulated with enamel paint to use our endoscope as a stimulating and/or recording electrode. The other edge end was polished to have a flat surface and scanned by the galvano mirror based laser scanner. We used resonance galvo mirror (CRS 4 kHz, GSI lumonics) to have fast frame rate (18-100 fps). The field of view was 215 to 300 μm in diameter. The distance between fibers, that determines spatial resolution of the endoscopic image was around 3 μm, enough for discriminating each cell body of the neurons. First, we recorded auditory responses of mouse's IC using a glass capillary containing calcium-sensitive fluorescent indicator (Oregon Green BAPTA A-1, Invitrogen, 800 μM/L). A craniotomy was performed at the position of 1.0 mm dorsal and 1.0 mm lateral to the lambda on a skull. We recorded local field potentials (LFPs) and occasionally single unit activities of the IC neurons against auditory stimuli. Sound stimulus was white noise burst with 50ms duration. The sound pressure level varied from 15 to 95 dB SPL (re: 20 μPa) in steps of 10 dB. Sound stimuli were randomly delivered from a ribbon tweeter (PR-R7III, Pioneer) placed 25 cm in front of the mouse. After characterizing LFP of each location in the IC, 1 μL Oregon green was injected by pressure. These procedures were repeated at the depth of 250, 650 and 1,050 μm from the brain surface 30 min. after dye loading. We inserted our endoscope into the same hole where the glass microelectrode was inserted. Applying the sound stimuli, the LFPs and the images of the IC were

recorded through the endoscope tip at the place where Oregon green was injected. The parameters of the sound stimuli were the same as LFP recordings. We could observe cell bodies labeled with Oregon green and sometimes could observe optical responses following LFP. Cell by cell analysis was sometimes possible. Above preliminary results suggest that our methods can record auditory responses of multiple neurons with cellular resolutions and will be useful in uncovering functional networks in the IC.

Title: Membrane potential dynamics and spiking correlations in the auditory cortex during spontaneous and tone-evoked activity *In vivo*

Authors: *M. GRAUPNER, A. D. REYES;
Ctr. For Neural Science, NYU, New York, NY

Abstract: Traditionally, auditory cortex is postulated to be organized tonopically such that the characteristic frequencies of individual neurons change continuously along the rostro-caudal axis (Stiebler et al. 1997; Hackett et al. 2011; Guo et al. 2012). However, recent studies with single neuron resolution suggest that the representation of frequency along the tonotopic axis may not be continuous, depending on the cortical layer: the frequency tuning of layer 2/3 neurons tend to be heterogeneous or "salt-and-pepper" (Bandyopadhyay et al. 2010; Rothshild et al. 2010) while those of L3/4 neurons seemed to be continuous (Windowski and Kanold 2013). Furthermore, different acoustic stimuli activate discrete and spatially segregated cell assemblies, further challenging the concept of a spatially continuous mapping (Batherllier et al. 2012). These findings suggest that the functional organization and the underlying network architecture are more complex than previously thought.
Here, we examine the functional connections between neurons and common synaptic drive from shared inputs. We perform simultaneous whole-cell and cell-attached recordings from pairs of

cells in the auditory cortex of ketamine/xylazine-anethetized mice in vivo (P30-45). We record the spiking activity in one cell and the subthreshold membrane potential in the other during spontaneous and tone-evoked activity. Using tone-triggered and spike-triggered average analysis, we examine the existence of a synaptic connection between the two recorded neurons and the amount of common synaptic inputs.
Preliminary results suggest that during spontaneous activity epochs, spatially distant neurons (>500 μm) tend to receive common spontaneous input even though their best frequencies differ substantially. Furthermore, during tone evoked activity, the magnitude of the common input (presumably from thalamus) decrease with increasing difference in best frequency. Together, these results suggest a tightly connected network which maintains a functional segregation for tone representation, possibly emanating from targeted thalamic drive. Combining the analysis of spiking activity and subthreshold activity on a single neuron basis advances our understanding of the interplay between the functional map and the actual connectivity in the auditory cortex and thereby helps to uncover the cortical organization of acoustic representation.

Title: Bijective maps between acoustic and cortical Spaces: Representation of tone frequency and intensity in auditory cortex

Authors: *A. D. REYES;
CNS, New York Univ., NEW YORK, NY

Abstract: The characteristic frequencies (CF) of neurons vary systematically along the rostro-caudal axis of auditory cortex. This tonotopic organization potentially provides a place code whereby the relative location of the activated neuron contains information about the frequency and intensity of a stimulus tone. However, the main predictions of tonotopy-based coding seem to be inconsistent with recent experiments and network simulations: the gradient in the CFs is imprecise and even a moderate intensity tone is likely to activate many neurons spaced over a large area. Thus, extracting information about tone stimuli using a purely place code is difficult. Here, we provide an alternative representation of tone frequency and intensity in auditory cortex.

Adhering strictly to the mathematical definition of maps and the limitations imposed by the anatomy and by the basic properties of neurons, we derive bijective (one-to-one, onto and hence invertible) maps from the acoustic space to cortical space. To obtain mathematically and biologically well-defined mappings, frequency must be represented by groups of neurons within a continuous area of cortex. The spatial extent of activated neurons increase with tone intensity. To maintain high resolution, there must be substantial spatial overlaps between adjacent groups representing different frequencies; individual neurons can be members of several groups. Indeed, classical cortical columns, which segregate neurons based on receptive field, will increase discontinuities and decrease the resolution. This model, which was derived using mathematical principles and a minimum of well-established neuronal properties, is general and may apply to other cortical areas that use topography to represent sensory input.

Title: Functional properties of VIP inhibitory neurons in the mouse primary auditory cortex

Authors: *L. MESIK[1], H. W. TAO[2], L. ZHANG[2];
[1]Unifersity of Southern California, Los Angeles, CA; [2]USC, Los Angeles, CA

Abstract: Detailed mapping of local neuronal circuitry will require a good understanding of its many underlying components. The apparent diversity of inhibitory neurons poses a particular challenge as these neurons are small, relatively few, and hard to target in vivo. In recent years, most attention has been paid to the two largest subgroups of these interneurons, those expressing parvalbumin(PV) and somatostatin(SOM). Other subclasses, such as the interneurons expressing the neuropeptide VIP (vasoactive intestinal peptide) remain less well studied. We applied two-photon imaging guided patch-clamp recording to characterize the functional responses of VIP interneurons in layer 2/3 of the mouse primary auditory cortex. Compared to PV neurons, VIP neurons respond relatively slowly, often integrating input over 10 or more milliseconds before spiking. However, their response is also more reliable than that of the similarly sluggish SOM

neurons. Overall, our results imply that the VIP neurons fulfill a functional role distinct from that of the other major inhibitory subgroups.

Title: Multielectrode array recording of propagation of activity evoked by electrical micro-stimulation in horizontal and coronal slices of the mouse auditory cortex

Authors: *H. KITAMURA, J. NISHIKAWA, T. TATENO;
Grad. Sch. of Information Sci. and Technol., Hokkaido Univ., Sapporo, Japan

Abstract: In the auditory cortex of mice, little is known about how propagating activity is generated by sound signals and where it propagates. Recent studies indicated that recording from in vitro brain slices with micro electrical stimulation gave some insight into in vivo propagating activity of the auditory cortex.
In this study, using multielectrode array (MEA) substrates, we recorded electrically evoked neural activity from horizontal and coronal slices of the mouse auditory cortex. After in vivo optical imaging by use of voltage-sensitive dyes in response to sounds, some fields in the auditory cortex were first identified, slices were then prepared and multielectrode recording was afterward carried out. We performed electrical stimulation at both shallow (II/III) and deep (V/VI) layers of the auditory cortex on electrodes on the MEA substrate, and recorded local field potentials (LFP), whose main components were likely to be EPSPs, IPSPs, and/or population spikes.
In the experiments, stimulation of a short current pulse (0.03 - 0.1 mA) evoked activity of LFP (0.05 - 1.0 mV) in proportion to the amplitude of the current. Firstly, after stimulating at deep layers, the activity evoked from the deep layers propagated to shallow layers and then propagated through the surrounding shallow layers. Moreover, results of evoked propagations through the shallow layers in horizontal slices on the MEA had some similarities in propagating directions as those obtained from optical imaging by voltage-sensitive dyes. Secondly, to separate the LFP signals into several components mediated by specific receptors, we applied several blockers to extracellular solutions. Thus, we found that a main component of the LFP

signals was likely to be AMPA receptor mediated currents, although NMDA receptor and other ion channels also had some contributions.
We are now developing artificial devises with a MEA and an acoustic sensor, which can be directly implanted in the auditory cortex. These results have a possibility to understand where appropriate sites are to evoke auditory neural activity and which temporal stimulation signals are most effective to evoke the activity in the auditory cortex.

Title: Intracortical multiplication of thalamocortical signals in mouse auditory cortex

Authors: *L.-Y. LI[1], Y.-T. LI[1], L. A. IBRAHIM[1], H. W. TAO[1], L. I. ZHANG[2];
[1]USC, Los Angeles, CA; [2]USC, LOS ANGELES, CA

Abstract: Cortical processing of sensory information initiates from the transformation of thalamically-relayed signals. In thalamorecipient layers of sensory cortices, the thalamic signals have been thought to be augmented and expanded by intracortical excitatory inputs. To determine the precise functional role of intracortical excitation in thalamocortical transformation, we silenced intracortical excitatory circuits in a reversible manner by optogenetically activating cortical parvalbumin positive inhibitory neurons. In vivo whole-cell voltage-clamp recordings were carried out in layer 4 of mouse primary auditory cortex to compare the isolated thalamocortical input with the total excitatory input evoked by auditory stimuli. We found that intracortical excitatory circuits preserved the frequency and direction tuning of thalamocortical input by linearly amplifying the thalamocortical signals while prolonging the response duration. There was no change in the spectral range of excitatory responses after cortical silencing, suggesting a lack of recruitment of distant inputs through horizontal circuits. The input-specific preamplification and the response prolongation by intracortical excitation will largely enhance the salience of afferent signals, and may ensure a robust, faithful and more persistent representation of thalamocortically relayed information.

Title: Spatiotemporal activity patterns in auditory cortex deviate from those predicted by the canonical microcircuit model

Authors: *B. M. KRAUSE[1,2], A. RAZ[2,4,5], D. J. UHLRICH[3], P. H. SMITH[3], M. I. BANKS[2,3]; [1]Neurosci. Training Program, [2]Dept. of Anesthesiol., [3]Dept. of Neurosci., Univ. of Wisconsin, Madison, WI; [4]Dept. of Anesthesiol., Rabin Med. Ctr., Petah-Tikva, Israel; [5]Dept. of Anesthesiol. and Critical Care Med., Sackler Sch. of Medicine, Tel Aviv Univ., Tel Aviv, Israel

Abstract: Introduction: Cortical columns integrate extrinsic and intrinsic afferent input to generate spatio-temporal activity patterns. This process is of fundamental importance for understanding the neural basis of perception and cognition. The canonical microcircuit model derived from studies of visual and somatosensory cortex posits that the cortical laminae are activated in a L4 to L2/3 to L5 sequence in response to core thalamocortical (TC) input. Matrix thalamocortical and descending corticocortical inputs terminating in layer 1 (L1) and infragranular layers are postulated to modulate this activation sequence. However, the applicability of this model to auditory cortex (A1) is unclear, as cell types and TC afferent termination patterns differ in A1 from other cortical areas.
Methods: We investigated the laminar profile of synaptic and spiking responses to TC, L1 and paired afferent stimulation in auditory TC slices prepared from 4-10 wk old male mice (B6CBAF1/J). Approximately whole-column (800x200 m) Ca imaging (OGB-1 AM) was used to identify spiking cells as a function of laminar depth. Synaptic and spiking responses on finer time scale were measured using patch clamp recordings from cells in layers 2 - 6.
Results: Auditory TC slices were observed to dwell almost exclusively in DOWN states, with rare spontaneous UP states but reliable evoked UP states in response to afferent stimulation.

Contrary to the predictions of the canonical microcircuit model, cells throughout the column receive TC synaptic input at near equal latency, and spiking in auditory cortical columns is dominated by cells in L5. Monosynaptic spiking is sparse (<5% at moderate stimulus intensity) and disynaptic spiking was not observed except in the context of UP state activity. The majority of cells that spike monosynaptically are interneurons, especially L5 Martinotti cells that project to L1. This ascending activation pattern is only weakly suppressed by L1 input.
Conclusions: These data suggest that the integrative properties of the cortical column may be altered substantially in DOWN states, and that modifications of the canonical microcircuit model may be required for columns in auditory cortex.

Title: A circuit basis for motor cortical modulation of auditory cortical activity

Authors: *A. NELSON, D. SCHNEIDER, J. TAKATO, F. WANG, R. MOONEY;
Duke Univ., Durham, NC

Abstract: Animals must distinguish sensations arising from their own movements from sensations arising from objects in their environment. This can be accomplished in part by transmitting a copy of the motor plan to relevant sensory systems. In the context of hearing, motor-related signals are thought to impinge on many levels of the auditory system, including in the cortex. Dysfunction of intracortical motor-auditory circuitry is believed to underlie symptoms of debilitating neuropsychiatric disorders, including the auditory hallucinations characteristic of schizophrenia and other forms of psychoses. Despite the importance of intracortical motor-auditory interactions in normal and diseased states, little is known about the synaptic and circuit mechanisms underlying this interaction. We performed a series of experiments in the mouse to detail the architecture and function of a specific population of motor cortical neurons that provide input to the auditory cortex and thus are well poised to transmit motor-related signals to the auditory cortex. Using dual retrograde tracing and intersectional viral anterograde tracing, we found that a subset of neurons in the medial agranular motor cortex that project to auditory

cortex and also project to subcortical regions, including periaqueductal gray (PAG), pons, and brainstem, highlighting a circuit capable of relaying copies of descending motor commands to the auditory cortex. Using in vitro whole cell physiology, optogenetics, and pharmacology, we find that motor cortical axons make excitatory synapses in the auditory cortex but exert a net inhibitory effect on both superficial and deep layer auditory cortical neurons through feedforward inhibition mediated in part by PV+ auditory cortical interneurons. Finally, using in vivo intracellular physiology, optogenetics, and sound playback, we show that directly activating motor cortical axon terminals in the auditory cortex suppresses spontaneous, tone-evoked, and naturalistic stimuli-evoked synaptic activity in auditory cortical neurons, and that this effect is dependent on the relative timing of motor cortical activity and auditory stimulation.

Title: Interlaminar processing in auditory cortex: Spontaneous and evoked responses of independent sources

Authors: *E. MUNRO[1], T. KHODAI[2], S. SAKATA[2], T. TOYOIZUMI[1];
[1]RIKEN Brain Sci. Inst. - Wako, Saitama, Japan; [2]Strathclyde Inst. of Pharm. and Biomed. Sci., Univ. of Strathclyde, Glasgow, United Kingdom

Abstract: The cortical local field potential (LFP) reflects synchronous activity of populations of neurons at various frequencies ranging up to 600 Hz. LFP signals have been successfully used to predict sensory stimuli or an animal's behavioral state. Although the LFP signal is known to be a summation of multiple neural sources, most conventional studies analyze it by looking at the current source density or blindly combing several LFP signals for decoding. In this study, we

investigate interlaminar processing in auditory cortex by applying independent component analysis (ICA) to recorded LFP signals, namely, by decomposing LFP signals into independent neural sources. Rats were anesthetized with urethane anesthesia, and recordings were taken from a 16 or 32 channel silicon probe inserted vertically into the auditory cortex. To compare normal neocortical processing with processing after trauma, we applied auditory trauma which consisted of 110 dB white noise played for one hour. We recorded spontaneous activity and reactions to short tones and long tones of various frequencies and intensities before and after the trauma. We applied ICA to data recorded during spontaneous activity, short tones, and long tones separately. ICA separates temporally independent neural sources and gives a spatial profile of how the time series of each source is projected onto the recording electrodes. From these spatial profiles, we are able to estimate the size and location of each neural source. ICA identified many sources from each layer. These sources include: a far away or wide-spread source producing a global slow oscillation, a layer 4 source that robustly responds to tones, and a strong layer 5 source. Average tone responses reveals multiple neural sources with similar spatial profiles that act distinctly to different tones and intensities, suggesting the existence of multiple groups of neurons in the same layers that uniquely code auditory information.

Title: Auditory cortical local subnetworks are characterized by sharply synchronous activity

Authors: *C. A. ATENCIO, C. E. SCHREINER;
Otolaryngology, UCSF, SAN FRANCISCO, CA

Abstract: In primary auditory cortex (AI), broadly correlated firing has been commonly observed. In contrast, sharply synchronous firing has been rarely seen and its properties and

functional consequences are not well understood. Therefore, we examined AI local subnetworks using cross-correlation analysis and spectrotemporal receptive fields (STRFs). Sharply synchronous firing responses were independent of layers and were present between all distinguishable cell-types. The sharpest synchrony was seen in supragranular layers and between regular spiking units. Synchronous spikes conveyed more stimulus information than non-synchronous spikes. Neighboring neurons in all layers had similar best frequencies (BFs) and similar STRFs, with the highest similarity in supragranular and granular layers. Spectral tuning selectivity and latency were only moderately conserved in these local, high-synchrony AI subnetworks. Overall, sharp synchrony is a specific characteristic of fine-scale networks within AI, and local functional processing is well-ordered and similar, but not identical, for neighboring neurons of all cell types.

Title: Gsx1 specified neurons are required for prepulse inhibition

Authors: *H. A. BURGESS[1], G. LI[1], N. CARRIER[2], S. A. BERGERON[1];
[1]Program in Genomics of Differentiation, NIH/NICHD, BETHESDA, MD; [2]Dept. of Pharmacol., Univ. of Texas Hlth. Sci. Ctr. San Antonio, San Antonio, TX

Abstract: Prepulse inhibition (PPI) of the startle response is a widely used paradigm for studying sensorimotor gating. During PPI a weak stimulus suppresses the magnitude of the startle response to an intense stimulus. Reduced PPI has been reported in neurological conditions including schizophrenia, highlighting the need to understand the basic neuronal circuitry that mediates this behavior. Previous work has shown that PPI is present in fish and has several characteristic features of mammalian PPI. To identify neuronal components of the PPI pathway we carried out a circuit breaking screen in larval zebrafish. We first performed a Gal4 enhancer trap, including neuronal restrictive silencing elements in the vector to enrich for lines with brain specific expression. We then genetically ablated trapped neurons in brain specific lines using a UAS:Nitroreductase transgene and tested larvae for PPI. After ablation, line *y252* showed defects in startle sensitivity and PPI that were strongly dependent on the interstimulus interval. Defects

in startle regulation were reproduced by acute optogenetic inhibition of the trapped neurons with UAS:Archaerhodopsin3 demonstrating that the defect is not secondary to a disruption in neural development. The most salient expression of Gal4 in *y252* is in a bilateral, dorsally positioned, longitudinal column of glutamatergic neurons in the hindbrain. These neurons are commissural and have neurites extending close to the Mauthner cell, the command neuron for the startle response. Using a UAS:Synaptophysin-RFP reporter, we found synapses from *y252* neurons in close apposition to the lateral dendrite of the Mauthner cell. We mapped the transgene insertion to a region close to the *gsx1* gene. *gsx1* shows transient expression in hindbrain neurons which is almost identical to *y252* Gal4 expression demonstrating that *gsx1* specifies neurons labeled in this line. The reported pattern of *Gsx1* expression in mouse closely resembles that in zebrafish, leading us to test *Gsx1* knockout mice for PPI. We found a robust attenuation of PPI in homozygous mutant pups, arguing that *Gsx1* neurons play a similar role in the PPI circuit in mammals. Together, these findings provide strong evidence that neurons required for PPI are glutamatergic commissural interneurons which likely make direct connections with startle command neurons and are conserved across vertebrates.

Title: Inhibitory components of synaptic PPI in the goldfish auditory startle circuit

Authors: *P. CURTIN[1], T. PREUSS[2];
[1]Biopsychology, City Univ. of New York, Hunter Col., New York, NY; [2]Psychology, Hunter College, CUNY, New York, NY

Abstract: Prepulse inhibition (PPI) is a sensorimotor gating process that reduces the excitability of startle responses when weak, non-startling stimuli are presented 20 -500 ms prior to startling stimuli. The Mauthner-cell (M-cell), the decision-making neuron of the teleost startle circuit, presents an ideal preparation for studying prepulse inhibition because it constitutes the final common path for tonic and phasic inhibitory mechanisms that contribute to PPI. Here we applied

in vivo electrophysiology and pharmacology in goldfish (*Carassius auratus*) to determine what inhibitory neurotransmitters produce PPI at the level of the M-cell circuit. The M-cell is extensively innervated by glycinergic and GABA-ergic projections from associated inhibitory networks. Accordingly, we applied strychnine to the brain to test the effects of systemic antagonism of glycine receptors on tonic and phasic inhibition of the Mauthner cell. The magnitude and time-course of PPI were quantified by presenting two auditory stimuli (prepulse and pulse) at inter-stimulus intervals (ISIs) ranging from 20 - 500 ms, and measuring the attenuation of M-cell sound-evoked post-synaptic potentials (PSPs) produced by prepulses. As expected, blockage of glycine receptors enhanced the intrinsic excitability of the M-cell, profoundly changing the waveform of the sound-response. These effects resulted in a significant enhancement of PSP amplitude and an increased latency to the peak of the sound response. Despite these changes in tonic excitability, the time-course and magnitude of PPI remained robust at all ISIs exceeding 50 ms. Strikingly, PPI at the shortest ISI tested, 20 ms, was largely abolished by strychnine administration, suggesting that the inhibition produced at this ISI is distinct from others, likely reflecting the contribution of the well-characterized feed-forward inhibitory system in the auditory startle circuit. These results suggest that the neurotransmitter mechanisms underlying PPI at the synaptic level are not glycinergic; further, the circuits that produce PPI are likely not mediated by the action of glycine receptors. Ongoing experiments focus on characterizing GABA-ergic components of PPI with local and systemic applications of the GABA antagonists.

Title: Mouse gene expression analysis following temporary threshold shift

Authors: *J. M. CEDERHOLM[1], K. E. FROUD[1], A. F. RYAN[2,3], G. D. HOUSLEY[1]; [1]Dept. of Physiol., Univ. of New South Wales, Sydney, Australia; [2]Surgery and Neurosciences, Univ. of California at San Diego, La Jolla, CA; [3]San Diego Veterans Admin. Med. Ctr., La Jolla, CA

Abstract: Acoustic overstimulation, and the associated hearing loss, is an increasing global problem in today's society, including occupational exposure (e.g. military, industrial) and an

increasing prevalence of sustained recreational exposure with the use of personal music players. Moderate noise exposure leads to a temporary threshold shift (TTS) of hearing sensitivity, reversible within hours to days, while higher noise exposure leads to a permanent threshold shift (PTS) either immediately, or by delayed impact evident with aging. Many cochlear structures are known to be affected by noise overstimulation, and changes in gene expression after PTS-inducing noise have also been identified. However, transcriptional responses underlying TTS, and likely reflecting physiological responses to acoustic stress, have not been investigated. We used a gene array approach to determine cochlear gene regulation in response to TTS-inducing noise in C57Bl/6J mice. Mice were anaesthetised with a ketamine/xylazine/acepromazine cocktail in accordance with University of New South Wales' Animal Care and Ethics Committee approval. Evoked auditory brainstem responses (ABR) were measured to broadband clicks, or 16 kHz tonepips, before and after the noise exposure (86 dB or 95 dB, 4 - 32 kHz, 30 min), to quantify the TTS. Cochlear RNA extraction was performed 1, 2, 4, 8 or 24 hrs after noise exposure. cDNA templates were hybridised to the Affymetrix® mouse gene array 1.1ST, with gene expression analysis performed using GenePattern software. The level of TTS following 86 dB noise was ~ 12 dB, which recovered within 96 hrs. Threshold shifts of ~ 40 dB were produced with the 95 dB noise, recovering within two weeks. 63 genes were significantly regulated compared to no-noise controls ($p<0.001$; $q<0.1$; minimum 2-fold change), with the largest number of responsive genes at 4 hrs. 18 of the genes found in the 86 dB study, were also found at 95 dB. The genes identified were mainly involved in transcriptional regulation, tight junction, morphology, cell migration, inflammatory and oxidative stress responses. We have shown, for the first time, transcriptional responses to TTS-inducing noise. The TTS-regulated gene set we have identified likely reflect cellular responses to noise stress that contribute not only to loss of sensitivity, but also to physiological hearing adaptation and protection from noise-induced hearing loss.

Title: Categorical perception of communication sounds and a learned category through sound discrimination training revealed by mismatch negativity in Mongolian gerbils

Authors: *Y. TORIGOE[1], K. I. KOBAYASI[2,3], H. RIQUIMAROUX[1,2,3];
[1]Grad. Sch. of Life and Med. Sci., [2]Biomed. Information, Fac. of Life and Med. Sci.,
[3]Neurosensing and Bionavigation Res. Ctr., Doshisha Univ., Kyoto, Japan

Abstract: Mongolian gerbils communicate with each other by vocalization. This study recorded mismatch negativity (MMN) in the auditory evoked potential (AEP) for measuring the categorical perception of communication sounds and the acquirement of an auditory category. Five animals were implanted an epidural electrode for measuring AEP. We synthesized stimuli mimicking "greeting call", which was produced by both males and females in friendly contact. A typical greeting call is an upward frequency modulated sound (upFMs) where the frequency sweeps from 29 to 34 kHz with duration of ca. 34 ms. About 80% of the call were observed between 27 to 37 kHz; therefore, a stimulus within the range was defined as "within" the greeting call range, and stimulus below or above the range were defined as "outside" of it.
In experiment 1; we used eight types of stimulus. Four types were upFMs. Their frequency swept in different range: 27-31 kHz (within), 32-37 kHz (within), 22-26 kHz (outside) and 38-43 kHz (outside). Four types downward (down) FMs were temporally reversed upFMs; all downFMs were regarded as "non-communication (non-cmm)" sounds. Durations of all stimuli were 34 ms. MMNs were recorded from awake animals when they were passively listening to a series of FMs played with standard oddball paradigms. MMN to upFMs elicited by across-boundary pair (change "within" to "outside") was larger than within pairs. MMNs to downFMs responding to across-boundary pair was not different from within pairs.
In experiment 2; we trained gerbils to discriminate FMs by Go/NoGo task with electric shocks. Both upFMs 32-37 kHz (within) and downFMs 37-32 kHz (non-cmm) were used as Go stimuli, while both upFMs 22-26 kHz (outside) and downFMs 26-22 kHz (non-cmm) were used as NoGo stimuli. After the training was completed, behavioral responses toward FMs between Go and NoGo stimulus were measured. The categorical boundary learned by the training was estimated as between 24-28 kHz and 27-31 kHz FMs for both up and downFMs. MMNs were recorded before and after training. MMN to upFMs across the boundary were significantly larger than within the boundary regardless of the training. The result was accordance with exp. 1, because the obtained boundary was roughly matching the lower limit of communication sounds. While, downFM pair across the obtained boundary elicited significantly larger MMNs than the pair within the boundary only after the training. In all, our study demonstrated that (1) differences in MMNs revealed that acoustic characteristics (frequency range and types of FM) of communication sound were encoded in gerbils' auditory system and (2) the MMN differences can be obtained through behavioral learning.

Title: Decrement in cochlear microphonics to a repeated sound in Mongolian Gerbil, Meriones unguiculatus

Authors: *S. BOKU[1], K. I. KOBAYASI[2,3], H. RIQUIMAROUX[1,2,3];
[1]Grad. Sch. of Life and Med. Sci., [2]Biomed. Information, Fac. of Life and Meidical Sci.,

Abstract: Variety of repeated sounds is overflowing in natural soundscapes. The adaptation or habituation to non-significant repeated sounds is fundamentally crucial to survive for many animals. In the auditory system, the stimulus-specific adaptation (SSA), a decrease in neuronal responses to repeated sound stimuli, has been reported at different levels along the central auditory pathway. However, SSA in the auditory periphery has not yet been studied well because there has been an auditory fatigue discussion. The cochlear microphonic (CM) is a useful tool for understanding the auditory periphery. The purpose of the present research was to examine SSA in the CM. Experiments were performed on five adult Mongolian gerbils (Meriones unguiculatus), the typical auditory animal model, with body weights between 75 and 90 g. The right cochlea of each gerbil was implanted a chlorinated silver-wire electrode at the round window to record CM under anesthesia, induced by a mixture injection of ketamine and xylazine. Awake gerbils were comfortably held with harness in a sound attenuated Faraday cage. A calibrated loudspeaker was set at a distance of 10 cm from the right ear. Tone bursts with 50 ms duration and 3 ms rise/fall times of two frequencies (f1: 4 kHz and f2: 2.8 kHz) were used for sound stimuli. Sound stimuli were presented in two paradigms. In a test paradigm, a block consisting of 50 repeated identical tone bursts (f1) followed by 10 repeated identical tone bursts (f2) was presented 15 times. All tone bursts had the same amplitude (70 dB SPL) and repetition rate (3 Hz). The other paradigm for control condition consisted of both frequencies (f1 and f2) with equal probability in pseudo-random order; however, repetitive rate was 6 Hz. Therefore, control paradigm contained the same number of tone bursts in the same time period as test paradigm. The averages of all CM response amplitudes were calculated. As results, we observed a reduction in CM amplitude before 50 presentations (f1) to repetitive test sound stimuli were presented, especially within first 20 presentations. In addition, after 10 repetitions of a different frequency (f2) for disadaptation, CM amplitudes responding to test frequency (f1) recovered. Whereas, in control stimuli, CM amplitudes did not change even though total number of tone bursts (f1) was identical to that for the test paradigm. The data may indicate that the decrement in CM amplitude is not caused by auditory fatigue because CM amplitude will not recover immediately following temporary inner ear impairment. Moreover, the reduction did not depend

on the amount of tone bursts in control. Therefore, the results suggest that SSA occurs in the auditory periphery.

Title: Organized motion direction selectivity mediated by response adaptation in the owl's inferior colliculus

Authors: *Y. WANG, J. L. PENA;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: Motion-direction selectivity (DS) is a common feature of sensory systems. However, mechanisms that confer DS in auditory space are not well understood. It is unclear whether DS in the auditory system uses similar mechanisms as those proposed in the visual and somatosensory systems or whether DS to motion is represented in an orderly manner in auditory nuclei. In the current study, we investigated these questions in neurons of the owl's external nucleus of the inferior colliculus (ICx) using apparent sound motion in a high density free-field speaker array. We found that preferred direction could be predicted by asymmetries in the spatial receptive field (RF). At the population level, we found a systematic increase in RF feature asymmetry which corresponded to the measured increase in directional preference for sounds moving toward frontal space as a function of eccentricity in spatial tuning. Response adaptation could explain DS observed in the ICx because firing attenuates the response to later stimuli. The strength of the attenuation or adaptation decreased with time between stimuli. A linear model based on spatiotemporal summation using excitation and adaptation parameters estimated from the data accurately predicted the direction-dependent response during sound motion.

Title: Towards an antibody toolkit for array tomography in avian species

Authors: *K. E. PANNONI[1], A. MUKHTAR[2], D. RYBKA[2], W. DEBELLO[2];
[1]Ctr. for Neurosci., Univ. of California, Davis, CA; [2]Ctr. for Neuroscience, Univ. of California, Davis, CA

Abstract: Array tomography is a method to determine the molecular fingerprint of each synapse within fixed tissue. It relies on antibody detection of synaptic and neuronal proteins. The large majority of commercially available antibodies were raised against immunogens derived from mammalian peptide sequences. Although these protein targets are in large part evolutionarily conserved (with important exceptions, e.g. synapsin), specificity of the antibodies for avian brain tissue must be determined empirically. We performed western blotting on protein homogenates derived from rat, mouse, chicken, barn owl, zebra finch and canary brain. Antibodies that produced expected banding patterns across mammals and birds were used as probes for array tomography. Arrays were made of the barn owl inferior colliculus, a model circuit for information processing, plasticity and learning. Successive imaging of stained, stripped and re-stained arrays produced high-resolution, seven-color image volumes of ~100,000 cubic microns. Antibodies to synaptic proteins SV2c, vGlut1/2, GAD and Homer 1 each produced dense, punctate staining. Punctae are being characterized manually, with object-based classifiers and with feature-based classifiers, to determine if they conform to expectations for synaptic sub-populations. Antibodies against tubulin revealed neuropil very similar to that observed in mammalian tissue. In summary, we have taken the first steps towards vetting of an antibody toolkit that should be widely applicable to avian neuroscience model systems.

Title: Neuronal circuits underlying attention-dependent learning in the barn owl

Authors: *D. SANCULI, W. DEBELLO;
Univ. of California Davis, Davis, CA

Abstract: Both the neural substrates underlying attention and the synaptic mechanisms underlying learning are beginning to be understood, yet little is known regarding their interface. Recent studies in the barn owl (*Tyto alba)* have shown that top-down allocation of an attention-like process can influence low-level responses to both visual and auditory stimuli. The control structure involved in this sensory modulation is the arcopallial gaze fields (AGF) and its target is the optic tectum (OT). The OT is also known to be the primary source of instructive information that guides adaptation to visually displacing prisms. This learning occurs reliably in juvenile owls even under passive conditions. In contrast, it does not occur in adults unless owls are required to hunt live mice, a highly engaging task. One possibility is that an attentional gate on delivery of instructive information develops during maturation from juvenile to young adult. If true, lesions of the AGF are predicted to halt learning in adult hunters but not in passive juveniles or juvenile hunters. To test this hypothesis, electrophysiological surveys are underway in five prism-adapted juveniles, to confirm reliable shifts in auditory tuning. Chemical lesions will be made in the AGF and the same individuals will be actively challenged as young adults. In addition, a cohort of naïve juveniles and naïve adults, with and without lesions, will be examined.

Title: Functional connectivity within and across structures in the barn owl midbrain in response to auditory and visual stimulation

Authors: *D. TOTTEN, W. DEBELLO;
UC Davis, Davis, CA

Abstract: We are using multielectrode arrays to measure correlations in firing between synaptically connected neurons in the barn owl auditory localization pathway. The targets are feedforward connections from ICCls to ICX and bidirectional connections between the ICX and

dOT. To simultaneously measure paired responses, a 7-channel array (Thomas Recording) with tight concentric spacing was deployed in one structure and a single tungsten electrode in the other. Auditory and visual receptive fields were determined using, respectively, dichotic noise bursts and static, looming or moving dots presented via a DLP projector. The auditory and visual tuning of all sites within the array was similar, and electrode tract reconstruction confirmed sampling of nearby neurons. Functional connectivity was determined using cross-correlation analysis with shuffle. Preliminary results were obtained from 3 owls with sites located in ICX or dOT. Correlograms were diverse in profile, indicating heterogeneous connectivity patterns even among neighboring neurons. Tight peaks were found in a subset of pairs, suggesting neurons with common drivers and/or monosynaptic interconnections. This approach is now being applied to analysis of prism-adapted owls, to probe both the circuit mechanisms that guide learning and the functional consequences of the structural re-wiring that is known to occur. ICCls = lateral shell of the central nucleus of the inferior colliculus. ICX = external nucleus of the inferior colliculus. dOT = deep layers of the optic tectum.

Title: Effects of fear conditioning on auditory steady-state responses in inferior colliculus

Authors: *A. V. LOCKMANN, F. A. G. MOURÃO, M. F. D. MORAES;
Physiol. and Biophysics, Univ. Federal De Minas Gerais, Belo Horizonte, Brazil

Abstract: In this work, we tested the hypothesis that associative-learning potentiates and modifies the timing of steady-state processing in local circuits of inferior colliculus (IC). Local field potentials were recorded over IC of freely-behaving rats submitted to paired or unpaired auditory fear conditioning. Auditory steady-state responses (ASSR) were elicited by a 10 kHz tone, amplitude modulated at 53.7 Hz, which was used as the conditioned stimulus (CS). Both

amplitude and phase of ASSR showed learning-related changes in paired group, but with inverse temporal dynamics. When animals were re-exposed to CS early on test, phase component consistently shifted from its pre-conditioning values. This initial shift reversed with repeated expositions to CS, and this reversal coincided with an increase in amplitude. These effects were not seen on unpaired group, suggesting that conditioning related changes on ASSR components reflected a modification in the pattern of local processing of CS due to associative-learning.

Title: Stimulus specific adaptation is stronger at short latencies in the inferior colliculus

Authors: *T. RUBIN[1], E. D. YOUNG[2];
[1]Biomed. Engin., Johns Hopkins, Baltimore, MD; [2]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Stimulus specific adaptation (SSA) allows auditory neurons to respond more strongly to a stimulus when infrequently presented, relative to the response when frequently presented. Since originally described in cortex (by Ulanovsky and Nelken), SSA has been demonstrated to occur in the inferior colliculus (IC), but not at lower levels. We are investigating SSA in the IC of awake marmosets; the phenomenon can be observed in this system unmodified by anesthesia, allowing late phenomena to be observed in tonic responses. Previously we showed robust SSA in this preparation. The properties of the neurons showing the strongest SSA suggest that they are in the external nucleus or dorsal cortex (collectively ICX) rather than in the central nucleus (ICC). As the ICX receives strong descending input from cortex and thalamus as well as ascending inputs from brainstem nuclei, the SSA in ICX may be produced by either descending inputs. Consistent with this hypothesis, ICX neurons often show complex temporal responses which may outlast a brief (50 ms) auditory stimulus by up to 100 ms. A simple hypothesis might be that short latency responses would reflect ascending inputs and not show SSA whereas long latency responses would reflect descending inputs and show SSA. To test this hypothesis we measured SSA across the driven responses of single neurons in ICC and ICX. We show that the extent of SSA does indeed vary between short and long latency components of responses.

Surprisingly, there is more SSA in short-latency responses (<~50 ms) than in later responses. This SSA correlated with both increasing spike front latencies and adaptation over the course of multiple stimuli. Our results thus suggest that SSA is created de-novo on the IC.

Title: Hierarchical network of vocalizations in songbird groups

Authors: *A. L. VYSSOTSKI[1], V. N. ANISIMOV[2], A. V. LATANOV[2], R. H. R. HAHNLOSER[1];
[1]Inst. of Neuroinformatics, Univ. of Zurich and ETH Zurich, Zurich, Switzerland; [2]Fac. of Biology, Moscow State Univ., Moscow, Russian Federation

Abstract: Vocalizations are an essential part of social interactions in birds. They have important biological functions in coordinating activity of group members. However, little is known about the structure of vocal interactions in bird groups. The main challenge for investigating vocal interactions and their biological significance in a bird group is to discriminate individual vocalizations of rapidly moving, sometimes simultaneously vocalizing individuals. We make use of recently developed back-attached ultra-miniature sound/acceleration recorders (SfN 2011, 692.08) and recorded vocalizations in groups of freely moving laboratory-housed zebra finches. Conveniently, the microphone picked up sounds from several birds, whereas the accelerometer recorded vocalizations only produced by the carrier. Accelerometer signals consisted of high-quality audio recordings up to almost 5 kHz, well suited for perfect classification of vocal elements even in the midst of other birds vocalizing.
We studied 3 groups of 4 male birds each and recorded their vocalizations during several days in a sound-proof chamber. We collected data during 2.5 morning hours when vocalization density was highest. Every other day during the 2.5 morning hours we introduced a female to the group

to study the development of vocal interactions between the males and the female.
We measured the strength of pairwise interactions between birds by computing cross-correlation (CC) functions of the number of selected vocal elements in sliding 250 ms time windows. To create a linear ranking of birds we also computed CC functions between calls in a given bird and calls in all other birds, to sort the birds by the times of their CC maxima (within a range of time lags typically smaller than 200 ms). This ranking reflects the average order of calls in the entire group.
We have found that communication networks determined by CCs in zebra finch groups have a stable hierarchical structure. The networks form rapidly in newly created groups and strengthen over the course of several days, where the strengthening is manifested in faster and more reliable call-call responses. Singing behaviors differed between individuals. Some animals tended to sing together whereas others avoided that tendency. Introduction of the female strongly decreased the number of songs produced by males and changed the hierarchy of their call interactions within the entire group. However, after female removal the original hierarchy recovered in most cases. These findings of rapid hierarchy formation suggest the existence of strongly pairwise attractive rules for the formation of communication networks that depend on the group composition as a whole.

Title: Modulation of spontaneous and sensory-evoked synaptic dynamics in A1 during auditory discrimination tasks in mice

Authors: *M. J. MCGINLEY[1], S. V. DAVID[2], D. A. MCCORMICK[1];
[1]Neurobio., Yale Univ., New Haven, CT; [2]Oregon Hearing Res. Ctr., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Sensory cortex is capable of remarkable plasticity in the coding of stimuli, particularly during complex behaviors. The dynamics of sensory coding and its plasticity have been extensively studied with extracellular single unit recordings and lower resolution measures of

population activity (e.g. EEG, LFP, and fMRI). However, whole-cell recordings of the membrane potential dynamics of cortical neurons have largely been restricted to anesthetized or passively awake and unengaged animals, yielding diverse and apparently conflicting results. For example, membrane potentials in some cortical areas of awake cats and mice are depolarized in a persistent UP state (Steriade, Timofeev, and Gernier, J Neurophysiol 85:1969-85, 2001; Haider, Hausser, and Carandini, Nature 493:97-100, 2013). However, other areas of the mouse cortex show different patterns of activity. Membrane potentials in auditory cortex of awake mice are hyperpolarized in a persistent DOWN state (Hromadka, Zador, and DeWeese, J Neurophysiol 109: 1989-95, 2013) and in barrel cortex of quietly awake mice they exhibit slow-oscillations reminiscent of sleep (Crochet and Petersen, Nat Neurosci 9:608-10, 2006). Task related plasticity in the membrane potential dynamics of cortical neurons has not been demonstrated.
Here, we perform whole-cell recordings in the primary auditory cortex of mice engaged in two auditory discrimination tasks of varying difficulty while head-fixed on a cylindrical treadmill. In the simpler task, mice are trained to distinguish complex noise stimuli (temporally orthogonal ripple combinations; TORCs) from a pure tone. Sounds are presented in trial blocks with 1-6 TORCs followed by a tone. The pitch of the tone is fixed during each training session but is varied randomly day-to-day. In the more difficult task the tone is embedded in a TORC with variable signal-to-noise ratio between trials. These tasks result in rapid changes in gain and shape of receptive fields for extracellular recordings in ferrets (Atiani, Elhilali, David, et al., Neuron 61:467-80, 2009). Mice were able to learn both tasks and perform them reliably for up to 1000 trials with sigmoidal psychometric curves and during whole-cell recordings. We find that membrane potentials are stable and frequently depolarized when animals are engaged in the difficult task, whereas they undergo slow fluctuations or sustained hyperpolarization when unengaged or unchallenged. Investigation of the effects of task performance on receptive fields is ongoing.

Title: Layer 6 corticothalamic projections actively maintain sound selectivity in the lemniscal subdivision of the medial geniculate body but provide gain control to a non-lemniscal subdivision

Authors: *A. R. CLAUSE[1,2], D. B. POLLEY[1,2];
[1]Eaton-Peabody Lab., Massachusetts Eye & Ear Infirmary, Boston, MA; [2]Otology and Laryngology, Harvard Med. Sch., Boston, MA

Abstract: Corticothalamic (CT) projections originating from layers 5 and 6 of the cortex (L5 and L6, respectively) make up the largest component of the auditory corticofugal system and provide a massive, specifically patterned input to the lemniscal and non-lemniscal subdivisions of the medial geniculate body (MGB). L5 and L6 CT projections have distinct innervation patterns, axon morphology, and functional properties. However, conventional approaches for neuronal silencing affect both L5 and L6 rather than isolating each laminar component. Accordingly, the effects of AC silencing on sound representations in the MGB have been mixed and difficult to interpret.

We have taken a chemical-genetic approach to selectively and reversibly inactivate L6 neurons in the mouse auditory cortex (AC) while simultaneously recording sound-evoked activity in the medial, dorsal, and ventral subdivisions of the MGB. The AC of both hemispheres was infected with a cre-dependent adeno-associated viral vector that drove expression of a mutant acetycholine receptor only in L6 pyramidal neurons. When activated by the systemic injection of its otherwise inert synthetic ligand, this receptor elicits robust membrane hyperpolarization. Unlike optogenetics-based inactivation, this approach, known as DREADDs, provides long-lasting neuronal inhibition (4 hrs in vivo) throughout a large, irregularly shaped expression area without the risk of tissue toxicity.

By chronically implanting multi-channel silicon probes mounted on a lightweight microdrive, we were able to record from neurons throughout the different subdivisions of the MGB in freely moving mice before, during, and after L6 inactivation. We presented a large battery of sound stimuli to examine the influence of L6 feedback on a various aspects of sound-encoding, such as pure tone tuning, conspecific vocalization responses, and representations of signals in noise. Preliminary results demonstrate that the L6 inactivation was associated with increased sound-evoked firing rates in the medial, but not ventral, subdivision, while tuning quality decreased in the ventral, but not medial, subdivision. CT feedback has been implicated in a wide array of functions, ranging from the dynamic modification of sensory filters to the adaptive re-mapping of sound localization cues, and is likely to be differentially active based on ongoing cognitive demand. Accordingly, current efforts are focused on comparing the effects of L6 inactivation when mice are in three listening conditions: anesthetized, awake and passively listening, and awake and actively monitoring sound cues to avoid an aversive stimulus.

Title: Enhanced but dysregulated experience-dependent plasticity in the aged brain due to reduced inhibition

Authors: *M. CISNEROS-FRANCO[1], E. DE VILLERS-SIDANI[2];
[1]McGill Univ. Integrated Program In Neurosci., Montreal, QC, Canada; [2]Montreal Neurolog. Inst., Montreal, QC, Canada

Abstract: During an early developmental period also known as the "critical period" (CP), cortical inhibitory networks are immature and passive exposures to environmental sounds readily shape the frequency tuning map of the primary auditory cortex (A1) (de Villers-Sidani et al., 2007). Maturation of cortical inhibition ultimately closes the CP, and early experience-dependent alterations in A1 tuning become consolidated and resistant to passive sound exposures. Moreover, a minimum inhibitory tone is necessary for the maintenance of this representational stability in the adult cortex (Pizzorusso et al., 2002).
In aged rats and humans, although learning is still possible, the process is usually slower and effects short-lived (Boyke et al., 2008; de Villers-Sidani et al., 2010). Notably, the inhibitory elements that are associated with the regulation of plasticity during early development are reduced in the aged brain (Caspary et al., 2008). This altered milieu could result in a progressive increase in representational instability in the aged A1, potentially contributing to the reduced effectiveness of learning in older individuals. Here we tested this hypothesis by comparing the effect of a short passive tone exposure on A1 frequency representation in young adult and aged rats. We found that such exposure resulted in a significant distortion of A1 frequency tuning in the older but not in the younger group. Additionally we found that such distortions could readily be erased by a subsequent exposure to a different tone. Finally we administered the GABA-A potentiator diazepam in the aged group during the exposure and found that it made A1 once again resistant to passive alterations in frequency tuning.
Our findings show that experience-dependent plasticity is paradoxically enhanced but dysregulated in the aging brain likely due due to an age-related reduction in inhibition. Such

instability could have a direct negative impact on the acquisition and persistence of learning in the aged brain.

Title: Learning strategy shift accounts for renormalization of sensory map plasticity

Authors: G. A. ELIAS[1,2], K. M. BIESZCZAD[1,2], *N. M. WEINBERGER[1,2];
[1]Cntr for the Neurobio of Learning & Memory, Univ. of California, Irvine, IRVINE, CA;
[2]Neurobio. and Behavior, Univ. of California, Irvine, Irvine, CA

Abstract: Representational plasticity (RP) is a *systematic learning induced bias in the representation of sensory stimuli along a dimension*. In the primary auditory cortex (A1) the degree of RP involves the learning strategy employed (Berlau & Weinberger, 2008, *Neurobiol Learn Mem*). A learning strategy to bar-press for reward from tone onset until receiving an error signal after tone offset (TOTE; tone-onset to error) produces an expanded representational area for the tone (Bieszczad & Weinberger, 2010, *Neurobiol Learn Mem*). However, expansions dissipate ("renormalize") with over-training (weeks) (Reed et al., 2011, *Neuron*). As learning strategy plays a critical role in the induction of RP, it may help explain renormalization. Therefore, we trained two groups of rats for different amounts of time in a discrimination task: one tone (CS+) signaled water reward contingent on a bar-press and two tones did not (CS−). Group 1 (n = 11) was trained to asymptotic correct performance (7−15 days, mean = 10) while Group 2 (n = 10) was over-trained for an additional two weeks. To promote use of a TOTE strategy, bar-presses made during and immediately following CS+ offset were rewarded. Rats in both groups learned to use the TOTE strategy and were indistinguishable during the first two weeks, in amounts of TOTE strategy use and levels of asymptotic performance. Over-training in Group 2 led to a decline in TOTE use, which was replaced by a strategy where bar-pressing, still initiated at tone-onset, was stopped before generating an error signal, *i.e.*, animals internalized the reward contingencies (iTOTE). Terminal mapping after training revealed that Group 1 exhibited CS+ specific area expansions, replicating prior findings. In contrast, Group 2 trained to high levels of iTOTE use had no expansions. Importantly, the amount of TOTE use was

positively correlated with the amount of CS+ area ($r = 0.50$, $p < 0.05$), while iTOTE use was negatively correlated with CS+ area ($r = -0.58$, $p < 0.01$). Thus renormalization appears due to a change in learning strategy, rather than a passive dissipation of area gain. As greater use of the over-training strategy led to greater loss of CS+ area, renormalization may reflect a shift from cortically-dependent cognitive memory to a more habit-like, possibly subcortically dependent, form of behavioral response (*e.g.*, Mishkin & Petrie, 1984, *Neuropsych of Memory*).

Title: Differential neuronal responses in ferret frontal cortex during performance of positive and negative reward versions of an auditory long-term memory task

Authors: *J. B. FRITZ, S. A. SHAMMA, P. YIN;
Neural Systems Lab, Inst. Syst Res., Univ. Maryland, College Park, MD

Abstract: An earlier study in ferret frontal cortex (FC) revealed persistent changes in neuronal responses to novel auditory target stimuli over a time course of minutes to hours following performance of auditory discrimination tasks (Fritz et al 2010). In order to explore the role of the FC in auditory memory, we developed a new auditory task that depends on information retrieval from an auditory long-term memory (LTM) store. Ferrets were trained to classify single tone-bursts into three frequency ranges (Low, Middle and High). Three animals were trained on a positive reinforcement (PR) task version, in which they learned to approach a waterspout for reward (Go-response) when the tone-burst fell in the Middle frequency range, and to avoid a time-out by not licking the waterspout after tone-bursts in either the Low or High frequency range (No-Go response). Five additional ferrets were trained on a conditioned avoidance (CA) version of the task, in which they received a mild shock if they licked to tones with frequency in the Middle range, but could lick freely through the tones in both Low and High range. Each trial thus consisted of the presentation of a single tone-burst that occurred randomly within one of the frequency zones, and the animal's response to this tone. After learning the frequency range

classification LTM task, 4 ferrets (2 in PR and 2 in CA) also learned a similar 3-zone classification for different rates of amplitude modulation (AMR) of white noise. Each daily session consisted of 100-200 trials on one or both tasks. After animals were trained, they were implanted with head-posts to secure head position during task performance. We recorded chronically from the FC of head-fixed ferrets, using a multiple electrode system (Alpha Omega). Preliminary neurophysiological results from the PR pitch LTM task indicate the presence of two major neuronal response types in FC that were strongly activated during performance and selectively preferred tonal frequencies that corresponded to behavioral choices rather than acoustic zones. FC neurons responded to either (a) the Middle range "Go" stimuli or (b) both Low and High range "No-go" tone-burst stimuli (Yin et al 2012). In contrast, during the CA pitch LTM task we only observed FC neuronal responses to the Middle range "No-go" tone bursts, even though the animal was performing the same pitch discrimination task. A similar response pattern was found during the AMR task in the same neuron population. These preliminary results provide insights into how the FC encodes, represents, classifies and retrieves the associative meaning of sensory stimuli during performance of auditory LTM pitch or AMR tasks under different reward conditions.

Title: Activity of auditory cortical neurons in monkeys performing a short-term memory task

Authors: *B. H. SCOTT[1], P. YIN[2], M. MISHKIN[1];
[1]Lab. Neuropsychol, NIMH, BETHESDA, MD; [2]Inst. for Systems Res., Univ. of Maryland, College Park, MD

Abstract: Short-term memory (STM) for visual stimuli has been shown to engage both prefrontal cortex (PFC) and the modality-specific cortical areas that support visual perception. Although monkeys can perform auditory STM tasks, their ability is limited relative to that in vision, and appears to depend on retention of a stimulus trace in a passive form of STM. The neural underpinnings of this putative trace are unknown, but by analogy to sensory memory in vision and touch, they are likely to engage non-primary auditory cortex, e.g., the rostral superior

temporal plane and gyrus, components of the ventral auditory processing stream that provide input to the PFC. We recorded single-unit activity across these regions while monkeys performed a serial delayed-match-to-sample (DMS) task. On each trial, the monkey grasped a bar to initiate the presentation of a sample sound (~300 ms duration), followed by 0-2 nonmatch sounds (delay interval ~1 s), before the sample was presented again as a match; the monkey released the bar to indicate a match. Among 280 sound-responsive neurons in 3 animals, we identified two phenomena potentially associated with mnemonic tasks. First, 35% of units exhibited a sustained change in firing rate (relative to the pre-trial baseline) during the delay interval (17% excitation, 18% suppression). Second, the auditory response was modulated by task context in 20% of units, with 7.5% showing match enhancement (relative to the sample presentation), and 12.5% showing match suppression. The prevalence of excitatory and suppressive effects differed between early and late phases of the trial: delay and match suppression were observed throughout the trial, but the proportion of units exhibiting delay or match excitation declined significantly after the presentation of the first nonmatch sound. The decline in excitatory response modulation following the first nonmatch sound coincides with a marked increase in behavioral error rate, suggesting that these signals may aid match detection. However, in the spiking activity there was no evidence of a stimulus-specific trace spanning the delay interval - analysis of firing rate in a sliding time window revealed that the variance explained by stimulus identity decayed to zero ~300 ms after stimulus offset for the population on average (whether during the task or during passive listening). The dynamics of spiking activity in the auditory ventral stream are consistent with characteristics of DMS performance, but additional sub-threshold mechanisms are likely to support the neural trace on which STM depends.

Title: Cortical oscillations and spiking activity associated with Artificial Grammar Learning in the monkey auditory cortex

Authors: *Y. KIKUCHI, A. ATTAHERI, A. MILNE, B. WILSON, C. I. PETKOV;
Inst. of Neurosci., Newcastle Univ. Med. Sch., Newcastle Upon Tyne, United Kingdom

Abstract: Artificial Grammars (AG) can be designed to emulate certain aspects of language, such as the structural relationship between words in a sentence. Towards developing a primate model system to study potential language precursors at the neuronal level, we obtained evidence that monkeys can learn relationships in sequences of nonsense words generated from an auditory AG and used functional MRI (fMRI) to study the brain regions engaged (Wilson et al., SFN, 2011). Here, we ask how monkey auditory neurons evaluate the within-word acoustics and/or between-word sequencing relationships, and whether these aspects engage theta and gamma oscillations, which are critical for speech processing in human auditory cortex (e.g., Giraud & Poeppel, Nat. Nsci. 2012). We recorded local-field potentials (LFPs) and single-unit activity (SUA) from 4 fMRI localised auditory core (A1 & R) and lateral belt (ML & AL) subfields in two Rhesus macaques (124 sites). During each recording session, the monkeys ware first habituated to exemplary sequences generated by the AG. We then recorded neuronal activity in response to identical nonsense words, either in the context of a sequence that followed the AG structure ('correct') or one that violated its structure ('violation'). In response to nonsense words, the LFP power significantly increased in a broad range of frequency bands (4-100 Hz), including at theta (4-10Hz) and low (30-50Hz) and high (50-100Hz) gamma frequencies. We also observed a consistent increase in the inter-trial phase coherence, in particular in the theta band. Moreover, a substantial proportion of the LFP sites showed differential responses to the nonsense words depending on whether the word was in the context of a 'correct' or 'violation' sequence. This was observed in a considerable proportion of sites in the theta (35/124 sites), low gamma (37/124) and high-gamma (25/124) bands. Moreover, the proportion of such sequence-context sensitive sites increased from core to lateral belt auditory fields (LFP: 18% vs. 82%; SUA: 39% vs. 61%). We provide evidence that monkey auditory neuronal responses, including theta and gamma oscillations, are associated with both the processing of nonsense words and the relationship between the words, as governed by the AG. These nonhuman primate results likely reflect domain general evolutionarily conserved neuronal processes, rather than those that are language specific in humans.

Title: ERP microstates and source imaging reveal progressive changes in cerebral processing of musical syntax with level of musical expertise

Authors: *C. E. JAMES[1,2], M. S. OECHSLIN[5], D. VAN DE VILLE[3], F. LAZEYRAS[3], D. BAVELIER[2], C. MICHEL[4];
[1]Univ. of Applied Sci. Western Switzerland, Geneva, Switzerland; [2]Fac. of Psychology and Educational Sci., [3]Fac. of Medicine, Dept. of Radiology and Med. Informatics, [4]Fac. of Medicine, Dept. of Fundamental Neurosciences, Univ. of Geneva, Geneva, Switzerland; [5]Intl. Normal Aging and Plasticity Imaging Ctr., Univ. of Zurich, Zurich, Switzerland

Abstract: While recording high density EEG, non-musician (N), amateur (A), and expert (E) musicians assessed a series of specifically composed string quartets with hierarchically manipulated endings. At musical closure, we implemented 2 levels of transgression, subtle (T1) and apparent (T2)), that differed in salience but remained both within the tonality of the piece (in-key). Pieces with transgressed endings were presented intertwined with pieces ending regularly (R). Participant groups were matched for age, sex and fluid intelligence; moreover, A and E only differed in training intensity, not in age of training onset. Behavioral sensitivity scores (d-prime) of both transgressions clearly separated participants as a function of expertise level. Classical ERP analyses exhibited significant Expertise x Transgression interaction between 200 and 600ms after stimulus onset (i.e. onset of musical closure). Amplitudes increased with expertise level, but differentially so for all three conditions (R, T1, T2). Results of spatio-temporal ERP analyses, in a 300-500ms time window after stimulus onset, nicely matched the behavioral results and yielded specific ERP topographies or "microstates" of information processing according to expertise. Expertise x Transgression x Microstate interaction showed gradual differences between levels of expertise for the incidence of certain microstates, grouping E against A & N for T1, and N against A & E for T2. Finally, computing inverse solutions (LORETA) of ERPs in this 300-500ms time window, we could show significant Expertise x Transgression interaction in the right middle and inferior temporal gyrus. Stronger activations manifested in these brain areas with increasing expertise, but for T2, the apparent transgression, A and E did not differ (Figure 1). These results strongly suggest that training intensity

progressively changes higher order cognitive brain functioning.

Figure 1: significant Expertise x Transgression interaction in the Right Middle and Inferior Temporal Gyrus (RMTG, RITG). Left panel: significant voxels superimposed on slices of MNI 152 template brain. Right panel: mean current density (μA/mm3) for each group and condition over 295-480 ms from stimulus onset. **R:** regular endings; **T1:** subtly transgressed endings; **T2:** apparently transgressed endings. **N:** non-musicans; **A:** amateur musicians; **E:** expert musicians.

Title: Occupationally induced hearing impairment: Is the error rate during auditory pattern recognition affected and does this produce mental stress?

Authors: E. EMMERICH, *F. RICHTER;
Inst. of Physiol. I, Univ. Hosp. Jena, Jena, Germany

Abstract: The impact of noise on the inner ear causing hearing damage or hearing loss as well as risk factors of noise has been often investigated in the past. Little is known, however, about non-aural influences of noise causing mental stress in hearing-impaired people. Noise can increase heart frequency, cardiac output, and also the systemic blood pressure together with endocrine

changes.
We investigated 20 workers (aged 41-62 years) from beverage industry with occupationally induced hearing impairment. In these volunteers we recorded the EEG from 31 channels (10-20 system) particularly from the auditory cortex, together with the electrocardiogram, breathing frequency and systemic blood pressure. The EEG was analyzed for auditory evoked potentials and for changes in frequency before and after stimulus presentation. Stimuli were either short samples of recorded sounds from the machines in the beverage industry (parent stimulus), or the same sounds with very small mistakes, e.g. interruptions equivalent to broken bottles (deviant stimulus). For comparison we presented synthesizer chords in-tune or slightly mistuned, respectively. Stimuli were presented in the oddball paradigm (ratio: 4 parent, 1 deviant). The workers were asked to mark every mistake by pressing a bottom.
The workers were able to recognize nearly all mistakes when workplace sounds were presented even at reduced sound pressure, but failed when synthesizer chords were used. Interestingly, in both stimulus presentations auditory evoked potentials clearly differed between parent and deviant stimuli. Only after inaccurate workplace sounds but not after mistuned synthesizer chords the EEG frequency shifted significantly towards higher frequencies in the beta wave band. Together with higher EEG frequencies, both heart rate and systemic blood pressure increased transiently, especially when several inaccurate workplace sounds were presented in succession. The workers told on uneasiness after such a series of inaccurate sounds.
The results showed that learning of specific occupational sounds during professional life supports auditory pattern recognition and is able to compensate to some extent the hearing impairment. Regardless of the hearing impairment, inaccurate auditory patterns at the workplace cause cardiovascular and EEG frequency changes indicating mental stress. This should be considered when extra aural influences of noise are to be evaluated.

Title: Pitch matching vocal training paradigm with audio cuing and F0 perturbation, a software only implementation

Authors: *B. ROGERS[1], A. L. PARKINSON[1], C. R. LARSON[2], D. A. ROBIN[1,3];
[1]Res. Imaging Inst., Univ. of Texas Hlth. Sci. Ctr., San Antonio, TX; [3]Dept. of Communication Sci. and Disorders, [2]Northwestern Univ., Evanston, IL

Abstract: The ability to control voice fundamental frequency (F0) is essential for successful and efficient speech production. Accurate voice F0 and amplitude control depend on error correction mechanisms that process sensory feedback. Pitch perturbation techniques have often been used investigate the role of auditory feedback in F0 control.
In this paradigm participants vocalize to match the pitch of audio cues while receiving intermittent pitch shifted feedback. Participants wear over the ear headphones for the presentation of audio cues and for giving real time audio feedback. An attached microphone is used to record vocalization.
The audio cues are phrases made up of single syllables such as "TA" or "STRA". Before the session participants will vocalize each cue syllable once. The cue vocalizations are stored and use to construct the prompt phrase for each trial in the session. One of the syllables of the cue may be shifted to a higher or lower frequency.
For each trial, the participant sees a visual cue and hears an audio cue. If the second syllable of the phrase "TA TA TA TA" is to be vocalized at a higher pitch, the second "TA" of the visual cue is positioned higher. In the associated audio cue, the second "TA" will be pitch shifted higher. Then, they are tasked with matching the audio cue exactly. During vocalization, the audio feedback may be perturbed up or down during the one syllable that is shifted. The participant's performance on matching the cue phrase is visually presented immediately as a set of matching bars to indicate how close each vocalized syllable was to the cue.
This paradigm is implemented in C++ using free or open source components. It runs on both Windows and Macintosh computers. A friendly graphical user interface is created using the QT framework (Nokia). The RtAudio API (McGill University) is used as a platform independent audio interface. The real time audio pitch shifting uses the smbPitchshift C++ FFT routine (Stephan M. Bernsee). The pitch of the captured vocalizations is determined by spawning an instance of Praat (University of Amsterdam). Latencies of the pitch shifted audio of less than 25ms have been measured using the built in audio of both Macintosh and Windows computers. Latencies of around 15ms have been measured using a fast PCI audio card.
This paradigm can be useful in studying error detection/correction, efference copy, and feedforward/feedback mechanisms. Target populations include the elderly, those with Parkinson's disease, stroke, or vocal disorders, as well as professional singers and musicians. The paradigm fits well with behavioral, imaging and electrophysiology studies.

Abstract: How are we able to easily and accurately recognize speech sounds despite the lack of acoustic invariance. One proposed solution to this long-standing question has been the existence of a neural representation of speech syllable perception that transcends its sensory properties. In the present fMRI study, we used two different audiovisual speech contexts both intended to identify brain areas whose levels of activation would be conditioned by the speech percept independent from its sensory source information. We exploited McGurk audiovisual fusion to obtain short oddball sequences of syllables that were either a) acoustically different but perceived as similar, or b) acoustically identical but perceived as different. We reasoned that if there is a single network of brain areas representing abstract speech perception, this network would show a reduction of activity when presented with syllables that are perceived as similar and an increase in activity when presented with syllables that are acoustically similar but perceived as distinct. Consistent with the long-standing idea that speech production areas may be involved in speech perception, we found that frontal areas were part of the neural network that showed reduced activity for sequences of perceptually similar syllables. Another network was revealed, however, when focusing on areas that exhibited increased activity for perceptually different but acoustically identical syllables. This alternative network included temporal auditory areas but no left frontal activations. In addition, our findings point to the importance of subcortical structures much less often considered when addressing issues pertaining to perceptual representations.

Title: Tract-based spatial statistics of absolute pitch: white matter differences in association fibers

Authors: *E. A. GARZA-VILLARREAL[1,2,3], A. DOHN[3], M. CHAKRAVARTY[4,5,7], M. HANSEN[3], J. P. LERCH[6], P. VUUST[3,8];

Biophysics, Univ. of Toronto, Toronto, ON, Canada; [7]Rotman Res. Inst., Baycrest, Toronto, ON, Canada; [8]The Royal Acad. of Music, Aarhus/Aalborg, Denmark

Abstract: The ability to identify a musical pitch without a reference is called 'absolute pitch' (AP). In this study we investigated white matter differences and its relation to the AP ability by performing tract-based spatial statistics (TBSS) and deterministic tractography to analyze diffusion tensor images. Thirty-five musicians entered the study, divided into two groups: AP possessors and musicians with no absolute pitch. The images were acquired using a 3 T GE MR system with an eight-channel Invivo head coil, with a high-resolution T1 SPGR 3D volume and a diffusion tensor imaging (DTI) sequences. The DTI images were preprocessed using FMRIB's FSL. The statistical analysis of the FA data was carried out using TBSS. After the overall analysis, we transformed the TBSS results back to native space, extracting the individual ROIs derived from the significant cluster (tbss_cluster) and we calculated mean area FA (maFA) in each. We then performed correlation analysis between each participant's maFA and a pitch identification test to confirm the relationship between AP ability and the white matter group cluster. Finally, we performed tractography in each subject using Diffusion Toolkit (DTK) and TrackVis software and the individual tbss_cluster as the seed. The TBSS analysis showed that APs had higher FA values compared to the non-APs ($p<.01$; TFCE- corrected) in a single significant cluster located in the right temporal lobe's sub-gyral white matter (center of gravity: x=38.4, y= -11.6, z= -12.5), within the path of the inferior fronto-occipital fasciculus, the uncinate fasciculus and the inferior longitudinal fasciculus. There was a significant positive correlation between the maFA and PIT ($r = .57$, $p < .001$). We determined that the main fiber bundles corresponded to association fibers, namely the inferior fronto-occipital fasciculus, the uncinate fasciculus and the inferior longitudinal fasciculus. In this study we show that the APs

have greater FA values than non-APs in the white matter within the right temporal lobe, and its FA value was strongly related to the AP ability.

Title: Anatomical and functional networks underlying audio-visual integration

Authors: *D. BRANG[1], J. ZWEIG[1], Z. J. TAICH[2], J. MISHRA[3], S. SUZUKI[1], S. A. HILLYARD[2], V. S. RAMACHANDRAN[2], M. GRABOWECKY[1];

Abstract: Our senses interact in daily life through multisensory integration, facilitating perceptual processes and behavioral responses. Anatomical and functional connectivity have been suggested as mechanisms underlying the ability to integrate information across the senses. Here we examined the role of both forms of connectivity in the modulation of visual processes by auditory cues. Multisensory interaction was quantified using the "sound-induced illusory flash" paradigm, in which a single visual flash paired with two auditory beeps frequently generates the novel percept of an illusory second flash. The role of anatomical connectivity was assessed by examining the relationship between the perception of an illusory second flash and individual differences in white matter connectivity (as assessed by diffusion tensor imaging) on 27 participants. Results revealed a significant positive correlation between the experience of an illusory second flash and enhanced anatomical connectivity (fractional anisotropy) between auditory and visual cortices, suggesting that increased connectivity increases auditory-visual interactions. A similar individual differences approach was applied to EEG phase and coherence data in a separate group of 28 subjects to examine the role of functional connectivity. Interestingly, the experience of an illusory second flash was significantly associated with decreased coherence between auditory and visual cortices, possibly due to increased inhibition of auditory cortex by visual cortex reducing these auditory-visual interactions. Thus, stronger anatomical connectivity increased, but stronger functional connectivity decreased auditory-visual interactions during this illusion. Altered multisensory processes have been identified in numerous clinical conditions in addition to healthy aging highlighting the need to understand the relationship between individual differences in multisensory processing and those of functional and anatomical connections.

Title: Meta-analytic connectivity modeling (MACM) of anterior vs. posterior superior temporal sulcus

Authors: *L. C. ERICKSON, J. P. RAUSCHECKER, P. E. TURKELTAUB;
Georgetown Univ., Washington, DC

Abstract: *Introduction*: The superior temporal sulcus (STS) is implicated in many functions, including audiovisual processes (Hein and Knight, 2008). Yet STS functional organization related to auditory and visual streams, including dorsal vs. ventral distinctions is not well understood. Auditory models (Rauschecker and Scott, 2009) predict that posterior STS mainly interacts with dorsal-stream regions, whereas anterior STS mainly interacts with ventral-stream regions. To examine this possibility, we conducted MACM (Zald et al., 2012) analyses that assessed which brain areas consistently coactivated with anterior, middle or posterior STS across studies in BrainMap (brainmap.org).
Methods: Regions of interest (ROIs) were created using the lpba40 atlas: left anterior STS (LaSTS), left middle STS (LmSTS), left posterior STS (LpSTS), right anterior STS, right middle STS and right posterior STS. Studies of normal subjects, reporting foci in STS ROIs were obtained from BrainMap (Sleuth). Activation likelihood estimation (ALE) analyses were conducted (GingerALE 2.1). To match sensitivity across ROIs, we equated active voxels across each ALE analysis (min. threshold of FDR $q < 0.05$, cluster threshold >100 mm^3). ALE subtractions isolated connectivity for specific STS regions (e.g., LpSTS – (LaSTS + LmSTS)).
Results: 1185 experiments and 14532 subjects were found. In general, areas associated with sensorimotor processing (e.g., parietal and premotor areas) coactivated with LpSTS more often than with other left STS regions. Areas associated more closely with ventral-stream function (e.g., hippocampus) coactivated more often with LaSTS than other left STS regions. There was some dorsal/ventral stream connectivity overlap and other coactivations were present. Some unpredicted patterns were observed (e.g., topographical coactivations with left STS and fusiform gyrus). Coactivation patterns were found for right STS.
Conclusions: In general, these findings suggest that left pSTS coactivates mainly with dorsal-stream regions, whereas aSTS coactivates more with ventral-stream regions. Examining connectivity patterns further may provide insight into STS organization and processing.

Title: Functional cross-subject mapping predicts brain activity to novel natural movies and speech

Authors: *N. Y. BILENKO[1], A. G. HUTH[2], S. NISHIMOTO[2], J. L. GALLANT[3];
[2]Helen Wills Neurosci. Inst., [3]Dept. of Psychology, [1]Univ. of California, Berkeley, Berkeley, CA

Abstract: Individual fMRI responses are highly variable, both anatomically and functionally. This variability makes it difficult to compare individual data in voxel-based fMRI analyses. Individual variability may be especially problematic when comparing data across modalities, such as when comparing cortical representations of natural speech and movies. Here we introduce a technique of functional cross-subject mapping that uses similarity of fMRI responses across individuals to reveal the underlying dimensions of cortical representation of natural stimuli within and across experiments. We show that this method can successfully predict individual subject responses to novel natural movies and speech, both within and across modality.
We recorded fMRI responses from four human subjects while they watched two hours of silent natural movies during steady fixation, and again later while they listened to two hours of natural speech. We used regularized kernel canonical correlation analysis with cross-validation to compute the functional mappings across individual subjects. First, two functional cross-subject mappings were estimated, one for natural movies, and another for natural speech. Ninety percent of the subjects' responses in each experiment were used to compute each of the functional

mappings. Then, the held-out ten percent of each subject's responses in each experiment were predicted by projecting the other subjects' held-out responses through each of the computed mappings. The accuracy of each mapping was quantified within and across experiment by computing the correlations of each subject's predicted responses with their actual fMRI responses.
Within-experiment predictions for the natural movie experiment were most accurate in the early and higher visual cortex, as well as brain areas associated with spatial attention and eye movements. Within-experiment predictions for the natural speech experiment were most accurate in the auditory cortex, temporal-parietal junction, superior temporal sulcus, and in frontal brain regions. Across-experiment predictions were highest in semantically selective visual areas, precuneus, parts of the auditory cortex, and frontal regions.
These findings demonstrate that the functional cross-subject mapping method accurately predicts each person's brain activity to novel natural stimuli, based solely on brain activity measured in different individuals. Furthermore, we show that this method can generalize across modalities, since a functional cross-subject mapping based on natural movie stimuli can be used to predict novel brain responses to natural speech stimuli and vice versa.

Title: The left prefrontal cortex controls information integration by combining bottom-up inputs and top-down predictions

Authors: *G. REMI[1,2], U. NOPPENEY[1,2];
[1]Univ. of Birmingham - Sch. of Psychology, Birmingham, United Kingdom; [2]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany

Abstract: In the natural environment our senses are bombarded with many different signals. To form a coherent percept, the brain should integrate signals originating from a common source and segregate signals from different sources. This psychophysics-fMRI study investigated how

the human brain combines bottom-up inputs (i.e. congruent VS incongruent signals) and top-down prior predictions (i.e. common source prior) to infer whether sensory signals should be integrated or segregated.
Sixteen participants were shown audio-visual movies of congruent (e.g. visual «Ti» with auditory /Ti/), incongruent (e.g. visual «Ti» with auditory /Pi/) and McGurk syllables (e.g. visual «Ki» with auditory /Pi/, which can be fused into the illusionary percept "Ti"). Critically, we manipulated participants' top-down predictions (i.e. common source prior) by presenting the McGurk stimuli in a series of congruent or incongruent syllables. On each trial, participants reported their syllable percept in forced choice procedure with 6 response options.
At the behavioural level, participants were more likely to fuse auditory and visual signals of a McGurk trial into an illusionary percept in congruent relative to incongruent contexts. This response profile indicates that participant's prior top-down predictions (i.e. common source prior) influence whether or not they integrate sensory signals into a coherent percept.
At the neural level, incongruent relative to congruent bottom-up inputs increased activations in a widespread left-lateralised fronto-parietal network. The left prefrontal activations also increased for McGurk trials, when participants selectively reported their auditory percept and did not fuse auditory and visual McGurk signals into a unified percept. Critically, this effect was enhanced for incongruent contexts when participants expected that sensory signals are incongruent and needed to be segregated.
Collectively, our results demonstrate that the left inferior frontal sulcus determines whether sensory signals should be integrated or segregated by combining (i) top-down predictions generated from prior incongruent trials with (ii) bottom-up information about sensory conflict in the incoming signals. Furthermore, it exerts top-down control that enables participants to process sensory signals independently and selectively report their percept in one sensory (i.e. here auditory) modality.

Title: Cross-modal re-organization in adults with mild-moderate hearing loss

Authors: *J. D. CAMPBELL, L. DURKEE, A. SHARMA;
SLHS, Univ. of Colorado At Boulder, Boulder, CO

Abstract: Sensory deprivation has been shown to elicit cross-modal re-organization in sensory cortices. Specifically, deaf adults show activation of auditory cortex in response to visual stimulation, indicating recruitment of auditory cortex for visual processing. Such cross-modal re-organization may lead to a competition of available resources if auditory input is re-introduced via amplification or electrical stimulation. Though cortical re-organization has been studied extensively in deafness, there is an absence of research investigating the degree of hearing loss at which cross-modal re-organization is initiated. It is possible that cortical plasticity may be initiated before profound hearing loss, or deafness, occurs. Given the lack of knowledge concerning the relationship between degree of hearing loss and cortical re-organization, our goals in this study were to 1) determine if visual cross-modal plasticity occurs in adults in the early stages of hearing loss (mild-moderate severity), 2) examine changes in auditory cortical re-organization that accompany early-stage hearing loss in adults, and 3) examine if cortical changes are related to auditory behavioral outcome. High-density EEG was recorded in 8 adults with normal hearing and 9 adults with mild-moderate hearing loss while passively watching visual grating stimuli, followed by passive listening to auditory speech stimuli. Auditory speech perception performance in background noise was also measured. Finally, source localization analysis was performed on group cortical visual and auditory evoked potentials (VEP and AEPs) in order to visualize re-organization. The hearing loss group showed three main findings: 1) VEP and AEP peak component amplitudes were significantly increased, 2) VEP component latency showed significant increases while AEP component latency showed significant decreases, 3) Auditory cortical areas were active in visual processing and frontal cortical areas were active in auditory processing, and 4) Amplitude and latency changes in the VEP and AEP components were significantly correlated to degree of hearing loss as well as the ability to perceive speech in background noise. These findings demonstrate that cortical re-organization begins in early-stage hearing loss for both visual and auditory modalities, and that cortical re-organization is related to poorer auditory performance in challenging environments.

Title: Somatosensory-to-auditory cross-modal plasticity in deaf children with cochlear implants

Authors: *G. J. CARDON, A. SHARMA;
Speech, Language, and Hearing Sci., Univ. of Colorado At Boulder, Boulder, CO

Abstract: *Objective:* Mounting evidence suggests that the maturation and plasticity of the cerebral cortex may play a significant role in predicting functional performance. For instance, it appears that a deficient sensory system has the tendency to re-organize through the recruitment of deprived sensory areas by intact modalities (i.e., cross-modal re-organization), and that recruited sensory modalities seem to suffer functional deficits. Deafness is a naturally occurring instance of sensory deprivation. Due to technology, such as cochlear implants (CI), sensory stimulation can be restored to deprived systems. However, not all CI recipients exhibit favorable functional performance. Somatosensory-to-auditory (SS-A) cross-modal re-organization has been demonstrated in deafness, though never in CI children. However, because the SS and A systems are responsive to virtually the same physical phenomena (i.e., mechanical pressure in the form of oscillations), and due to the highly plastic state of the developing brain, it is plausible that SS-A cross-modal re-organization could occur in deafness and be related to functional outcome in CI children. Thus, we aimed to investigate SS-A cross-modal re-organization in CI children, and whether the degree of SS-A cross-modal re-organization was related to variability in functional abilities.
Methods: Two groups of children were recruited: 1) children with normal hearing; 2) cochlear-implanted children. Each participant underwent high-density EEG testing in response to both auditory and somatosensory stimulation. Assessment of both cortical auditory and somatosensory evoked potential (CAEP; CSEP) waveform components was performed. Current density reconstruction was also carried out to ascertain the sources of cortical activity in response to each type of stimulation.
Results: Results from both evoked potential analysis and current density reconstruction suggest that CI children, but not those with normal hearing, showed SS-A cross-modal re-organization. Additionally, CI children with poor speech perception performance presented with a greater degree of SS-A cross-modal re-organization than those with more favorable functional abilities.
Conclusions: Our findings indicate that SS-A cross-modal re-organization can occur in deaf children who use CIs. The degree of this cortical re-organization also appears to be related to functional outcome. These findings contribute to our understanding of experience-dependent compensatory cortical plasticity in humans. Furthermore, understanding, and being able to harness, cortical plasticity could lead to advancements in clinical management of CI users.

Title: Visual-tactile integration in the human brain: A combined EEG-fMRI study

Authors: *D. WANG[1,2,3], D. Q. MIAO[1,2], B. COE[3,4], J. GALLIVAN[3,4], G. BLOHM[3,4];
[1]Dept. of Computer Sci. and Technol., Tongji Univ., Shanghai, China; [2]Key Lab. of Embedded Syst. and Service Computing, Ministry of Educ., Shanghai, China; [3]Ctr. for Neurosci. Studies, Queen's Univ., Kingston, ON, Canada; [4]Canadian Action and Perception Network (CAPnet), Toronto, ON, Canada

Abstract: Multi-sensory integration is at the heart of sensory processing and is crucial for perception and action. Much research on multi-sensory integration has been carried out in monkeys primarily focusing on sub-cortical structures. To gain insight into spatio-temporal mechanisms of human multi-sensory integration in the cortex, we investigated visual-tactile integration for the guidance of eye movements.
We simultaneously recorded EEG (256 sensors) and fMRI (3T) signals in a fast event-related design from 10 subjects while performing a delayed saccade task to visual (V), tactile (T) or combined visual-tactile (congruent (VT) or incongruent (V~T)) stimuli located on their right forearm. Four stimulus locations (2 left, L1-L2; 2 right, R1-R2) were approximately equally spaced (5cm apart) centered on the visual midline and a fixation LED was positioned 5cm above the center of the stimuli. We used a 4×4 factorial design (SPM8) for the fMRI analysis with factors condition (V, T, VT, and V~T) and target location (L1, L2, R1, and R2) and statistics were FWE corrected of $p<0.001$.
Compared to baseline, we found bilateral activation in FEF, mIPS, V3 and V6 and left (contralateral) S1 during the delay period of the saccade. Comparing uni-sensory and multi-sensory stimulation (V+T>VT and V+T<VT), significant differences arose in the right (ipsilateral) middle cingulate, FEF and V3. Contrasting VT > V~T conditions, led to significant effects in the left superior and posterior middle frontal cortex (SFC, pMFC). Time-frequency response analysis of EEG signals in parietal sensors revealed a decrease in gamma-band (60-

70Hz) synchronization during the whole memory period and an increase in alpha- (10Hz) and beta-band (20Hz) synchronization 500ms into the delay period for multi-sensory stimulation. Our results show a large network of occipital, parietal, and frontal areas involved in multi-sensory visual-tactile integration. We also show specific brain areas involved in multi-sensory conflict detection (SFC and pMFC). Finally, our EEG analysis points towards multiple frequency components related to sensory, motor, and memory processing reflecting visual-tactile integration. To our knowledge, this is the first imaging study providing both high spatial and high temporal resolution for human multi-sensory integration in cortex.

Title: Correlation of functional and structural visual stream connectivity with V1 tactile-evoked BOLD responses in patients with retinitis pigmentosa

Authors: *S. I. CUNNINGHAM[1], J. D. WEILAND[1], P. BAO[2], B. S. TJAN[3];
[1]Biomed. Engin., [2]Neurosci. Grad. Program, [3]Dept. of Psychology, USC, Los Angeles, CA

Abstract: Previous fMRI studies have demonstrated that vision loss is correlated with cross-modal responses in primary visual cortex (V1), where the amount of tactile-evoked activity increases as vision gets worse in late-blind individuals. Some studies suggest that the dorsal

visual stream (specifically visual association areas of the parietal lobe) may be a region where visuotactile information is integrated in sighted individuals, while blindness may cause both dorsal and ventral visual streams to process tactile stimuli. The purpose of this study is to determine if tactile-evoked V1 responses are associated with changes in brain functional and structural connectivity following vision loss. Four late-blind retinitis pigmentosa patients and 2 sighted subjects underwent resting-state fMRI and diffusion tensor imaging scans in a 3T Siemens MRI scanner; all subjects had previously completed an fMRI tactile-discrimination study. Regions of interest (ROIs) were selected to include voxels along both ventral and dorsal visual pathways. In order to determine the functional connectivity between pairs of ROIs in each subject, we calculated the correlation coefficient, r, between the residual time courses of each ROI in a pair after regressing out the head-motion parameters and signals from the ventricles and white matter. Structural connectivity between a pair of ROIs was determined using probabilistic tractography to measure the volume, V, of fiber bundles connecting both regions of interest. Both r and V for each ROI pair were evaluated as a function of vision loss and the extent and strength of tactile-evoked activity in V1. Tactile-evoked V1 activities were found to be negatively correlated with resting-state connectivity and fiber volume between the inferior parietal lobe ROI and ROIs in V5, middle temporal area (MT), lateral occipital complex (LOC), and inferior temporal area (IT). Our preliminary findings suggest that tactile-evoked activity in V1 is related to changes in resting-state connectivity and fiber volume between the inferior parietal cortex and other regions of the visual stream (including areas V5, MT, LOC, and IT). This result suggests that changes in parietal-visual association areas are related to tactile processing in the blind.

Title: Cross-sensory phase reset impacts coherence between sensory and motor cortices: An electro-corticographic study

Authors: *M. R. MERCIER[1,2], M. SOPHIE[1], I. C. FIEBELKORN[1,3], J. J. BUTLER[1], T. H. SCHWARTZ[2], J. J. FOXE[1];
[1]Dpt. of Pediatrics & Neuroscience, Albert Einstein Col. of Med., Cognitive Neurophysiol. Lab.,

Bronx, NY; [2]Neurolog. Surgery, Weill Cornell Med. Col., New York, NY; [3]Psychology, Neurosci. of Attention & Perception Lab., Princeton Univ., Princeton, NJ

Abstract: It is generally accepted that brain oscillatory activity reflects fluctuations of neuronal excitability. Different phases of an oscillation correspond to high and low excitatory states. Thus synchronized activity can lead to temporal windows of communication between brain regions involved in a given task (Fries, 2005). It is also the case that the phase of ongoing oscillations can modulate processing of incoming information. "Cross-sensory" stimulation can impact activity in a unisensory cortical region (e.g., visual inputs modulating oscillatory activity in auditory cortex) by resetting the phase of ongoing oscillations (Lakatos et al., 2007 ; Mercier et al., 2013). It has been hypothesized that such early multisensory integration leads to observed speeded reaction-times (Molholm et al., 2002). Here we sought to test for a relationship between this cross-sensory phase resetting mechanism and communication between sensory and motor cortices following multisensory stimulation.

Using intracranial recordings in epileptic patients (n=4), subdural electrical brain activity was recorded while patients performed a simple reaction time task. Stimuli consisted of randomly ordered Auditory-alone (A), Visual-alone (V) and Audio-Visual stimuli (AV). Participants were to press the same button in response to any stimulus, regardless of sensory modality.

For unisensory conditions, analyses revealed cross-sensory phase reset of lower frequencies (δ and θ bands ; 3-8Hz) in unisensory cortices, with auditory-driven phase reset over visual cortex, and visual-driven phase reset over auditory cortex. For the audio-visual condition, stronger phase resetting was observed in both auditory and visual cortex compared to unisensory conditions. Focusing on communication between sensory and motor cortices, significant coherence was observed for the same low frequency bands. The audio-visual condition lead to stronger coherence compared to the uni-sensory conditions, whether considering coherence between auditory and motor or visual and motor regions.

These data support the idea that cross-sensory phase reset plays a role in multisensory interaction in sensory cortices, and that this cross-sensory phase reset can lead to increased synchronization between sensory cortices and motor cortex in the context of a multisensory reaction time task. In conclusion, our study illustrates how neuronal populations from anatomically segregated brain regions can impact each other by resetting the phase of ongoing activity and how multisensory interactions can facilitate communication between sensory and motor cortex through increased coherence.

Title: Number of temporally accurate steps during dance video game correlates with the activity in the middle temporal gyrus and the frontopolar cortex

Authors: *Y. NOMOTO[1], J. A. NOAH[2], A. TACHIBANA[3], S. BRONNER[4], S. SHIMADA[1], Y. ONO[1];
[1]Dept. of Elec. Eng., Meiji Univ., Kanagawa, Japan; [2]Dept. of Psychiatry, Yale Univ., New Haven, CT; [3]Seijoh Univ., Aichi, Japan; [4]Northeastern Univ., Boston, MA

Abstract: We used near-infrared spectroscopy to investigate how multimodal sensory integration influences coordinated motor outputs when subjects were able to move freely as they would in the real world. Subjects played a dance video game which requires integrated processing of visual, audio and tactile inputs and motor outputs in two conditions: with and without music (Audio). We focused on two brain areas, the middle temporal gyrus (MTG), an area of multisensory integration, and the frontopolar cortex (FPC), an area associated with multitask decision making. Subjects (21 male, 5 female; 26.1 +/- 1.7 years) responded by pressing the correct arrow button (up, down, left and right) on a dance mat at the correct time with their foot to play the game. We studied cortical function using a block design with 30s of dance play followed by 30s of rest repeated five times. Gameplay performance was scored by the number of temporally accurate steps, which corresponded to proper arrow button press within +/- 22.5ms of the correct time. All subjects showed a bell-shaped oxyHb waveform in the MTG, in which high-performance players took a longer time to reach to peak amplitude than low-performance players. Elimination of music during gameplay increased the cumulative amount of oxyHb signal in the MTG in high-performance players while it decreased in low-performance players. The oxyHb waveforms in the FPC were different among players; high-performance players showed a small oxyHb increase followed by a steep and sustained decrease during the task period, while low-performance players showed box-car shaped with prolonged activation. In spite of the presence or absence of music, the cumulative amount of oxyHb signal in the FPC had a negative correlation with the number of temporally accurate steps. In addition high-performance players had little difference in the oxyHb response in the FPC between the two conditions (with and without audio), while low-performance players showed greater activity during the condition that they perceived to be more difficult. These results suggest that the MTG plays a role in the successful integration of visual and rhythmic cues and that high-performance players are able to integrate visual and internally-generated rhythm to make accurate steps even without external auditory rhythmic cues. The FPC is involved in processing prospective memory while multitasking and may work to compensate for insufficient integrative ability of visual and

rhythmic cues in the MTG in low-performance players. The relative relationships between these cortical areas may indicate high to low performance levels when performing cued motor tasks.

Title: Enhanced multisensory processing in musicians

Authors: *J. ROY[1,2,3], S. LANDRY[1,2,3], J. LÉVESQUE[2,3], F. CHAMPOUX[1,2,3];
[1]Univ. De Montréal, Montréal, QC, Canada; [2]Ctr. de Recherche en Neuropsychologie et Cognition (CERNEC), Montréal, QC, Canada; [3]Ctr. de recherche interdisciplinaire en réadaptation du Montréal métropolitain, Inst. Raymond-Dewar, Montréal, QC, Canada

Abstract: Recent investigations have revealed that long-term musical training promotes brain plasticity and generates reorganization in regions affecting multisensory processing. In addition to these anatomical and activation changes, recent studies have also shown behavioural alterations in multisensory processing induced by long-term musical training. While past investigations of multisensory integration have suggested an enhanced ability, only audiovisual modalities have been studied as of yet. The aim of this study was to examine whether musical training enhanced multisensory integration and segregation abilities for other modalities, namely audiotactile. Two non-speech audiotactile illusory tasks were administered to a group of highly trained musicians and a group of non-musicians. Control conditions revealed that unisensory (detection and discrimination) capabilities were identical across groups. For the first task, musicians were able to segregate auditory and tactile information effectively in the context of an audiotactile illusion, whereas non-musicians were not. For the second task, unlike non-musicians, musicians did not experience any illusory change of tactile perception in presence of modified auditory stimulations. Results from these investigations reveal that musicians have reduced susceptibility to auditotactile illusions, suggesting that auditory and tactile information can be processed more independently in musicians than in non-musicians. These results imply

that long-term musical training has an influence on multisensory processing.

Title: Structural brain differences associated with sensory profiles

Authors: *M. T. VAN KESTEREN[1,2], M. R. VAN SCHOUWENBURG[1,3], D. R. RUITER[2], G. FERNÁNDEZ[1,4];
[1]Donders Inst. for Brain, Cognition and Behaviour, [2]Dept. of Anat., [3]Dept. of Psychiatry, [4]Dept. of Cognitive Neurosci., Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands

Abstract: The adult sensory profile questionnaire (Brown et al., 2000) is widely used to assess sensory processing alterations in patient populations with difficulties in this domain, e.g. patients suffering from autism or schizophrenia. However, not much is known about the brain regions related to sensory processing differences in the healthy population, while assessing individual variations in the size of these associated regions could be highly informative as a reference database for comparison with data from groups of patients. Therefore, we here examined structural brain differences related to scores on the adult sensory profile questionnaire in a large healthy female student population (n = 90) to determine brain regions implicated in sensory processing differences. All four factors of the questionnaire, low registration, sensation seeking, sensory sensitivity, and sensation avoiding, were separately examined in relation to grey matter volume as calculated with Voxel-Based Morphometry (VBM) methods on structural brain scans obtained with functional Magnetic Resonance Imaging (fMRI). Results show that higher scores on low registration, sensation avoiding, and sensory sensitivity were related to larger grey matter volume in the bilateral parahippocampal gyrus and extending into the fusiform gyrus. Additionally, higher scores on sensory sensitivity were also related to larger grey matter volume in the bilateral inferior parietal sulcus, and higher scores on sensation seeking were related to larger grey matter volume in the right insula. Finally, lower scores on low registration, thus representing high registration abilities, were related to larger grey matter volume in the thalamus. These results are indicative of grey matter differences in diverse sensory brain regions as related

to sensory profile scores in healthy young participants. These findings therefore provide important reference data on the differential volumes of specific brain regions related to sensory profiles in the healthy population, thereby serving the quest to determine brain regions and networks that are malfunctioning in patient populations. The brain regions found in this experiment can thus be used to focus future research on sensory processing mechanisms within these regions, both in healthy participants and in patients.

Title: Reconfiguration of network hub structure after propofol-induced unconsciousness

Authors: U. LEE[1], H. LEE[2], *G. A. MASHOUR[1];
[1]Anesthesiol., Univ. of Michigan, ANN ARBOR, MI; [2]Physics, POSTECH, Pohang, Korea, Republic of

Abstract: Introduction: General anesthesia induces unconsciousness along with functional changes in brain networks. Considering the essential role of hub structures for efficient information transmission, we hypothesized that anesthetics have an effect on the hub structure of functional brain networks.
Methods: Graph theoretic network analysis was carried out to study the network properties of 21-channel electroencephalogram data from ten human volunteers anesthetized on two occasions. The functional brain network was defined by phase lag index, a coherence measure, for three states: wakefulness, loss of consciousness induced by the anesthetic propofol, and recovery of consciousness. The hub nodes were determined by the largest centralities. The correlation between the altered hub organization and the phase relationship between electroencephalographic channels was investigated.

Results: Topology rather than connection strength of functional networks correlated with states of consciousness. The average path length, clustering coefficient and modularity significantly increased after propofol administration, which disrupted long range connections. In particular, the strength of hub nodes significantly decreased. The primary hub location shifted from the parietal to frontal region in association with propofol-induced unconsciousness. The phase lead of frontal to parietal regions in the alpha frequency band (8-13 Hz) observed during wakefulness reversed direction after propofol and returned during recovery.
Conclusions: Propofol reconfigures network hub structure in the brain and reverses the phase relationship between frontal and parietal regions. Changes in network topology are more closely associated with states of consciousness than connectivity and may be the primary mechanism for the observed loss of frontal-to-parietal feedback during general anesthesia.

Title: Parietal short intracortical inhibition: parietal double-pulse transcranial magnetic stimulation

Authors: R. W. PAINE[1], A. N. KARABANOV[2], C.-C. CHAO[3], *M. HALLETT[1];
[1]Human Motor Control Sec, NINDS/NIH, BETHESDA, MD; [2]Danish Res. Ctr. for Magnetic Resonance & Dept. of Exercise and Sport Sci., Copenhagen Univ. Hosp. Hvidovre, Hvidovre, Denmark; [3]Dept. of Neurol., Natl. Taiwan Univ. Hosp. No.7, Taipei City, Taiwan

Abstract: Intracortical circuits in the motor cortex have been analyzed using double pulse transcranial magnetic stimulation (TMS), but these circuits have only rarely been studied in other cortical regions. Previous experiments have shown that transcranial magnetic stimulation (TMS) of parietal cortex may facilitate or inhibit subsequent motor cortical evoked potentials. We investigated whether intraparietal circuits can be affected by double-pulse TMS, thereby altering parietal excitability, influencing the functional connection to the primary motor cortex, and thus

providing a means of assessing the intraparietal circuits.
23 healthy volunteers received TMS while seated at rest. The facilitatory and inhibitory effects on motor cortex by parietal conditioning pulses seen in previous studies were replicated. The subjects also received double-pulse stimulation of the parietal cortex consisting of a pre-conditioning TMS pulse followed by a conditioning pulse, and then a test pulse to the motor cortex. Intervals of 2, 4, and 8 ms between the parietal pre-conditioning and conditioning pulses were tested. There was significant neutralization of parietal-motor cortical facilitation by a parietal pre-conditioning TMS pulse presented 2 ms before the parietal conditioning pulse. There was also a non-significant trend toward neutralization of parietal-motor cortical inhibition by a parietal pre-conditioning TMS pulse presented 2 ms before the parietal conditioning pulse. These results suggest the existence of parietal short intracortical inhibition (pSICI) which is analogous to the short intracortical inhibition (SICI) that has previously been observed in motor cortex.

Therapeut., Columbia Univ., New York, NY

Abstract: We used a visual perceptual closure task to investigate the influence of both synesthesia, as a hyper-synchronization model, and of schizophrenia, as a hypo-synchronization

model, on the threshold of conscious perception. In grapheme-color synesthetes, letters and numbers evoke color. Synesthesia may involve hyperbinding of color and graphemes; at the neural level, binding processes are associated with increased synchronization between different features. In schizophrenia patients, neuronal synchronization is impaired and problems with perceptual processing exist.
Twenty synesthetes, 20 controls, and 15 schizophrenia patients viewed letters and numbers that elicited synesthesia for the synesthetes, and non-synaesthetic control stimuli (symbols). Stimuli were embedded in a noise background, which was colored congruently with the synesthetic color (for synesthetes) or neutrally colored (symbols). The amount of noise was parametrically varied and the visibility threshold of the embedded grapheme was determined by subjective visibility ratings. A bottom-up (increasing contrast of the grapheme) as well as a top-down (decreasing contrast) condition was included to assess hysteresis (memory) effects that aid recognition in the top-down condition.
We observed clear differences in the threshold of perception across groups in the bottom-up condition. Schizophrenia patients showed reduced recognition of the stimuli compared to the other groups, for both letters and symbols. Synesthetes in turn showed a clear behavioral advantage with a lower threshold of perception than controls, specific for the synesthesia-inducing condition (letters). Thus, synesthetic hyperbinding seems to aid synesthetes during closure. We observed a clear effect of top-down predictions - a lower perceptual threshold when subjects could anticipate the stimuli. Critically, the perceptual gain was similar in size for all groups, indicating that schizophrenia patients, in our paradigm, do not show impairment in top-down processing.
Time-frequency analyses of magnetoencephalography data showed induced gamma band activity (50-70 Hz and 80-100 Hz) over occipital sensors. For letters, synesthetes showed increased gamma power compared to controls (50-70 Hz). Schizophrenia patients showed less gamma power in the 50-70 Hz band than controls. Source localization (50-70 Hz) of successfully identified graphemes revealed activity in early visual areas (V2/V3) and in color area V4 and parietal cortex. We suggest that altered gamma activity in synesthetes reflects hyperbinding and that bottom-up deficits of perception in schizophrenia are related to gamma band activity.

Title: Development of an evaluation method for degrees of synesthetic perception

Authors: *D. NAKAJIMA[1], H. MAZAKI[1], R. YAYAMA[1], K. KATAHIRA[1], A. SHIRAIWA[1], E. AIBA[1,2,3], N. NAGATA[1];
[1]Kwansei Gakuin Univ., Sanda, Hyogo, Japan; [2]Natl. Inst. of Advanced Industrial Sci. and Technol., Hyogo, Japan; [3]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Synesthesia is a perceptual phenomenon in which one sensory stimulus involuntarily induces perception in another sense. Being able to easily distinguish between synesthetes and non-synesthetes would be useful in developing laboratory research on synesthesia. However, many current methods are based on self-reported experience, which is not sufficient for objectively discriminating between synesthetes and
non-synesthetes. Thus, in this study, we have attempted to develop and test a method that discriminates between synesthetes and non-synesthetes and that also evaluates the degree of individuals' synesthetic perception by utilizing a task to which synesthetes and non-synesthetes were expected to respond with different patterns. The test consisted of an evaluation task that measured participants' emotional responses to combinations of letters and colors for grapheme-color synesthesia and combinations of music and color for sound-color synesthesia. We then attempted to develop an objective indicator based on their response patterns. We focused on high repeatability and clarity of evaluation, which seem to be criteria for judging degrees of synesthetic perception that are unique to and typical of synesthetes. Using the task mentioned above, we tested 11 participants. Seven of them were previously identified as synesthetes and four were non-synesthetes. In order to confirm response repeatability, the experiments were conducted twice, and the second experiment was executed at least a week after the first one. In addition, during the second experiment, the order of stimulus presentation was changed compared to the first experiment. As expected, the repeatability of the evaluation of each stimulus was higher in the group of synesthetes than in the non-synesthetes. Furthermore, as the synesthetes showed emotional responses
to each stimulus more clearly, it may be possible to construct a continuous scale discriminating between synesthetes and non-synesthetes based on these two criteria of "repeatability" and "clarity."

Title: Investigating the links between spatial-numerical interactions and sequence processing using patterned TMS

Authors: *N. BIEN[1], A. T. SACK[2], C. SCHILTZ[1];
[1]Univ. of Luxembourg, Walferdange, Luxembourg; [2]Maastricht Univ., Maastricht, Netherlands

Abstract: Number perception often results in response facilitation: small numbers facilitate left hand responses, while large numbers speed up right hand responses (spatial numerical association of response codes; SNARC1). There is currently debate about whether it is the cardinality (magnitude) aspect of numerical processing that causes spatial facilitation2, or rather ordinality aspects associated with working memory coding / sequence coding strategies3,4. SNARC has also been linked to crossmodal assocations and even to spatial sequence synesthesia5,6. The neural bases of the SNARC effect are still elusive, but are mostly hypothesized to be found in parietal and frontal brain regions that are part of the dorsal 'where' processing stream7,8.

Here, we investigated if, and how, magnetic disruption (patterned TMS) of a region in right middle temporal gyrus (rMTG), previously linked to processing of overlearned ordinal sequences9, affects SNARC performance in healthy adults. In addition, we assessed the spatial layout and strength of their numerical mental representations, and correlated it with SNARC performance. Finally, we linked SNARC characteristics to sequence processing performance.

We found a significant SNARC effect in our n=30 sample ($p = 0.0001$). After inhibitive patterned TMS over sequence processing region rMTG, this SNARC effect was significantly reduced ($p = 0.027$), confirming the relevance of ordinal sequence information retrieval for spatial-numerical interactions.

However, TMS preferentially affected participants with strong left-to-right mental-numerical representations ($p=0.048$). This implies that sequence information processed in the rMTG especially contributes to spatial-numerical associations in people with stronger left-to-right mental numerical representations.

Finally, we found that whereas TMS over rMTG in general impairs sequence processing performance, it actually improves the below-average performance of the subgroup of our sample that displays the strongest SNARC effect: they perform below average on sequence processing, but improve to a normal level after disruption of the rMTG sequence processing area.

In conclusion, our data provide important new input to ongoing debates about spatial-numerical processing, especially considering the cardinal vs. ordinal nature of the effect, and individual

differences in spatial-numerical associations.

Title: Gender differences in cortico-subcortial network coupling during facial expressions

Authors: *F. R. LOAYZA[1,2], J. BUENDÍA[3], M. CELORRIO[2], F. VILLAGRA[2], B. HONTANILLA[3], M. PASTOR[2,3];
[1]Fac. of Mechanical Engin., Litoral Polytechnic Univ. (ESPOL), ESPOL, Ecuador; [2]Neuroimaging, Ctr. for Applied Med. Res., University of Navarra, Pamplona, Spain; [3]Clinica Univ. of Navarra, University of Navarra, Pamplona, Spain

Abstract: Objective: To investigate the neural mechanism underlaying facial expressions and gender differences observed during post-surgery facial paralysis rehabilitation, using fMRI.
Background: Facial paralysis rehabilitation is influenced by several factors mainly dependent of denervation time and muscle atrophy. It has also been reported that gender plays an important role in rehabilitation, being women whose perform better spontaneous facial expressions than men after surgery. Facial expressions are mainly controlled by two neuronal networks: the involuntary “emotionally driven” and the voluntary. However, little is known about the relationship between them, and moreover whether these are gender dependent.
Methods: We recruited 24 healthy volunteers (11F) to perform an fMRI experiment. The paradigm included two visually presented tasks: smile, chew and a fixation cross. For the motor

tasks, subjects were instructed to perform a slight smile/chew face movement minimizing jaw movements. Facial kinematics were also measured (CLIMA System). Imaging data were processed using SPM8-Dartel. At the second level, we used 2-way ANOVA with factors gender and task. Psichophysiological Interactions analyses (PPI) were used to evaluate connectivity of the key pre-motor regions during both tasks. A 2-way ANOVA was also used to compare PPI results.
Results: Kinematics of facial movements did not show any significant gender differences. The imaging results showed similar brain activity between male and female subjects during facial movements without significant differences between them. However, PPI results showed significant gender differences: The main effect of gender showed differences in the interaction of bilateral facial premotor region with bilateral anterior cingulate cortex including pre-SMA, amygdala and hippocampus, and to the thalami, including prefrontal, motor and premotor thalamic regions.
Conclusions: Our findings suggest that the degree of coupling of a cortico-subcortical network mediating simple facial expressions may be gender dependent.

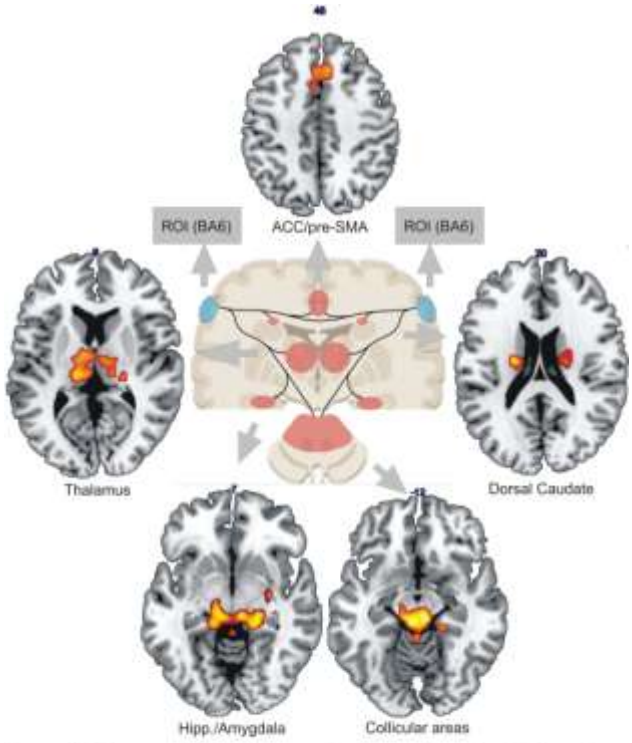

Image depicts connectivity changes in the cortico-subcortical pathway related to gender differences during facial expressions p<0.001 FDR cluster corrected

Title: Direct comparison of network connectivity revealed by resting-state fMRI and concurrent TMS-fMRI

Authors: *J. M. YAU[1], M. B. NEBEL[3], J. HUA[2], J. E. DESMOND[1];
[1]Neurol., Johns Hopkins Univ., BALTIMORE, MD; [2]Russell H. Morgan Dept. of Radiology and Radiological Sci., Johns Hopkins Univ., Baltimore, MD; [3]Kennedy Krieger Inst., Baltimore, MD

Abstract: Brain regions collaborate in distributed networks. With resting-state functional connectivity analyses, network architecture is inferred from spatially distributed, coherent low-frequency BOLD fluctuations. Resting-state connectivity patterns tend to conform to anatomical connectivity maps and there is a high correspondence between functional connectivity patterns and task-evoked coactivation patterns revealed by conventional functional neuroimaging. Despite these demonstrations, the direct relationship between correlated spontaneous BOLD fluctuations and acute neural processing remains untested in healthy adults. Because transcranial magnetic stimulation (TMS) can be used to causally evoke neural responses in targeted brain regions and in remote but connected areas, this research tool offers a unique opportunity, when paired with fMRI, to relate rs-fMRI network analysis and dynamic neural processes.
Here, we demonstrate that TMS-evoked BOLD activation patterns closely relate, but are not identical, to resting-state functional connectivity. During each scan session, we first acquired rs-fMRI data from participants, prior to TMS administration in the scanner. While participants remained at rest in concurrent TMS-fMRI scans, we causally evoked distinct and robust BOLD activation patterns with targeted brain stimulation. Using TMS target locations as region-of-interest seeds, we computed seed-based correlation maps with a separate rs-fMRI dataset (Kirby 21; http://mri.kennedykrieger.org/databases.html). Defining networks using this large and independent dataset enabled us to generate robust statistical masks that we used to query and compare each participant's rs-fMRI data and concurrent TMS-fMRI data. We found substantial overlap in TMS-evoked BOLD activation patterns and seed-based functional connectivity, providing evidence for the hypothesis that resting-state BOLD fluctuations reflect intrinsic network architecture that supports acute and dynamic neural processing. However, TMS also

evoked responses that were distinct from seed-based connectivity patterns indicating that concurrent TMS-fMRI may reveal additional network relationships.

Abstract: The bed rest protocol is designed by NASA and offers researchers from a variety of backgrounds the possibility to study bed rest as an experimental analog for space flight. It has been shown that extended exposure to a head-down tilt position can resemble many of the effects of a low-gravity environment (Seaton et al., 2009). Here, we use a head-down tilt bed rest intervention to investigate the neural and neurocognitive effects of extended duration reduced sensory inputs and increased cephalic fluid distribution (Koppelmans et al., 2013). Thus far, complete data including resting state MRI of two participants have been acquired through the bed rest facility located at the University of Texas Medical Branch (Galveston). Subjects remained in bed with their heads tilted down 6 degrees below their feet for 70 consecutive days. Behavioral measures and neuroimaging assessments were obtained at seven time points: a) two measurements took place approximately 7 and 12 days before bed rest; b) three measurements took place at approximately 7, 30, and 65 days during bed rest; and c) two measurements took place at approximately 7 and 12 days after bed rest. Functional connectivity magnetic resonance imaging (FcMRI) analysis was performed to assess the connectivity between eighteen regions of interest (ROI). Based on a prior study (Van Dijk et al., 2009) six of the ROIs were identified to be in the default mode network, six ROIs were identified to be in the attention network, and the remaining six were identified to be in the motor, visual and auditory cortex. The connectivity

matrix of the ROI regions was analyzed using graph theory for all seven time points (Rubinov and Sporns, 2010). We report that during the first week of bed rest, connectivity between regions strengthened throughout the brain, and then gradually returned to baseline levels as the bed rest period continued and remained at baseline levels during post bed rest testing.

Title: Multisensory processing in the zebrafish escape circuit

Authors: *A. M. LACOSTE, D. SCHOPPIK, D. N. ROBSON, J. M. LI, F. ENGERT, A. F. SCHIER;
Harvard Univ., Cambridge, MA

Abstract: Animals use multiple sensory systems to create an accurate perception of the world and to inform behavioral decisions. Understanding how neural circuits responsible for behavior integrate multisensory cues from the environment is a challenge due to the complexity of the networks involved. The large number of neurons in most vertebrate preparations necessitates a statistical approach to sensory representation and downstream decoding. By contrast, the Mauthner neuron-mediated zebrafish escape circuit is small and well-characterized. Yet it is a

sophisticated network responsible for a behavioral decision essential to the animal's survival. This circuit allows us to answer questions of neural computations in a transparent, behaving brain, at the level of individual genetically accessible neurons. We are investigating how a previously uncharacterized excitatory interneuron in the circuit encodes different types of stimuli to influence escapes.

Title: A thalamic reticular nucleus circuit that regulates the selection of sensory inputs

Authors: *S. AHRENS[1], S. JARAMILLO[1], S. GHOSH[1], C. LAI[2], J. Z. HUANG[1], B. LI[1]; [1]Cold Spring Harbor Lab., Cold Spring Harbor, NY; [2]Idiana Univ., Bloomington, IN

Abstract: Selective processing of some sensory stimuli at the expense of others is a fundamental brain function. The thalamic reticular nucleus (TRN) is thought to gate the transmission of information en route to the cortex. TRN neurons, which are exclusively GABAergic, receive glutamatergic inputs from the cortex and thalamus, and send projections to the thalamus where they directly modulate the activity of thalamic relay neurons. However, its role in selecting behaviorally relevant sensory cues is unclear. Here, we probed and manipulated the somatostatin (SOM+) class of neurons in the TRN, which highly express ErbB4, a gene that is involved in controlling glutamatergic synapse maturation and function and linked to psychiatric disorders such as schizophrenia. We have generated SOM/ErbB4-/- mice in which ErbB4 gene is ablated in SOM+ neurons in the TRN. Using ChR2 to selectively stimulate the cortical or thalamic input onto TRN neurons in brain slices, we found that the absence of only one copy of ErbB4 in SOM+ TRN neurons is sufficient to alter cortico-thalamic (CT) transmission but without affecting thalamo-cortical (TC) transmission. As a consequence the feed-forward inhibition of TRN neurons onto thalamic relay neurons driven by the CT-pathway is also altered. Moreover, we found that ErbB4 deficiency in SOM+ TRN neurons alters the performance of mice in behavioral tasks engaging competition of either within-modality or across-modalities sensory inputs. Our results indicate that the SOM+ TRN neurons are required for the selection of

salient sensory information, and furthermore reveal an unexpected role of ErbB4 in this process by controlling specific synapses in the cortico-TRN-thalamic circuitry.

Title: Potentiation of feed-forward inputs in auditory cortex after visual deprivation

Authors: *E. R. PETRUS[1], H.-K. LEE[2];
[2]Mind/Brain Inst., [1]Johns Hopkins Univ., Baltimore, MD

Abstract: The loss of vision causes sensory compensation in spared sensory modalities. For example, blind individuals experience enhanced performance on auditory discrimination tasks, such as tone localization (Roder et al. 1999) and pitch discrimination (Gougoux et al. 2004). The underlying synaptic changes associated with these cross-modal adaptation were first observed as global changes in the strength of excitatory synaptic inputs, which was measured as alterations in miniature excitatory post synaptic current (mEPSC) amplitudes, in visually deprived mice (Goel et al. 2006). mEPSC amplitude changes occurred in primary visual cortex (V1), with inverse changes in somatosensory (S1) and auditory (A1) cortices after seven days of dark exposure (DE). In A1, mEPSC amplitudes change in a lamina specific manner following DE, with a potentiation seen in layer 4 (L4) neurons, and a reduction in layer 2/3 (L2/3) neurons. The potentiation of inputs to L4 neurons in A1 was due to a stronger thalamocortical input. Furthermore, DE resulted in a stronger feed-forward input to L2/3 from L4. Lateral inputs to L4 were reduced in strength, which indicates an increase in the strength of feed-forward signal to lateral input ratio in A1 after DE. These changes in synaptic weights may be a mechanism underlying the enhancement of auditory performance in blind individuals.

Title: Auditory signals affect the responses of neurons in early visual stages of awake rats

Authors: *C.-I. YEH[1,2,3], K.-S. LEE[1,2];
[1]Psychology, [2]Neurobio. and Cognitive Sci. Ctr., [3]Grad. Inst. of Brain and Mind Sci., Natl. Taiwan Univ., Taipei, Taiwan

Abstract: Detecting changes is a critical feature of sensory processing. This ability can be enhanced by integrating information from different sensory modalities in natural environment. In the visual system, light increments and decrements are processed through parallel ON and OFF channels from the retina to the lateral geniculate nucleus (LGN). The ON and OFF channels then converge for the first time in the primary visual cortex (V1). Similarly in the auditory system, UP (stimulus onset) and DOWN (stimulus offset) signals remain segregated before converging in the primary auditory cortex (A1) (He, J. 2001, Scholl et al., 2010). A recent study has shown that the visual responses of most V1 neurons are greatly suppressed by auditory signals in rodents (Iurilli et al., 2012). However, it is unclear whether auditory signals may modulate V1 ON and OFF channels differently or the audio-visual modulation may depend on the degree of congruence (e.g. UP-ON versus DOWN-ON). We addressed these questions by recording from 82 V1 units and 30 LGN units in awake Long-Evans rats. Brief auditory and visual stimuli (200 ms) were presented simultaneously, and a total of 25 bimodal conditions (5x5) were used (auditory stimuli: mean: 80 dB; UP/DOWN: +13% and +25%; visual stimuli: mean: 70cd/m2; ON/OFF: +35% and +70%). Preliminary results showed that the effect of the bimodal stimulation was predominantly sub-additive for neurons in both regions - the bimodal responses were weaker than the linear combination of the two excitatory unimodal responses. Interestingly, the sub-additive bimodal response to the OFF-DOWN pair in V1 was significantly lower ($P<0.05$) than the responses under other visuo-auditory stimulus pairs. In contrast, there is no significant difference for LGN neurons among the four pairwise conditions, though the response tendencies in LGN and V1 were very similar. Overall, these results suggest that a linear combination of auditory and visual responses cannot explain the complex interaction between ON/OFF channels and UP/DOWN channels. We are applying a weighted linear model with various combinations of auditory UP/DOWN and visual ON/OFF inputs to search for possible mechanisms.

Title: Early multisensory interactions revealed through simultaneous recordings from superior and inferior colliculus in the ferret

Authors: I. STITT, E. GALINDO-LEON, F. PIEPER, K. J. HOLLENSTEINER, G. ENGLER, *A. K. ENGEL;
Dept. of Neurophysiol. and Pathophysiology, Hamburg, Germany

Abstract: The mammalian superior (SC) and inferior colliculi (IC) are highly conserved midbrain structures that are located very early along the visual and auditory processing pathways, respectively. Although the IC is thought to be primarily an auditory structure, it does receive inputs from multiple sub-cortical and cortical non-auditory structures, such as the SC. Indeed, previous studies in the barn owl have shown that the external nucleus of the IC responds to visual stimulation following pharmacological disinhibition in the avian equivalent of the SC, the optic tectum. However, the multisensory interplay between these two midbrain structures remains poorly understood in mammals. We recorded multi neuron activity (MUA) and local field potentials (LFP) from the SC and IC simultaneously with silicon multichannel probes in the anaesthetised ferret. Visual stimuli consisted of flashes and drifting gratings, while auditory stimuli consisted of clicks and pure tones. To assess multisensory effects, flashes and clicks were presented with stimulus onset asynchronies from 0 to 200ms in 10ms steps. Although flash stimuli failed to evoke spiking activity in IC neurons, we consistently observed a visually-evoked concentration of LFP oscillatory phase in the 6-10Hz and 15-30Hz frequency bands. Interestingly, phase-locking was not accompanied by an increase in oscillatory power, suggesting that visual stimuli only modulate the phase of ongoing oscillations. To determine the temporal order of flash-evoked phase-locking between midbrain structures, we computed the phase slope index (PSI) between all SC and IC probe contacts. Flash-evoked oscillatory phase changes (15-30Hz band) occur first in the superficial SC, followed by the IC, and then later by the deep layers of the SC. This suggests the superficial layers of the SC as a possible source of phase modulation in the IC. We found several cases in which MUA responses to clicks in the IC

were significantly modulated by preceding flash stimuli. In such cases, click responses were either enhanced or suppressed at specific stimulus onset asynchronies, suggesting flash-evoked oscillatory phase-locking may modulate auditory responses. Previous studies in the auditory cortex have observed similar modulation of auditory responses by somatosensory or visual stimuli. These authors suggest that resetting oscillatory phases might bias local networks towards high or low states of excitability, amplifying or suppressing responses to subsequent auditory inputs. Our data indicate that similar mechanism may be operating in the ferret IC.

Title: Responses of prefrontal multisensory neurons to mismatching faces and vocalizations

Authors: *M. M. DIEHL[1], M. D. DILTZ[2], L. M. ROMANSKI[2];
[1]Psychiatry, Univ. of Puerto Rico, Sch. of Med., San Juan, Puerto Rico; [2]Univ. of Rochester Sch. Med. & Dent., Rochester, NY

Abstract:
Evidence has suggested that the multisensory integration of social communication information enhances perception compared to the processing of unimodal stimuli. The ventral frontal lobes are one of several brain regions involved in processing social communication information including faces and vocalizations. We have previously demonstrated that single neurons in ventrolateral prefrontal cortex (VLPFC) respond to and integrate conspecific vocalizations and their accompanying facial gestures (Sugihara, et al, 2006; Diehl and Romanski, 2011). We were therefore interested in how VLPFC neurons responded differentially to matching (congruent) versus mismatching (incongruent) facial and vocal stimuli. We recorded VLPFC neurons during the presentation of movies with congruent or incongruent species-specific facial gestures and vocalizations as well as their unimodal components. Recordings showed that a subset of multisensory VLPFC neurons exhibited a significant change in neuronal activity during incongruent vocalization movies. Furthermore, the majority of these incongruent-responsive cells exhibited incongruent suppression during the early phase of the stimulus period, whereas

other incongruent-responsive neurons exhibited incongruent enhancement in the late phase of the stimulus period when compared to the neuronal responses for congruent audiovisual stimuli. These results suggest that ventral prefrontal neurons are sensitive to differences between congruent and incongruent face-vocalization stimuli that may be important in identity processing or more generally, recognition, and confirms the role of VLPFC in the processing and integration of multisensory communication information.

Title: Multisensory integration in non-human primates during a sensory-motor task

Authors: *F. LANZ, V. MORET, E. M. ROUILLER, G. LOQUET;
Dept. of Med., Univ. of Fribourg, Fribourg, Switzerland

Abstract: In everyday life our central nervous system receives signals via several sensory modalities, processes them and integrates information in order to finally produce an appropriate behaviour. The amazing part is that such a multisensory integration brings all information into a unified percept. A common approach to start investigating this property is to show that discrimination is better and faster when multimodal stimuli are used as compared to unimodal stimuli. This is what we did in our non-human primates' model (n=2) engaged in a detection sensory-motor task where visual and auditory stimuli were displayed individually or simultaneously. Our protocol allowed us to extract several types of behavioural data at every trial: a reaction time (RT) between the percept and the arm movement, a percentage of successes and errors, and the evolution as a function of time of these data to describe the impact of progressive training. As expected, the results showed shorter RTs when the subjects got combined stimuli. The gains were approximately 20msec, as compared with the auditory stimulus alone and 40msec as compared with the visual stimulus alone. These gains were similar for both subjects. In addition the number of correct responses increased when combined stimuli were delivered. The successes and errors percentages demonstrated that subjects are mainly doing execution errors rather than detection errors. We discussed such a multisensory advantage

through redundant signal effect (RSE) which decreases perceptual ambiguity, increases the speed of stimulus detection and improves the preciseness of a performance (RT facilitation).
To get a better understanding of how visual and auditory inputs are combined to generate a unified perception we collected electrophysiological data during behavioural sessions. Single units were derived from the premotor cortex and compared to previous recordings from our laboratory in another polysensory area: the temporal lobe. The results showed that some neurons presented a modulation during a period corresponding to the RTs. In response to an individual stimulus (visual or acoustic) these modulations consisted in inhibitory responses, temporal modifications, delays or an increase of activity. When two stimuli were simultaneously presented, some other neurons responded with either more spikes discharges or a total inhibition. These preliminary steps towards the ambitious goal of gaining access to the knowledge of multisensory integration could help as well to better understand still undiscovered mechanisms of some neurological disesases.

Cognitive Neurosci., Fac. of Psychology and Neuroscience, Maastricht Univ., Maastricht, Netherlands; [8]Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands; [9]Ernst Strügmann Inst. for Neurosci., Frankfurt, Germany

Abstract: Current understanding of cortical rhythms and their relationship to asynchronous local activity during sensory and motor processing is still incomplete. Previous studies suggested that variations in oscillatory activity in the alpha band (8-12 Hz) may gate information between task-relevant cortical areas by inhibiting activity in task-irrelevant areas (Klimesch 2007, Jensen 2010). Thus, modulation of alpha activity may be predictive of relative engagement or disengagement of different cortical systems during different tasks. However, the relationship of such modulatory alpha activity to population-level cortical activity in the high gamma range (70-170 Hz), and the relationship between these neural signals across different tasks, remains undefined. Our ongoing study is investigating the temporal and spatial dynamics of the modulations in the gamma and alpha-bands during auditory and motor tasks. We recorded electrocorticographic (ECoG) activity from subdural electrode grids in five human subjects with epilepsy and one macaque monkey during the presentation of natural auditory stimuli and a simple motor task. Our results confirm that gamma activity accurately tracks task-related behavior and demonstrate that alpha activity is predictively suppressed in task-relevant areas, and increased in task-irrelevant areas, respectively (i.e., for auditory stimulation, alpha suppression in auditory areas and alpha increase in motor areas). Our findings also demonstrate that in the auditory system, alpha suppression trails gamma activity, but precedes gamma activity in the motor system. This finding prompts the hypothesis that cortical excitability may be a result of sensory stimulation, but a facilitator of motor movements. We expect that with additional refinements in our analyses, this work will contribute to our understanding of general mechanisms of the coordination of auditory and motor function in the brain.

Title: Corticocortical connections of area 5 in macaque monkeys support the existence of functionally distinct medial and lateral regions

Authors: *D. F. COOKE[1,2], J. PADBERG[3], C. M. CERKEVICH[4], J. H. KAAS[4], L. KRUBITZER[1,2];
[1]Ctr. Neurosci, UC Davis, DAVIS, CA; [2]Psychology, UC Davis, Davis, CA; [3]Biol., Univ. of Central Arkansas, Conway, AR; [4]Psychology, Vanderbilt Univ., Nashville, TN

Abstract: The rostral bank of the macaque intraparietal sulcus (IPS) and the adjacent gyral surface caudal to area 2 constitutes the original Brodmann Area 5 (BA5). This region in posterior parietal cortex (PPC) has been divided into multiple cortical fields with sometimes-conflicting schemes of organization, but all evidence points to a sensorimotor function of BA5 related to reaching and grasping. We term the rostrolateral portion of BA5 lateral area 5 (5L), distinguishing it from surrounding cortex based on its functional organization and cortical architecture. The medial portion of BA5 overlaps the medial intraparietal area (MIP) and the functionally-defined parietal reach region (PRR). To further distinguish medial and lateral portions of area 5 we examined corticocortical connections of area 5 in macaque monkeys. Retrograde tracers (cholera toxin B, Fluoro-ruby, Fast Blue) were injected into electrophysiologically-identified portions of the hand representation in both lateral and medial portions of BA5. Resulting connectional data were related to histologically identified boundaries. We observed two distinct patterns of connections for lateral versus medial portions of BA5. In addition to dense intrinsic connections, 5L received dense connections from portions of areas 3a, 3b, 1 and 2 that correspond to the representation of the forelimb, from similar locations in M1, and from medial portions of BA5. Sparse to moderate connections were also observed from S2, areas 7b, 7a, premotor cortex, cortex medial to area 5 and the supplementary motor area (SMA) extending onto the medial wall.
In sharp contrast, medial BA5 received little or no input from anterior parietal cortex, M1, S2, 7b, or lateral area 5. Instead, it received dense connections from SMA, large portions of prefrontal cortex, the lateral portion of premotor cortex and from anterior cingulate cortex on the medial wall.
Our results demonstrate that cortical connections of lateral and medial portions of area 5 are distinct. Based on these data, 5L is closely associated with areas in anterior parietal cortex that process both cutaneous and proprioceptive inputs from the hands as well as motor cortex. Such inputs would be necessary for integration of forelimb posture, object properties and hand actions, a role suggested by functional studies of lateral area 5. In contrast, medial BA5 (MIP/PRR), proposed to code the intention to reach, has connections with regions of the brain associated with motor control, executive function and decision making. Further, the lack of connectivity from primary motor and anterior parietal cortex is consistent with medial BA5's putative higher-level involvement in motor control.

Title: A quantitative analysis of the topology of subcortical projections to the macaque cortex

Authors: *A. R. RIBEIRO GOMES, C. LAMY, P. MISERY, C. DEHAY, K. KNOBLAUCH, H. KENNEDY;
Stem-Cell and Brain Res. Inst., Bron, France

Abstract: Cortical areas can communicate directly, via cortico-cortical connections, and indirectly, via cortical subcortical cortical loops (CSCL). CSCL exist when the afferents to cortical area X in a subcortical structure are located in close proximity to the afferents to cortical area Y. The aim of the present study is two-fold: Firstly, to identify subcortical structures that participate in CSCL. The distance separating areas X and Y are expected to influence the existence of CSCL (Shipp et al., 2003). We have therefore examined CSCL with respect to two pairs of areas, a widely separated pair (areas 7m and 10) and a near by separated pair (areas V1 and V4). Secondly, to identify the range of structures projecting to each area and to quantify the projections of each. Two high sensitive and distinguishable retrograde tracers (FsB and DY) were injected in the target areas. High frequency plots of back-labeled neurons in subcortical structures were completed. The weight of the projection was expressed as the fraction of labeled neurons (FLNsc) in individual structures with respect to the total number of subcortical labeled neurons.
The subcortical input to areas V1, V4, 10, and 7m ranged between 3% and 8% of the total extrinsic input to these areas, the remaining 92% to 97% originated from the cortex. The two populations of neurons projecting to areas 7m and 10 were intermingled in the claustrum, intralaminar thalamic nuclei, mediodorsal thalamic nucleus, amygdala and basal forebrain. The two populations of back-labeled neurons following injections in area V1 and V4 were

intermingled in the claustrum, the pulvinar and the amygdala.
The strongest projection to both pairs of areas arises from the claustrum, followed by thalamus. Only in the case of V1 and V4 did a higher order thalamic nucleus form a strong CSCL. Given the high FLNsc value of the projection of the claustrum to all injected areas its CSCL could play an important role in long-distance communication between cortical areas (Crick& Koch, 2005).

Title: Local and long-range connections from cortex and thalamus target specific, complementary sub-cellular compartments of corticospinal neurons

Authors: *B. A. SUTER, G. M. G. SHEPHERD;
Dept Physiology, Feinberg Sch. Med., Northwestern Univ., Chicago, IL

Abstract: Corticospinal neurons (CSP) exhibit intriguing morphology: they form a prominent apical tuft in layer 1, and their perisomatic dendrites sample about half the thickness of cortex. We first quantified the three-dimensional dendritic arbors of identified corticospinal neurons (CSP) in mouse motor cortex (N=24) and found that dendritic length density across cortical layers is well predicted by somatic depth. The perisomatic and tuft compartments are separated by a thick apical trunk and may serve as substrates for a variety of computations, including coincidence detection. We wondered to what degree different projections target specific subsets of the corticospinal arbor and used optogenetic techniques to address this question. Retrograde tracing from motor cortex identified candidate origins of long-range input to corticospinal neurons. Anterograde viral delivery of channelrhodopsin-2 (ChR2) into thalamus or secondary somatosensory cortex (S2) resulted in photoexcitable axons in motor cortex; in utero electroporation delivered ChR2 to the major local input pathway (layer 2/3). Laser-scanning

photostimulation during whole-cell recordings from identified CSP revealed the subcellular localization of synapses. We found that synapses from local, long-range cortical (S2), and thalamic origins overlap in the perisomatic region, and target specific, complementary sub-regions of the apical CSP dendritic arbors. These morphological and synaptic mapping results together suggest that synaptic projections preferentially target not only specific subcellular compartments, but also specific sub-laminar populations of a single neuron class.

Title: Selective connectivity of layer 6 corticothalamic neurons with other classes of projection neurons in mouse motor cortex

Authors: *N. YAMAWAKI[1], I. R. WICKERSHAM[2], G. M. G. SHEPEHRD[1];
[1]Physiol., Northwestern Univ., Chicago, IL; [2]Media Lab., MIT, Cambridge, MA

Abstract: Motor cortex (MC) contains 3 major classes of projection neurons: pyramidal tract (PT) neurons, exemplified by corticospinal neurons; intratelencephalic (IT) neurons, exemplified by callosally projecting corticostriatal neurons; and, layer 6 corticothalamic (CT) neurons, distinguished by their axonal projections to motor thalamus (VA/VL) and the thalamic reticular nucleus. In mouse MC, we investigated the connectivity of CT neurons with CT, IT, and PT neurons using a combination of optogenetic and electrophysiological methods. We injected deletion-mutant rabies virus encoding channelrhodopsin 2 and a fluorescent protein (RV-ChR2, Kiritani et al., 2012, J. Neurosci.) into motor thalamus, contralateral striatum, or spinal cord, to label CT, IT, or PT neurons, respectively. Inert fluorescent retrograde tracers were also injected in these locations, allowing us to perform whole-cell recordings from identified projection neurons in brain slices while photostimulating the ChR2-expressing population. Preliminary results indicate a striking paucity of excitatory connections between (layer 6) CT and (layer 5B) PT neurons. In contrast, both CT and IT neurons in layer 6 received excitatory inputs from IT neurons. These results, together with previous evidence (Kiritani et al., 2012), indicate that IT neurons are upstream to both CT and PT neurons, but CT and PT neurons are mostly not directly interconnected.

Title: The control of firing pattern of midbrain periaqueductal gray neurons *In vivo*

Authors: *H. SUBRAMANIAN;
The Univ. of Queensland, Herston, Australia

Abstract: The midbrain periaqueductal gray (PAG) functions as an important component of the emotional motor system, as an integrator of behavioral responses. The PAG can be called the 'survival nucleus' because these behavioral responses are essentially coping strategies to face environmental and emotional challenges. In this context, the PAG maintains critical circuitries that control micturition, cardiovascular system, pain and analgesia and, lordosis. Respiration and vocalization being an essential activity for survival and emotional expression is also represented in the PAG (Subramanian et al., 2008; Subramanian, 2013; Subramanian and Holstege, 2013). However it is not known what type of activity patterns the PAG neurons express in vivo. In this study PAG was mapped for extracellular neuronal activity within its various subregions in vivo. Drugs were applied by direct microiontophoresis to activate silent cells and test their drug sensitivity.

In sodium barbiturate-anesthetized, spontaneously breathing and gallamine-paralyzed rats, PAG cells were found to be either nonfiring or sporadically firing. These cells were located in the lateral and ventrolateral PAG. The nonfiring PAG cells could be activated by iontophoresis of the excitatory amino acid glutamate. Cells made to fire in this manner ceased activity when glutamate ejection was terminated. Spontaneoulsy active cells were very few, restricted to the dorsal PAG region and these cells recorded extracellularly typically fired in a slow, irregular pattern. These were either non-bursting cells with a near normal distribution, or burst-firing cells typically showing a bimodal distribution.

Overall the PAG was found to be predominantly quiescent in the resting state.

However activation of the vagus or other peripheral respiratory and non-respiratory afferent interventions caused immediate activation of PAG neurons. In such instances, PAG cells showed two distinct types of activity patterns; 1) single spike firing and burst firing.

The functional implications of PAG neuronal activity are thus discussed in terms of descending motor and autonomic control.

Title: Stimulation of melanocortin 4 receptors in the brainstem inhibits GABAergic/somatostatin interneuron activity

Authors: A. LEWIN, S. VICINI, R. A. GILLIS, *N. SAHIBZADA;
Pharmacol., Georgetown Univ. Med. Ctr., WASHINGTON, DC

Abstract: Melanocortin 4 receptors (MC4-R) have been extensively documented as being important regulators of energy balance. Their distribution corresponds well with forebrain and hindbrain nuclei that have been shown to influence food intake and body weight. In the hindbrain, of particular importance are nuclei that comprise the dorsal vagal complex (DVC). Of these nuclei, the nucleus tractus solitarius (NTS) and the dorsal motor vagal nucleus (DMV) are also key regulators of gastric motility. Recently (Richardson, et al., 2013), we reported that stimulation of MC4-R in the DVC differentially affects gastric motility via a vagally mediated circuit. In particular, stimulation of MC4-Rs in the NTS inhibits gastric motility, whereas their activation in the DMV excites it. The inhibition of gastric motility by MC4-R stimulation correlates well with reduction in food intake reported for MC4-R ligands injected into the NTS. Since gastric motility is controlled to a large extent by a GABAergic projection from the NTS to the DMV (Herman, et al., 2009) we wondered if our MC4-R stimulation was directly engaging this circuit or inhibiting a local inhibitory circuit. To test this, we performed cell-attached and whole-cell recordings from red fluorescent protein (RFP) labeled somatostatin (SOM) NTS

interneurons in brainstem slices of transgenic mice. In all neurons studied, bath application of α-MSH suppressed the neural activity of SOM neurons in the medial NTS. To further determine their role in the NTS-DMV axis, electrophysiological recording were made from DiI labeled gastric projecting DMV neurons in transgenic mice expressing channelrhodopsin-2-RFP in SOM interneurons. Stimulation of SOM interneurons in the NTS with light increased the firing frequency of the DMV neurons. This was in contrast to local stimulation of SOM interneurons in the DMV, which inhibited their firing. These preliminary findings suggest that α-MSH elicits its effect on gastric motility in the NTS by inhibiting GABAergic SOM interneurons. Furthermore, they suggest that these interneurons modulate the activity of premotor neurons of the DMV by either disengaging inhibitory output from the NTS or increasing local inhibition of the DMV.

Title: Oxytocin mediates early experience-dependent crossmodal plasticity of excitatory synaptic transmission in the sensory cortices

Authors: J.-J. ZHENG[1], S.-J. LI[1], X.-D. ZHANG[1], W.-Y. MIAO[1], *X. YU[2];
[2]Chinese Acad. of Sci., [1]Inst. of Neurosci., Shanghai, China

Abstract: During the early postnatal period, neural activity, both in the form of spontaneous electrical activity and natural sensory stimulation, is critical to the formation of functional neural circuits. In addition to inducing changes within the target sensory cortex, sensory experience can also crossmodally affect other brain regions. Here, we report a novel form of plasticity in neonatal mice, where early sensory experience crossmodally regulates development of all sensory cortices via oxytocin signaling. Specifically, unimodal sensory deprivation from birth through whisker-deprivation or dark-rearing reduced excitatory synaptic transmission of layer 2/3 pyramidal neurons both in the correspondent sensory cortex, and crossmodally in other

sensory cortices. On the other hand, increasing natural sensory experience through environment enrichment significantly increased excitatory synaptic transmission in both barrel and visual cortices. Molecularly, cortical level of the neuropeptide oxytocin was bidirectionally regulated by sensory experience. Importantly, in vivo application of oxytocin elevated excitatory synaptic transmission in multiple sensory cortices, and significantly rescued the effects of sensory deprivation through oxytocin receptor mediated signaling. Together, these results further iterate the importance of multimodal sensory experience to early cortical development. We also identified a novel function for oxytocin signaling in promoting crossmodal, experience-dependent cortical development. The link between sensory experience and oxytocin signaling may be particularly relevant to autism spectrum disorders, where hyper- or hyposensitivity to sensory inputs is prevalent and oxytocin is a hotly debated potential therapy.

Title: Ultrasonic vocalization in perinatally underfed pups, and massage stimulation effects

Authors: D. LOPEZ-JIMENEZ, M. REGALADO, *M. A. SALAS;
Developmental Neurobio. and Neurophysiol., UNAM, Queretaro, Mexico

Abstract: Undernutrition produces brain morphological alterations in some areas including the caudal nucleus ambiguus (Ambc). The Ambc innervates the intrinsic laryngeal muscles, which are involved in ultrasonic vocalizations (UVs) production. Early in life, the plastic changes and auditory experience can modulate the recognition of the frequency sound specificity by the auditory thalamocortical pathway. The integration of this information, let to reproduce a sound as UVs. Somatosensory pathway is closely related to the auditory pathway in the context that the Ambc hypoplasia caused by perinatal undernutrition (PU) can be partially reduced by massage stimulation (MS). The current study analyzed the UVs at 15 PN days in Control (CG), Underfeed (UG), Control stimulated (CSG) and Underfeed stimulated (USG) groups. MS was applied 10-min daily (days 4-15 of age). The UVs were obtained by an ultrasonic microphone and recorded

as an audible signal using a bat sound Software Spectrum Analyzer 3.0. Descending calls (n=10) were analyzed by spectrum power decomposition considered as frequency and intensity. The results, indicated that dominant frequency and power intensity scores were reduced ($p<0.05$) in the UG. The aim of this study was to demonstrate that MS could induce plastic changes to prevent the damage caused by PU in UVs.

Title: Single unit activity in the monkey hippocampus related to short-term memory

Authors: *J. H. WITTIG, Jr., B. J. RICHMOND;
NIMH, BETHESDA, MD

Abstract: Single-unit activity was recorded from the hippocampus of one rhesus monkey as it performed a short-term memory task. Each trial started when the monkey grabbed a touch-sensitive bar. The task was to view a sequence of 2, 4 or 6 images on a computer monitor and report, by releasing the touch-sensitive bar either early or late, whether or not the last image of the sequence matched any of the preceding images. Each image was presented for 750 ms, with a 500 ms delay between successive images. Images were familiar and were presented repetitively throughout the testing session. In half of the trials the last image matched an image from the current sequence (early release rewarded), and in the other half of the trials it did not (late release rewarded). Behavioral performance was above 80% correct for each sequence length. We recorded the activity of 65 single units using up to 4 acute electrodes per daily testing session (25 total sessions). Approximately half of the recorded units (37 of 65) exhibited a significant change in spike rate during the last image that depended on whether or not the last image matched an image from the current sequence. For these units, an ANOVA showed that 6-45% of the trial-to-trial variance in spike rate during the last image was accounted for by match versus non-match status. We hypothesized that the observed change in spike rate reflected either a neural correlate of short-term memory of the last image (i.e., match versus non-match), or anticipation of the upcoming motor response (i.e., early versus late release). To control for the possibility of a motor-related signal, for 22 of the 65 units, we also recorded activity during a task that had the same motor requirements (early versus late release) but no short-term memory requirements

(response based on the identity of the last image, not whether it matched a preceding image). Approximately half of the units recorded during both tasks (12 of 22) had different spike rates during the last image when the task differed but the upcoming motor response was the same. We have identified three categories of single-unit activity in the monkey hippocampus immediately preceding the behavioral response to a remembered image: non-task, motor, and short-term memory related.

Title: Differential effects of TE and rhinal cortical lesions on serial recognition in rhesus monkeys

Authors: *M. A. ELDRIDGE, E. C. MASSEAU, R. C. SAUNDERS, B. J. RICHMOND; Lab. of Neuropsychology, NIMH, Bethesda, MD

Abstract: There is considerable evidence suggesting that area TE and the rhinal cortex of the inferior temporal cortex play an important role in the recognition of visual stimuli. Pharmacological, cooling and ablation studies have established a critical role for perirhinal cortex in delayed matching and non-matching to sample (DMS and DNMS) tasks. Neurophysiological recordings have found neural correlates for recency and familiarity memory within area TE, perirhinal cortex and entorhinal cortex.
We tested three TE-lesioned monkeys, three rhinal-lesioned monkeys (perirhinal + entorhinal) and three controls on a serial recognition task that did not require simultaneous comparisons between stimuli. In each trial the monkey had to indicate whether the stimulus displayed was presented for a first or second time within the session by releasing a lever in one of two intervals: either immediately after the stimulus appeared (first interval) or later when a small central target changed from red to green (second interval). Stimuli were repeated once within the session, with the interval being 0-128 stimuli. The stimulus set consisted of 6000 images of animals in natural scenes. No stimulus was reused within a 30-day period.
Performance was analyzed using signal detection theory. Control monkeys reliably differentiated between the first and second presentations of a stimulus at all but the longest intervals, 64 and

128 intervening stimuli. The ability of TE-lesioned monkeys to distinguish first and second presentations fell from a low level (considerably worse than controls) at short intervals (0 - 8 intervening stimuli) to chance levels beyond that. The performance of the Rh-lesioned monkeys was indistinguishable from that of controls, suggesting there are some types of recognition memory in which rhinal cortex may not play a role.

Title: Modelling visual categorisation experimental observations from monkeys with a reinforcement learning-based spiking neural network

Authors: *S. CHANDRA[1], M. A. G. ELDRIDGE[1], F. P. HARTMANN[2], J. P. NADAL[2], B. J. RICHMOND[1];
[1]49 Convent Drive,, Natl. Inst. of Health, NIMH-LN,, Bethesda, MD; [2]Lab. de Physique Statistique, École Normale Supérieure, Paris, France

Abstract: Visual perceptual categorization is the process through which we assign objects into categories based on some similarity in their appearance. We have shown that monkeys easily learn to discriminate between cats and dogs in a small sample set, and to generalize this ability to never-before-seen exemplars. The perceptual difficulty of the discrimination was increased by 'morphing' together pairs of cats and dogs. This produced a set of stimuli with varying degrees of feature ambiguity (with cat:dog ratios of 100:0, 90:10, 80:20 ..... 0:100). The likelihood of a monkey assigning a cue to a particular category varies sigmoidally with the morph level of the cue. There is a small bias towards one category, presumably because rewards are asymmetrical, that is, only one category is rewarded (Eldridge, et.al., SfN 2012).
Here we present a reinforcement learning-based spiking neuron model reproducing the experimental observations. The model is a neural network with only input and output layers. The input layer neurons all have tuning curves of the same shape (eg. sigmoids, triangles, rectangles, etc.), each neuron with its own parameter values. Each input neuron represents one stimulus on a continuum of stimuli, i.e., the centers of the turning curves are ordered. The spikes from the

neurons of the input layer are summed with adjustable weights by the lone output layer neuron that uses a sigmoidal function to map the summed input into the probability of making the choice leading to reward. The network learns the adjustable weights through reinforcement learning with temporal discounting (in simulations we take temporal discounting over the last 5 trials). The predicted behavioral choices match the experimental findings in producing a sigmoidal performance curve, including the bias toward the rewarded category seen in the behavioral data. We study the model analytically and prove a universality property such that the predicted behavioral results are independent of the shape of the tuning curves of the neurons. Thus, it appears the form of the tuning curves for neurons for this simple type of reinforcement driven categorization need not play a critical role in learning simple perceptual categorization.

Title: Anti-correlated spike rates associated with working memory activity in macaque dorsolateral prefrontal cortex

Authors: *M. LEAVITT[1], F. PIEPER[3], A. SACHS[4], J. MARTINEZ-TRUJILLO[2]; [2]Physiol., [1]McGill Univ., Montreal, QC, Canada; [3]Neurophysiol., Univ. of Hamburg-Eppendorf, Hamburg, Germany; [4]Dept. of surgery, Div. of neurosurgery, The Ottawa Hospital, Ottawa Hosp. Res. Institute, Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Neurons in the primate dorsolateral prefrontal cortex (dlPFC) are known to exhibit selective activity during the delay period of spatial working memory (SWM) tasks. It has been hypothesized that functional interactions between these units may be involved in SWM maintenance, but whether and how these units interact with each other remains poorly understood. In order to investigate this issue, we recorded responses of multiple single units in

dlPFC area 8a of two macaca fascicularis using microelectrode arrays. The task consisted of fixation on a central spot for 494-800ms, then presentation of a circular sine wave grating at one of 16 randomly selected locations for 507ms. The offset of the grating was followed by a delay period that could last between 494-1500ms and ended with the offset of the central fixation point, cuing the animals to make a saccade to the remembered stimulus location. We recorded the activity of neurons in blocks of 32 channels and sorted spikes using Plexon software (Plexon Inc, TX). We isolated responses of 191 single units for a total of 1170 neuronal pairs. Neurons were classified as being selective (one-way ANOVA, $p<.05$) for the spatial location of the stimulus during the stimulus presentation period (visually-selective, n = 106, or 56%) and the delay period (memory-selective, n = 125, or 66%). We then computed spike-rate correlations and quantified the proportion of significant positive and negative spike rate correlations as well as the proportion predicted by chance (shuffled correlations) in each group for each task epoch. Correlations between stimulus-selective neurons and correlations between memory-selective neurons were greater than zero during the fixation and memory periods ($p < .05$, Sign test, Bonferonni-corrected), but not the stimulus period ($p > .05$, Sign test, Bonferonni-corrected). The proportion of significant positive correlations was also greater during the memory period than during the stimulus period ($p > .05$, chi-square test, Bonferonni-corrected) in both stimulus-selective neurons and memory-selective neurons. Importantly, the proportion of significant negative correlations was greater during the memory period than during the stimulus period ($p > .05$, chi-square test, Bonferonni-corrected) only between memory-selective neuronss. Our results suggest that interactions between neurons in the dlPFC increase during the maintenance of SWM, and these interactions vary based on neurons' selectivity.

Title: MRI-assisted single-unit recording revealed precise neuronal map in the perirhinal cortices of macaque monkeys performing a visual pair-association task

Authors: *K. W. KOYANO[1], M. TAKEDA[1], T. MATSUI[1,2], Y. OHASHI[1], T. HIRABAYASHI[1], K. KAKIZAWA[1], T. WATANABE[1], Y. MIYASHITA[1,2];
[1]Dept. of Physiol., The Univ. of Tokyo Sch. of Med., Tokyo, Japan; [2]Dept. of Physics, The Univ. of Tokyo Sch. of Sci., Tokyo, Japan

Abstract: The perirhinal cortex is a part of the medial temporal lobe system and is known to be important for visual stimulus-stimulus associative memory. Although previous single-unit studies in this area have revealed activity patterns for each neuron, spatial profiles for these neurons, especially along the depth direction within the cortex, were difficult to determine because of technical problems with localizing recorded neural activities *in vivo* with fine resolution at a sub-millimeter scale. Here, we recorded single unit activities from the perirhinal cortices of two macaque monkeys performing a pair-association memory task, and precisely mapped the position of all the recorded activities at a resolution of 150 μm with the assistance of high-resolution structural magnetic resonance imaging (MRI) (Matsui et al. 2007, Koyano et al. 2011). In each recording session, we semi-chronically implanted a tungsten microelectrode at a target region and performed single-unit recording in an awake state and MRI scanning under anesthesia (a fast spin-echo sequence with a 4.7-T Bruker MRI scanner, TE/TR = 60/3000 ms) alternately on successive days. The recording track in each session was reconstructed from the microelectrode tip positions on the MRI images similarly to the way that conventional acute-experiment studies reconstruct from electrolytic lesions on histological sections. The reconstructed neuronal map (n = 1145 neurons) revealed a cluster of neurons selective for visual cue stimuli (one-way analysis of variance, $p<0.01$) within area 36 of the perirhinal cortex, shaped like a cylindrical column. Within the cluster, the stimulus-selective neurons located in the deeper region frequently showed strong stimulus selectivity during the delay period following a cue-stimulus presentation, while those located in more superficial region showed the delay selectivity only occasionally. These results indicate that neurons in the perirhinal cortex were not randomly distributed but were spatially organized according to their response properties both in terms of their cylindrical clustering within the perirhinal cortices as well as their functional dissociation across the cortical depth within the cluster.

Title: Dissociation between behavioral flexibility and persistent memory of cue-reward contingency represented by the activities of perirhinal (PRh) neurons in macaque monkeys

Authors: *M. K. ERADATH[1,2], T. MOGAMI[1], K. TANAKA[1];
[1]Lab. for Cognitive Brain Mapping, Brain Sci. Institute, RIKEN, Saitama, Japan; [2]Joint Frontier Studies, Grad. Sch. of Sci. and Engineering, Saitama Univ., Saitama, Japan

Abstract: To clarify the nature of reward-related activities in PRh cortex, we recorded responses of PRh cells under a task in which the cue-reward contingency changed depending on the contextual time frame. Visual cue presentation and reward delivery were repeated twice in each trial, in a sequence of cue, reward (or no reward), cue, reward (or no reward) with temporal delays at each interval. The monkeys had to keep pressing a bar and fixating the gaze until the timing of second reward delivery was over. There was a fixed cue-reward contingency in the first part of trial (half of 24 cues predicted reward, and the remaining cues predicted no reward), whereas reward was randomly provided in the second part. The gaze-fixation break frequency and water-tube-sucking strength showed that the monkeys anticipated the reward condition in the first part, but not in the second part. Responses of PRh cells to reward-contingent cues were different from those to no-reward-contingent cues in the first part, but not in the second part. Thus, it has been shown that activities of PRh cells integrate the cue-reward contingency with the contextual time frame. After several months of recordings, we shifted the cue-reward contingency from the first to second part of trial: the reward delivery was now random in the first part but contingent on cues in the second part. The monkeys' behavior followed the change within a few days, whereas many PRh cells continued to exhibit differential responses in the first part for about a month. Reward-anticipatory activities eventually moved to the second part after this period. These results suggest that the reward-anticipatory PRh activities are not a simple reflection of monkeys' anticipation or motivation, but are more persistently dependent on the past long-term experiences. Finally, we introduced the contextual change within each daily session. The cue-reward contingency existed only in the first part of trial for the first 400 trials, and then moved to the second part for the remaining trials of the day. The monkeys' behavior followed the contextual change within 100 trials. Many PRh cells showed reward-anticipatory activities in the contingent part only before or after the contextual change, although some others

followed the contextual change. The quick switch of monkeys' behavior might occur by alternatively turning on two groups of PRh cells that memorized cue-reward contingency in different parts of trial.

Title: Timescale limitations of perceptual expectation on fMRI repetition suppression

Authors: *E. J. WARD, M. M. CHUN;
Yale Univ., New Haven, CT

Abstract: Predictive coding theories propose that the brain actively anticipates forthcoming stimuli and events (e.g. Friston, 2005), reducing processing demands when sensory evidence matches a predictive template and generating an error signal to increase processing when input deviates from the template. One fMRI measure of processing demands is repetition suppression, in which the fMRI signal is lower for repeated items. Thus, when a stimulus is predictable (such as when it is more likely to repeat), predictive coding accounts posit larger repetition suppression (greater amplitude difference between first and subsequent presentations) -- prior studies confirmed that increased probability and expectation of a repetition resulted in greater repetition suppression for images repeated in quick succession (Summerfield et al., 2008). Repetition suppression can occur across short and long repetition intervals, even with many intervening stimuli, but the mechanisms that drive the effect may differ for different timescales (Epstein et al., 2008). Therefore, in this study, we investigated whether perceptual expectancy, manipulated by varying the probability of stimulus repetition, can modulate repetition suppression at long intervals and with intervening items. We scanned 22 participants while they viewed sequences of scenes, many of which repeated after 7 seconds (no intervening scene) or 17 seconds (one intervening scene) at either 25% or 75% probability. We measured repetition suppression between the first and second scene presentations. In the parahippocampal place area (PPA), repetition probability (perceptual expectation) did not affect the magnitude of repetition

suppression, indicating that perceptual expectation effects at short lags may not extend to long intervals. These results have implications for models of short- and long-interval repetition suppression and suggest timescale limitations for theories of predictive neural coding.

Abstract: One of the fundamental questions in neuroscience is to understand how encoding of sensory inputs is maintained across neuronal networks in cerebral cortex to influence sensory processing and behavior. We examined the brain's remarkable ability to spontaneously evoke previous visual experience in the absence of sensory input. Published studies using single-cell electrophysiology in cat visual cortex and monkey visual area V4 have shown that ongoing activity resembles previously evoked responses to natural movies or image sequences (Yao et al., Nature Neuro, 2007; Eagleman & Dragoi, PNAS, 2012). Surprisingly, given reactivations fundamental role in sensory processing whether and how reactivation occurs in human cortex is unknown. We decided to explore reactivation in the context of human electrocorticography (ECoG) recordings. We measured neuronal activity as changes in the local field potentials in four human patients and assessed reactivation (number of electrodes = 444) across multiple frequency bands in response to dynamic visual stimulation. The experiment consisted of multiple trials in which human subjects were exposed to either short cartoon movies or blank screens. Each session began and ended with 25 blank fixation trials (pre and post), while the visual sequence consisted of 50 interleaved movie and blank trials. On all trials, subjects were required to maintain fixation in the center of a computer screen while performing a letter identification

task. To evaluate cortical reactivation we assessed the degree of similarity between the ECoG signals filtered across frequency bands. Specifically, we computed the distance between the Hilbert amplitude sequences during pre and movie, D(pre, movie), and between the HA sequences during movie and blank, D(movie, blank). If D(movie, blank) was significantly higher than D(pre, movie) across trials, the electrode was considered to exhibit cortical reactivation. We observed that, irrespective of cortical location, the highest percentage of reactivation electrodes (~ 60%) was found in the gamma-band (32-128 Hz). Is reactivation localized to a specific cortical region? We observed the highest percentage of reactivation electrodes (~ 44%) in the frontal (N = 35) and temporal lobes (N = 29). Numerous control experiments assessed the degree of reactivation during the inter-trial-interval, in response to different movie/blank conditions and the capacity of signal in during the post. Our results indicate a surprising degree of plasticity in human cortical networks in the absence of visual stimulation that may constitute the neural basis of learning by stimulus exposure in the absence of attention.

Title: A resource view on visual short-term memory for multi-feature objects

Authors: *H. SHIN[1], R. VAN DEN BERG[3], W. MA[2];
[1]Neurosci., [2]Baylor Col. of Med., Houston, TX; [3]Computat. and Biol. Learning, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Studies of visual short-term memory (VSTM) for multi-feature objects have typically asked three questions: 1) Do observers remember integrated objects or individual features? 2) Can observers remember the same number of features regardless of how many objects they belong to? 3) Do salient irrelevant features affect performance? These questions are often studied in the framework that VSTM has a discrete, limited capacity. In an alternative view, VSTM resource is a continuous quantity; the more resource a feature receives, the higher its precision. Within this new framework, we reformulate the above questions as: 1) Is resource shared between features? 2) Are the resources for different features independently allocable to objects?

3) Can salient irrelevant features be ignored during decision-making?
We used the same change localization paradigm to answer all three questions. In Experiment 1, human subjects briefly viewed four ellipses with random orientations and colors. After a 1-second delay, a second display containing four ellipses appeared, exactly one of which had changed. In the one-relevant-feature condition, the change occurred always in the same feature - either orientation or color. In the two-feature condition, the change occurred randomly in either feature. Observers reported the location of the change.
We found that psychometric curves were identical between both conditions, suggesting that VSTM resource is not shared by features. To rule out that resource is shared by features but the irrelevant feature automatically takes up resource, we compared the one-relevant-feature condition with a truly-one-feature condition that used colored discs or grey ellipses. Performance was not affected by the presence of the irrelevant feature.
To address the second question, in Expt. 2, we compared the two-feature condition from Expt. 1 to a condition in which the features of each item are spread out over two objects (producing 8 single-feature objects) and to the two-feature condition with set size 8. We found that performance in the 'spread-out' condition lied in between performance in both two-feature conditions, suggesting that some but not all feature resources are allocated together.
Finally, we compared the one-relevant-feature condition from Expt. 1 to a condition in which all objects change in the irrelevant feature and only one changes in the relevant feature. Performance was identical between both conditions, suggesting that observers can ignore changes in the irrelevant feature.
We conclude that there exist independent pools of VSTM resource for orientation and color, but they are distributed over objects in a partially dependent manner.

Title: Contrasting left and right perirhinal cortex recruitment during visual processing of verbal and non-verbal stimuli

Authors: *M. A. DALTON, M. HORNBERGER, J. R. HODGES, O. PIGUET;
Neurosci. Res. Australia, Sydney, Australia

Abstract: Background The medial temporal lobes (MTL) contain structures that are crucial for memory processing including the hippocampus, parahippocampal gyrus and perirhinal cortex. Recent evidence suggests that the perirhinal cortex sits at the apex of the ventral visual processing stream and is involved in binding higher order representations of complex visual stimuli. As such, in addition to mnemonic processing, this region is implicated in perceptual processing. In addition, functional neuroimaging and clinical lesion studies indicate that information in the MTL may be lateralised depending on the type of material being processed, with left and right MTL preferentially engaged in processing verbal and non-verbal stimuli respectively. While functional neuroimaging studies have provided support for each of these positions, no study has directly contrasted MTL contributions to visual processing of semantic and non-semantic stimuli in the same group of subjects. The aim of this study was to determine the extent to which the perirhinal cortex is involved in visual processing of verbal and non-verbal stimuli. **Methods** Twenty right-handed adults (6 females; mean age = 26 years) participated in an fMRI experiment comprising two memory tasks: (i) a recognition memory task using compound words, (ii) a recognition memory tasks using complex symbols. The neural correlates of visual processing for each stimulus type were analysed using fMRI data from the encoding phase of each task. The fsl-feat software package was used to analyse the data. **Results** We observed increased BOLD signal in the left perirhinal cortex during visual processing of compound words. In contrast, increased BOLD signal was observed in the perirhinal cortex bilaterally during visual processing of complex symbols with a greater cluster size and signal strength in the right perirhinal cortex. We found no evidence for recruitment of other MTL substructures in either condition. **Conclusions** The results of this study provide evidence that (i) the perirhinal cortex is recruited during visual processing of verbal and non-verbal stimuli and (ii) that there is asymmetrical recruitment of the left and right perirhinal cortex during perception of verbal and non-verbal stimuli respectively. These findings have important implications for theoretical models of MTL involvement in visual processing.

Title: Biophysical mechanism of the omitted stimulus response

Authors: *N. DESHMUKH[1], F. S. SOO[1], G. W. SCHWARTZ[3], M. J. BERRY, 2[2];
[1]Mol. Biol., [2]Princeton Univ., Princeton, NJ; [3]Univ. of Washington, Seattle, WA

Abstract: The retina constitutes the earliest stage of visual processing. Surprisingly, even without feedback from the brain, the retina is capable of detecting complex stimulus patterns. Retinal ganglion cells respond to interruptions of periodic flash sequences with an extra burst of action potentials. Over a broad range of flash train frequencies, the latency of this Omitted Stimulus Response (OSR) corresponds precisely to the time of the missing flash (Schwartz *et al., Nat Neurosci.* 2007). However, the biophysical mechanisms by which the retina generates this extra response and entrains to the frequency of the flash sequence have not been determined. Several competing models have been proposed to explain the origin of the OSR. One class of models proposes a frequency-tunable resonant element in ON bipolar cells that continues to oscillate when the flash sequence is interrupted. Ganglion cells combine this additional oscillatory input from the ON pathway with the OFF pathway to generate the OSR (Gao *et al., Network* 2009). An alternative hypothesis is that appropriately timed OSRs in the input currents of ganglion cells are simply due to temporal integration of several flashes and can be explained by a simple linear-nonlinear model with a spike threshold. (Werner *et al., J. Neurophysiol.* 2008). In order to distinguish between these and other possibilities, we characterized the responses of individual ganglion cells and bipolar cells to single flashes and interruptions of flash trains using whole-cell patch clamp recording.
Voltage-clamped bipolar cells show strong adaptive gain control during periodic flash sequences and can generate an extra synaptic current in response to both single flashes and the interruption of a flash train. These nonlinearities in the input current are not consistent with either model of the OSR. Additionally, the timing of this extra response does not depend on stimulus period. In contrast, voltage-clamped retinal ganglion cells exhibit strong OSRs in their excitatory input currents. These data suggest that a period-dependent transformation of the extra response occurs at the bipolar to ganglion cell transfer.

Title: The role of bipolar cells in direction selectivity circuitry examined by a novel fluorescent labeling technique

Authors: *A. POLEG-POLSKY, J. S. DIAMOND;
Synaptic Physiol. Section, NIH/NINDS, Bethesda, MD

Abstract: Retinal on-off Direction Selective Ganglion Cells (DSGCs) respond to images moving in a specific direction across the retina. This computation is thought to rely on directionally tuned input from Startburst Amacrine Cells (SACs) and Bipolar cells. In a previous study we postulated that tuning of bipolar cells' input may be an artifact of inadequate space clamp when recording DSGC activity with a somatic patch electrode.
To probe directly whether bipolar cells are directionally selective, we developed a novel technique of loading bipolar cells with fluorescent indicators by a mechanical tissue manipulation. This new method produces very bright and sparse labeling of individual bipolar cells while preserving light responses. By filling the cells with OGB-1 and performing two-photon imaging from axon terminals of bipolar cells and dendrites of patched DSGCs we could simultaneously record pre- and post-synaptic calcium signals and EPSPs. Our initial findings are consistent with directionally unselective bipolar signals.
To examine how synaptic inputs from multiple sources are integrated in a DSGC we performed a multi-compartmental computer simulation of a DSGC. The simulation revealed that directionally unturned glutamatergic inputs from bipolar cells can produce tuned NMDAR currents due to postsynaptic interactions with inhibitory inputs from SACs. Our simulation suggests that NMDAR conductance can uniquely increase the gain of a DSGC without reducing the direction selectivity of the response.

Title: Model-based analysis of an electrically-coupled amacrine cell network in primate retina

Authors: *A. K. HEITMAN[1], M. GRESCHNER[2], G. D. FIELD[3], P. H. LI[1], D. AHN[1], A. SHER[4], A. M. LITKE[4], E. J. CHICHILNISKY[1];

Abstract: Amacrine cells are the most diverse cell class in the retina, and many of the ~25 distinct types are poorly understood. Using dense multi-electrode recordings in primate retina, we recently discovered a novel polyaxonal amacrine cell (PAC) type via its electrical coupling to ON-parasol ganglion cells. To understand how this PAC type shapes visual signals transmitted to the brain, here we introduce model-based quantitative analysis of inhibitory interactions between PACs and ON-parasol cells during visual stimulation.
PACs were identified using the electrical image, i.e. the average voltage deflection across the multi-electrode array during a spike (Litke et al, 2004). The electrical image revealed the soma and axon of recorded cells. However, additional structure in the electrical image also revealed multiple outwardly radiating processes, likely corresponding to axons of PACs electrically coupled to ON-parasol cells (Dacey & Brace, 1992). Analysis of spontaneous activity revealed negative correlations between ON-parasol cells coupled to PACs and other ON-parasol cells near the PAC axons. Thus, PACs mediate lateral inhibition in the ON-parasol network.
To understand the functional impact of PAC inhibition, we developed model-based quantitative analysis of network interactions during visual stimulation. A generalized linear model (Pillow et al, 2008) was fitted to ON-parasol cell spike trains, capturing their dependence on the visual input and their association with simultaneously recorded spikes from PACs coupled to ON-parasols. During a white noise stimulus, negative correlations between distant ON-parasols were undetectable, presumably due to larger stimulus driven response fluctuations. However, clear inhibitory interactions lasting 2-3 ms were observed as feedback terms in model fits. To understand the effects of this inhibition during structured visual stimulation, responses to a central (excitatory) grating with a peripheral (suppressive) grating were recorded. Comparison to simulations suggested that each ON-parasol cell receives inhibitory input from tens of PACs. These results indicate that an electrically coupled network of PACs provides homotypic surround suppression to a major pathway in the primate visual system.

Title: Morphology of tyrosine hydroxylase-immunoreactive amacrine cells in the retina of developing gerbil

Authors: H. IMADA[1], K. SAKAI[2], *E.-I. MIYACHI[1];
[1]Dept Physiol, Fujita Hlth. Univ. Sch. Med., Toyoake, Aichi, Japan; [2]Dept Anat, Fac Clin. Engin, Fujita Hlth. Univ. Sch. Hlth. Sci., Toyoake, Aichi, Japan

Abstract: The development of dopaminergic neurons in the mammalian retina has been studied by using immunocytochemical method with antibody against tyrosine hydroxylase (TH) . We examined the shape, localization and cell population change of the TH-immunoreactive (TH-IR) amacrine cells in the gerbil (*Meriones unguiculatus*) retina from postnatal day (P) 1 to adult. Gerbils were given a dose of Nembutal, and then perfused transcardially with 0.1M phosphate buffer (PB; pH 7.4) for wholemount preparations, with 0.1M phosphate buffer added to 4% buffered paraformaldehyde for sections. After removed eyeballs were frozen with a rapid jet of liquid carbon dioxide, they were cut with section of 16μm using a cryostat. The sections and wholemount preparations were incubated in rabbit anti-tyrosine hydroxylase for 24h at 4°C. They were examined by ABC (avidin-biotin-peroxidase complex) staining method. We have found two kinds of TH-IR amacrine cells (type A and type B). The two types were clearly different in the shape of somata and stratification of TH-IR dendrites in the inner plexiform layer (IPL) at P7. Type-A TH-IR cells had monostratified dendrites extending in the outermost layer of the IPL, while type-B cells had dendrites extending in the middle of IPL. At P7, type-A somata were observed in the inner part of the inner nuclear layer (INL), its dendrites extended into the outer part of the IPL. Type-B somata were located in the inner part of the newly formed INL. Its dendrite was observed to spread in the middle of the IPL. At P14, type-A somata had grown considerably. The stem dendrites branched from the thickly stained and larger pyriform soma, spreading horizontally only in the outermost of the IPL. Type-B somata had also grown considerably, the dendrites went through TH-IR fibers of the outer part of the IPL, and then spread in the middle of the IPL. At P28, type-A somata became spherical and significantly larger, and more thickly stained, located in the vicinity of outermost layer of the IPL. The dendrites of type B extended in the middle of the IPL, where the point-like layer was observed.

In adult type A, densely stained, round-shaped and large somata were located in the innermost part of the INL, and their dendrites with varicosities extended into the outermost part of the IPL. Adult type-B somata, on the other hand, were stained weakly, with their thin dendrites penetrating the outer part of the IPL. These results suggest that two kinds of dopaminergic amacrine cells have different developmental properties in the developing gerbil retina. Eye opening is an important period for the maturation of dopaminergic amacrine cells and for the maturation of the IPL.

Title: Feedback from horizontal cells to cones: An unexpected synthesis of an ephaptic and a pH-mediated system

Authors: *R. VROMAN, L. KLAASSEN, M. HOWLETT, J. KLOOSTER, T. SJOERDSMA, M. KAMERMANS;
Retinal Signal Processing, Netherlands Inst. For Neurosci., Amsterdam, Netherlands

Abstract: Horizontal cell (HC) to cone photoreceptor negative feedback generates the centre-surround organization of the bipolar cells. The mechanism behind this inhibitory communication has been a matter of debate in the last decades and is mainly centred on two hypotheses: an ephaptic and a proton-mediated mechanism. We show that negative feedback is mediated by an unexpected synthesis of both mechanisms. The ephaptic mechanism is extremely fast without a delay and does not add any significant filtering to the signal. The pH modulation mechanism is much slower, with a time constant of 189 ± 25 ms and depends on the release of ATP via Pannexin 1 (Panx1) channels located on the HC dendrite. Instead of acting on purinergic receptors, the ATP is extracellularly hydrolysed to AMP, phosphate groups and protons by the ecto-ATPase NTPDase1. The phosphate groups and protons form a pH buffer with a pKa of 7.2,

acidifying the synaptic cleft. This leads to an inhibition of the presynaptic calcium channels and consequently decreased glutamate release from the photoreceptor. Hyperpolarisation of the HCs closes the Panx1 channels leading to a decrease in pH buffer capacity resulting in an alkalinisation of the synaptic cleft and disinhibition of the calcium current. The result is an increase in glutamate release. Our findings not only resolve a longstanding controversy in retinal research, it also shows a fully novel form of synaptic modulation. Since Pannexin 1 and NTPDase1 are abundantly expressed throughout the central nervous system, it is likely that this mechanism is more widely spread than just in the first retinal synapse.

Title: Horizontal cells inhibit photoreceptors via an unconventional GABA- and pH-sensitive mechanism in rat retina

Authors: X. LIU[1], A. A. HIRANO[1], X. SUN[1], N. C. BRECHA[1], *S. A. BARNES[2]; [1]UCLA, Los Angeles, CA; [2]Dalhousie Univ., Halifax, NS, Canada

Abstract: Horizontal cells send inhibitory feedback to photoreceptors, helping form centrer-surround antagonistic receptive fields in the retina, but the neurotransmitter and the mechanisms underlying this signalling are not known. The proteins responsible for conventional Ca^{2+}-dependent release of GABAergic synaptic vesicles are present in mammalian horizontal cells so

we investigated this mechanism as the means by which horizontal cells inhibit photoreceptors. Using Ca^{2+} imaging in rat retinal slices, we confirmed that horizontal cell depolarization with kainate inhibits and horizontal cell hyperpolarization with NBQX disinhibits the Ca^{2+} signals produced by activation of Ca channels in photoreceptors, actions that were blocked by HEPES. While 100 μM Co^{2+} reduced photoreceptor Ca^{2+} signals, it disinhibited them at 10 μM, an effect reminiscent of earlier studies where low [Co^{2+}] eliminated feedback. The low [Co^{2+}] disinhibition was pH-sensitive, being eliminated by HEPES. We localized L-, N-and P/Q-type Ca channels in rat horizontal cells, and showed that both the N-type Ca channel blocker ω-conotoxin GVIA and the P/Q-type Ca channel blocker ω-agatoxin IVA increased Ca^{2+} signals in photoreceptors in a pH sensitive manner. Pronounced actions of GABAergic agents on feedback signals to photoreceptors were observed, and are pH-sensitive, but are inconsistent with direct inhibition by GABA of photoreceptor [Ca^{2+}]. Patch-clamp studies revealed that GABA activates a conductance having high bicarbonate permeability in isolated horizontal cells, suggesting that the commonality of pH-sensitivity throughout these results could arise from a GABA autofeedback action in horizontal cells. This conductance increase could change cleft pH with concomitant inhibitory influences on photoreceptor Ca channels.

Title: Evaluating post synaptic densities and ribbon synapses in mouse models of glaucoma

Authors: *T. A. JENRETTE[1], C. BENOIST[2];
[1]Georgia State Univ., Jonesboro, GA; [2]Med. center, Vanderbilt Univ., Nashville, TN

Abstract: The Calkins lab works toward the overall goal of better understanding both why and how glaucoma causes vision loss. Glaucoma has been described as a disorder for which the major risk factor is elevated intraocular pressure (IOP) leading to damage of the optic nerve. This however, is a simple explanation for a complex problem. Current glaucoma treatments focus on lowering the IOP and not on preserving the cells in the retina and their function. Because treatment is not aimed at preserving or recovering the function of retinal cells, glaucoma eventually progresses and results in blindness. Additionally, lowering IOP fails to aid patients suffering from normal tension glaucoma, a form of glaucoma in which IOP is not elevated but progression of the disease is the same. A better understanding of the mechanisms underlying retinal degeneration in glaucoma would make preventative or regenerative treatment options possible. Previous research has shown that RGCs undergo significant and detrimental changes during the early stages of glaucoma, and that there is an inverse relationship between elevated IOP and the number of retinal ganglion cell (RGC) bodies, dendrites and synapses in the retina. In this experiment, we evaluated the number of RGC synapses in the retinas of DBA/2J and microbead injected C57 mice by performing immunohistochemistry with antibodies specific for the synaptic proteins post-synaptic density protein-95 (PSD-95) and RIBEYE. DBA/2J mice are a strain that is predisposed to two forms pigmentary glaucoma (IPD and ISA). Glaucoma occurs in these mice as a result of the crumbling of the iris pigment or iris stroma that blocks aqueous humor drainage and elevates IOP. In the C57 mouse model (MOM) glaucoma is induced via microbead injection into one eye to block outflow and increase IOP. The other eye receives a saline injection and thus serves as the control. In either model, the elevated pressure damages the retina and allows us to examine the effect of IOP on RGC synapses. Confocal images indicated a decrease in the number of PSD-95 and RIBEYE positive synapses in retinas with elevated IOP. These data suggests a correlation between IOP and the number of synapses present. Future studies will reveal more information about specific signaling events that lead to synaptic loss.

Title: The interplay between proton gradients and chloride flux in retinal amacrine cells

Authors: *V. S. KRISHNAN, E. GLEASON;
Louisiana State Univ., Baton Rouge, LA

Abstract: Previous research from our lab has shown that nitric oxide (NO) releases Cl^- from an internal store and that the release is dependent upon a transient acidification of the cytosol (Hoffpauir 2006; McMains and Gleason 2011). Our strongest candidates for internal Cl^- stores are endosomal compartments which contain 20-60 mM Cl^- and maintain a low pH via the V-type H^+ pump. Furthermore, coupled antiport of H^+ and Cl^- has been shown for ClC transporters which are known to reside on endosomal membranes. Here we test the hypothesis that the distribution of protons across internal membranes influences the ability of NO to release internal Cl^-. We have previously reported that the weak bases methylamine (MA, 10mM) and chloroquine (CQ, 100µM) reliably reduced the LysoSensor fluorescence signal. This effect is likely due to the buffering action of MA and CQ in acidic compartments such as endosomes where LysoSensor accumulates. To test the consequences of buffering on the NO-dependent release of internal Cl^-, we made whole cell voltage clamp recordings from individual chick amacrine cells in culture. Voltage ramps were delivered in the presence of GABA (20µM) to activate $GABA_A$ and the reversal potential ($GABA_{rev}$) of the current was measured under different conditions. The initial reversal potential of the GABA-gated current was more positive in MA and CQ (internal solution) than under control conditions (p=0.01 for both) suggesting that cytsolic Cl^- was elevated when endosomal pH was buffered. After NO, $GABA_{rev}$ moved negative under buffering conditions suggesting that cytosolic Cl^- was taken up into the store or expelled from the cell. To test whether the H^+ gradient across internal membranes was required for the NO-dependent release of internal Cl^-, we used the protonophore carbonyl cyanide 4-(trifluoromethoxy)phenylhydrazone (FCCP, 1µM) to collapse H^+ gradients and bafilomycin (1µM) to inhibit the V-type H^+ pump. In LysoSensor experiments, we consistently observed a reversible reduction in LysoSensor fluorescence with both reagents consistent with H^+ leaking from acidic compartments. In voltage clamp experiments, we held amacrine cells at -70mV under Cl–free internal and external conditions to isolate the Cl^- store. Pulses of GABA (20µM, 400msec) were applied to test whether cytosolic Cl^- was available to carry an inward current. Under control conditions, no GABA-gated currents were observed until NO was applied. In FCCP external solution, the NO-dependent release of internal Cl^- was not observed. These results suggest that the H^+ gradient across internal membranes is an important component in the machinery that controls the NO-dependent release of internal Cl^-.

Title: Circadian-induced AMPA Receptor plasticity in retinal ganglion cells

Authors: *M. D. PEDISICH, S. NAWY;
Neurosci., Albert Einstein Col. of Med., Bronx, NY

Abstract: The retina is a dynamic tissue that can process a wide range of visual inputs. To do so, network and synaptic properties of retinal cells must be adaptive. Long term adaptations can take place in accordance to circadian rhythm and a number of processes in the retina oscillate with a day/night cycle. AMPA receptor (AMPAR) composition and membrane density are key to plasticity in many parts of the central nervous system, including in the cortex, hippocampus, and cerbellum, and may play a similar role in the retinal ganglion cell (RGC) membrane. All signals in the retina converge on RGCs, which are the sole output of the retina. Previous work has suggested that short-term changes in AMPAR subunit composition can adjust the sensitivity of RGCs to light. Furthermore, AMPARs have been shown to be able to switch from a cycling state to a non-cycling state depending on long-term activity. Here, our goal is to understand how AMPAR cycling in RGCs is induced and how it affects the function of RGCs in the retinal circuit. A change in AMPAR cycling states in the membrane of RGCs is circadian-driven and relies on rod/cone photoentrainment. Further, receptor cycling induces changes in the synaptic properties of the RGCs which change their sensitivity to light. RGCs during subjective night, expressed an smaller relative number of GluR2-containing AMPARs while RGCs during subjective day mediated AMPAR response almost entirely via GluR2-containing AMPARs. This phenomenon persisted in a circadian-driven fashion and affects the relative light sensitivity of the RGC.

Title: ipRGCs mediate ipsilateral pupil constriction

Authors: *T. M. SCHMIDT[1], A. C. RUPP[1], K. S. CHEW[1], B. YUNGHER[3], K. K. PARK[3], S. HATTAR[2];
[1]Biol., [2]Biology, Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]Univ. of Miami, Miami, FL

Abstract: A recent finding demonstrated a larger constriction in the direct versus consensual pupillary light reflex (PLR) across several light intensities. In explanation, the authors provided evidence that the mammalian iris is directly photosensitive and requires the photopigment melanopsin, known for rendering a subset of retinal ganglion cells (RGCs) intrinsically photosensitive (ipRGCs). This exciting discovery challenged the dogma that the mammalian retina, and, specifically, ipRGCs are the only contributors to PLR. Given the identification of a novel pupil pathway, we sought to determine the relative contribution of ipRGCs and the iris muscle itself to the direct PLR. To achieve this, we performed optic nerve crush to kill RGCs (including ipRGCs) and study the intrinsic iris muscle PLR in isolation. We were surprised to find that the direct PLR was abolished 8 weeks following injury, suggesting that RGCs are necessary for this reflex. To correlate RGC death with the lack of pupil constriction, we measured the PLR for the first week following optic nerve crush and found that some constriction persisted in the initial days following injury and then declined as RGCs began to die. This indicates that RGCs are sufficient to drive the PLR independent of any brain circuitry. In support of these findings, we found that neuronal firing is critical for the PLR, as tetrodotoxin abolished pupil constriction except for a small response at very bright light intensities. Given these findings, we examined whether ipRGCs could directly mediate constriction via a direct projection from the retina to the iris muscle. In support of a role for ipRGCs in the direct PLR, we observed genetically labeled ipRGC axons coursing through both the dilator and constrictor muscles of the iris. We also found that although the consensual PLR is essentially lost in animals lacking the ipRGCs that project to pupil centers in the brain, the direct pupil constriction persists. In these animals, 200 ipRGCs remain, and they only project to circadian brain centers. Combined, these results indicate that the 200 ipRGCs also project to the iris to drive the direct PLR. Importantly, ipRGCs do not drive the PLR as motor neurons, but instead modulate acetylcholine release from parasympathetic fibers, as we find that atropine (a metabotropic acetylecholine receptor antagonist) application completely blocks direct pupil constriction. Collectively, these results demonstrate that ipRGCs project to the iris muscle directly, where they are sufficient to drive pupil constriction independent of the central pupil pathway or of any intrinsic photosensitivity of the iris muscle.

Title: Novel light response mutants identified in a pupillometry screen of ENU mutant mice

Authors: *G. BANKS[1], T. OSBORN[2], C. A. POTHECARY[3], S. N. PEIRSON[3], R. G. FOSTER[3], P. M. NOLAN[1];
[1]MRC, Oxfordshire, United Kingdom; [2]Mary Lyon Ctr., Oxford, United Kingdom; [3]Nuffield Lab. of Ophthalmology, Univ. of Oxford, Oxford, United Kingdom

Abstract: Non visual light response pathways in the eye and brain are key components in the regulation of sleep and circadian rhythms. Recent evidence has also implicated such pathways in mood and the pathology of depression. In order to better study and understand such processes we are performing a screen for mutations in light response pathways. To facilitate this we are using the pupillary light response (PLR) as a screening tool. The PLR is a non-visual response to light during which the iris of the eye constricts in response to illumination causing a decrease in pupil diameter. In our screening protocol mice are positioned so as to expose one eye to a light source while the contralateral eye is imaged, allowing us to track the PLR.
Our initial baseline studies have demonstrated strain related differences in the PLR. As expected mice carrying the *rd1* mutation have a reduced PLR compared to other strains. However *rd1* mutants also show an age related decrease in the PLR not found in non-*rd* mice. Interestingly mice carrying the *rd8* mutation did not show significant defects in the PLR but did also show an age related decrease in the PLR not observed in non-*rd* mice. Furthermore aged *rd8* mutant mice also showed a faster post illumination recovery compared to all other strains, including *rd1* mutants.
We have also begun a pupillometry screen of both F1 progeny and G3 pedigrees from ENU mutagenized male mice maintained at MRC Harwell. Thus far this screen has identified two mutant mouse lines characterised by defects in the PLR. Our PUPIL1 mouse line shows a mild reduction in PLR similar to that observed in melanopsin knockout mice. In contrast the PUPIL2 mutant line shows a severe reduction in PLR more similar to that observed in the *Trpm1* knockout line. We have mapped the PUPIL2 mutation to chromosome 13 and further genetic mapping is currently underway to enable us to identify the causative mutation. Once the causative mutation has been identified further characterisation will be performed at a

behavioural, histological and molecular level.
We hope that our data demonstrates that the PLR can be utilized as an informative, non-invasive, high throughput screening technique.

Title: Intravitral engraftment of mesenchymal stem cells loading on hydrogel in the ischemic rat retina

Authors: *J. LEE[1], J.-M. SHIN[1], S.-S. PAIK[1], C. YEUM[2], G. CHAE[2], I.-B. KIM[1], M.-H. CHUN[1], S.-J. OH[1];

Abstract: Endeavor for development of a brand-new therapeutic strategy is also engaged for treating incurable neural retinal diseases. For this establishment, mesenchymal stem cells (MSCs) transplantation into the retina is ceaselessly tried and various techniques were designed. We aimed to test a biodegradable hyaluronic acid (HyA)-based hydrogel as a stem cell carrier, in order to upgrade the migratory potential of MSCs using a rat model of retinal ischemia-reperfusion injury (IR). IR model was made by a transient and extreme elevation of intraocular pressure via raising hydrostatic pressure value of 120 mmHg for 1 hour through a needle cannulation into the anterior chamber of the one side eyeballs of Sprague-Dawley rats. At 1 week post IR, DiI-labeled MSCs of three passages loaded on HyA-based hydrogel were applied on a dose of 1×10^5 cells/10 μl into the vitreous body of both IR and contra-lateral control eyeballs. HyA-based hydrogels were prepared with two different pH modulations. As a control for MSC carrier, 0.01 M phosphate buffered saline (pH 7.2, PBS) was used. MSC application was reserved for 3 weeks. MSCs localization and morphological alteration were accessed by immunohistochemistry and the visual function. The whole-mount retinas of all experiments were processed for anti-GFAP and anti-Iba1 immunohistochemistry and retinal sectional preparations were processed for anti-GFAP, -NGF, - BDNF, and -glutamine synthetase (GS)

immunohistochemistry. Among them, MSCs were much more accumulated in the border between the inner limiting membrane and the vitreous body loaded on HyA-based hydrogels than on PBS. Basic pH hydrogel showed higher localization than neutral pH one. All these antisera immunoreactivity appear in the Mueller cells and astrocyte in IR and differential downregulation after MSC application hydrogel treatment. Upon MSCs application on HyA-hydrogels, the ERG responses were significantly increased compared IR rats, more apparently in scotopic stimulation than in the photopic condition. These findings demonstrate that biodegradable HyA-based hydrogel is excellent for MSC localization in MSC transplantation into damaged retina and the MSCs delivered on those exert influence to some extent on functional reparation.

Title: P2X7 receptor activation modulates light-evoked retinal ganglion cell synaptic responses and microglial morphology

Authors: *S. CHAVDA[1], P. J. LUTHERT[2,3], T. E. SALT[1];
[1]Dept. of Visual Neurosci., [2]Ocular Biol. and Therapeut., UCL Inst. of Ophthalmology, London, United Kingdom; [3]NIHR Biomed. Res. Ctr. in Ophthalmology, London, United Kingdom

Abstract: ATP-gated P2X7 receptors (P2X7Rs) are expressed by various retinal cell types, including retinal ganglion cells (RGCs) and microglia, and are known to modulate glutamatergic neurotransmission in the central nervous system (CNS). P2X7Rs are also associated with the induction of microglia-derived cytokine release and neuronal injury, phenomena which are

common to many neuroinflammatory conditions in the retina and CNS. However, the role of P2X7Rs in the modulation of retinal synaptic function remains elusive. Using a dark-adapted, ex vivo mouse retinal wholemount preparation, the present study aimed to characterise the effect of P2X7R activation on light-evoked NMDA receptor (NMDAR)-mediated RGC synaptic responses, and on microglial morphology.
ON and OFF field excitatory post-synaptic potentials (fEPSPs) were recorded from the ganglion cell layer of acutely isolated retinal wholemounts (adult, male C57BL/6 mice) in response to a light stimulus (1s-duration LED flash, repeated every 3s). The NMDA receptor-mediated component of the responses was pharmacologically isolated with a Mg2+-free Krebs medium containing NBQX, picrotoxin, strychnine and tetrodotoxin). Additional drugs were applied to the bathing medium. Retinae were stained for microglia (α-IBA-1/IgG-Alexa488) and visualised with confocal microscopy.
The mGluR6 agonist, L-AP4 induced a reversible depression of the ON but not the OFF RGC fEPSP, consistent with mGluR6 activation at the photoreceptor-ON bipolar cell synapse. The NMDAR antagonist, D-AP5 reduced both ON and OFF RGC fEPSPs, confirming that the responses were mediated through NMDARs. BzATP (300μM), a P2X receptor agonist, depressed the ON (78±2% of control; $P<0.05$) but not the OFF RGC fEPSP peak amplitude. The effect of BzATP on the ON RGC fEPSP was reduced by the selective P2X7R antagonist, A438079 (10μM; 31±2% reduction; $P<0.05$) but not by suramin (10μM), a non-selective P2X receptor antagonist (ineffective at P2X7Rs at the dose tested), consistent with P2X7R activation. Additionally, adenosine (300μM) potentiated the ON response (110±2% of control), ruling out a possible effect of Bz-adenosine (a catabolic product of BzATP) on P1 receptors. Furthermore, BzATP caused an increase in microglial arbour area under similar conditions.
It is proposed that P2X7R activation depresses ON RGC glutamatergic synaptic transmission, as well as inducing changes in microglial morphology. Since P2X7Rs are well known for their function in microglia-derived cytokine release, this could also have implications for neural-immune interactions in the retina and CNS.

Title: Nitric oxide modulates OFF bipolar cell responses in the retina

Authors: *O. SCHMACHTENBERG, A. H. VIELMA;
Cinv-Universidad De Valparaiso, Valparaiso, Chile

Abstract: Nitric oxide (NO) is involved in retinal signal processing, but its cellular actions are only partly understood. The main source of retinal NO is a subset of amacrine cells, which signal onto ON bipolar, amacrine and ganglion cells. Previous studies showed that NO inhibits ganglion cell OFF responses, but while NO is an established modulator of ON bipolar cells, little is known about its effects on OFF bipolar cells. We investigated if NO regulates glutamate responses in OFF bipolar cells through the activation of the soluble guanylyl cyclase-cGMP pathway. To this end, OFF bipolar cells were recorded in vibratome sections of rat retina with whole-cell patch clamp and identified by morphological and electrophysiological criteria. The cells were stimulated with a brief puff (1 s) of glutamate in the outer plexiform layer, while their axonal arbors in the inner plexiform layer were superfused with a long (10 s) puff of NO donors (NOC-12 and SNP) or the cGMP analogue 8-bromo-cGMP. Both NOC-12 and 8-bromo-cGMP eliminated the slow component of the response to glutamate, while the amplitude of the fast component remained unchanged. Addition of the soluble guanylyl cyclase inhibitor ODQ to the intracellular solution prevented this effect, suggesting a mechanism dependent on cGMP. Perfusion with the NO synthase inhibitors 7-NI and L-NNA prolonged the timing of the glutamate response, which could be reversed by the NO donors. These results show that NO alters the glutamate response characteristics of OFF bipolar cells, and confirm that the retinal OFF pathway is modulated by NO.

Title: LKB1 and AMPK regulate synaptic remodeling in old age

Authors: *M. A. SAMUEL[1], P. E. VOINESCU[1], B. N. LILLEY[1], R. DE CABO[2], M. FORETZ[3], B. VIOLLET[3], D. G. VAVVAS[4], J. R. SANES[1];
[1]Harvard Univ., CAMBRIDGE, MA; [2]Natl. Inst. on Aging, Baltimore, MD; [3]Inst. Cochin, INSERM, Paris, France; [4]Harvard Med. Sch., Boston, MA

Abstract: Age-related declines in neural function result in part from alterations in synapses. Unfortunately, very little is known about the molecular pathways that underlie these changes in part because most age-related synaptic alterations are subtle and difficult to quantify, owing to the small size of the synapses and the complexity of brain circuitry. We therefore focused on a large, easily-visualized synapse in the outer retina that undergoes dramatic alterations in old mice and humans. In old retina, numerous ectopic synapses develop in the photoreceptor layer along aberrant processes arising from horizontal and bipolar cell neurons. We show that defects in the LKB1 and AMPK energy regulatory pathway underlie these alterations. In old animals, synaptic remodeling is accompanied by specific decreases in the levels of both LKB1 and active AMPK (phosphoT172-AMPK), while the levels and phosphorylation state of other LKB1 targets are unaffected. In the absence of either LKB1 or AMPK, young mice develop retinal defects similar to those that occur in old wild type animals. Using conditional alleles, we examined the cellular basis of this remodeling and show that LKB1 and AMPK function specifically in photoreceptors to directly modulate rod axon localization. Moreover, restoring AMPK genetically in either old or LKB1-deficient animals rescues the synaptic alterations. Pharmacological (metformin) or dietary (caloric restriction) interventions that increase AMPK activity also attenuate age-related synaptic changes. Conversely, alterations are exacerbated in mice fed a high-fat diet. Together, these results identify a molecular cause of age-related synaptic remodeling and suggest that energy homeostasis pathways play a critical role in preserving neural function in old age.

Title: Inhibition controls the occupancy of the readily releasable pool of vesicles at the rod bipolar synapse to normalize contrast coding

Authors: *N. W. OESCH, J. S. DIAMOND;
NINDS/NIH, Bethesda, MD

Abstract: The nervous system often encodes changes in signal level, rather than absolute level allowing for efficient coding of inputs over a large range. In the visual system, where this challenge is particularly acute, the measure of difference between luminance values is referred to as contrast. Recently, we demonstrated that the excitatory rod bipolar cell (RBC) synapse in the retina both computes contrast and relays luminance information in its synaptic output, and we demonstrated that contrast is calculated by stepping between different steady-state levels of readily releasable pool occupancy. This mechanism, in isolation generates a contrast signal that varies with background, yet our perception of contrast remains constant across the entire range of vision. Here we demonstrate that synaptic inhibition onto the RBC axon/synaptic terminal influences the occupancy of the readily releasable pool of vesicles at the RBC synapse to both normalize the contrast gain as well as extend the range of backgrounds over which both contrast and luminance can be coded by RBC synaptic output.

Title: Multiple layers of inhibition to DSGCs are differentially modified by light

Authors: *A. HOGGARTH, S. TRENHOLM, A. MCLAUGHLIN, G. AWATRAMANI;
Dept. of Biol., Univ. of Victoria, Victoria, BC, Canada

Abstract: Introduction
Lateral inhibition mediated by horizontal/amacrine cells is known to be down-modulated in dark-adapted conditions (Barlow et al., 1956), leading to a loss of the inhibitory surround receptive fields of retinal ganglion cells. If and how ganglion cells can maintain their computational ability

in the face of such changes in their receptive filed organization is not clear. Here, we examine the impact of background light levels on the response properties of directionally selective ganglion cells (DSGCs), which rely heavily on inhibition for their ability to code direction.
Methods
DSGCs identified in the Hb9::eGFP transgenic mouse retina were targeted for whole-cell and extracellular patch clamp recordings, using 2-photon laser scanning microscopy. Mice were dark adapted for a minimum of 2 hours prior to experimentation. Responses to stationary or moving (in eight directions) spot stimuli of increasing sizes centered over the soma were measured at different background light levels that straddled the rod and cone thresholds (10-2 R*/s to 103 R*/s).
Results
In light-adapted conditions, small spots (~200 um) evoked stronger responses in DSGCs, compared to larger spots (1000 um; <50%), indicating the presence of strong inhibitory surround. Under dark-adapted conditions, this inhibitory surround essentially disappeared. Despite these changes in surround inhibition, responses to moving stimuli remained DS. To understand how DS could be maintained despite the loss of inhibition to the circuit we measured inhibitory (Vhold 0 mV) and excitatory (Vhold -60 mV) current in voltage-clamped DSGCs. Interestingly, we found that regardless of the adaptational state, the strength of direct excitation and inhibition to DSGCs scaled in parallel. In light-adapted retina, both inhibition and excitation decreased when the spot size was increased above 200 um, while in the dark-adapted state they increased as a function of spot size. These results indicated that surround inhibition co-modulates direct excitation and inhibition, at a level presynaptic to the DSGC. In addition, we find that the balanced changes in excitation and inhibition permitted conventional null direction inhibition (inhibition evoked by stimuli moving in the null direction) to veto excitation across all light levels.
Conclusions
Light levels appear to selectively modulate wide-field inhibition that functions to co-modulate local excitation and inhibition to DSGCs, allowing them to code the same direction over a large range of light intensities with distinct spatiotemporal characteristics.

Title: PlexinA4 restricts retinal ganglion cell axon arborization in the superior colliculus

Authors: *S. G. THAKAR, Y. ZOU;
UCSD, La Jolla, CA

Abstract: Precise connections between retinal ganglion cells and their brain targets, such as the superior colliculus (SC), are essential for visual system function. Axon terminal arbors of different retinal ganglion cells (RGCs) assume characteristic columnar and laminar specific patterns in the SC, which allows them to synapse on specific cell types. Based on the expression patterns of semaphorin ligands and receptors, we tested the role of a semaphorin receptor component, PlexinA4, in controlling RGC axon targeting. The *Calretinin-eGFP* (*CB2-GFP*) transgenic mice selectively express GFP in transient OFF-RGC, which target the deeper retinorecipient layer of the SC (lower stratum griseum superficialis, lSGS). *CB2-GFP* mice were crossed into the *PlexinA4* knockout line to evaluate OFF-RGC axon pathfinding and targeting. We find that *PlexinA4*$^{-/-}$ RGC axons grow and steer normally down the optic nerve and find their appropriate overall targets, the lateral geniculate nucleus and SC, and within those targets, *PlexinA4*$^{-/-}$ RGC axons do not display topographic mapping defects. However, *PlexinA4*$^{-/-}$ RGC axons did exhibit severe defects in the laminar location of their axon arbors in the SC. In *CB2*$^{+}$*:PlexinA4*$^{-/-}$, and to a lesser degree *CB2*$^{+}$*:PlexinA4*$^{+/-}$, the OFF-RGC axon arbors invade the more superficial layer of the SC (upper stratum griseum superficialis) rather than remain restricted to the lSGS as they do in *wild-type* mice. These data indicate PlexinA4 is required for normal layer specific targeting of OFF-RGC axons in the SC, and suggest that, like for RGC dendrites, repellant mechanisms may serve to restrict RGC axon arbors within their target region.

Title: The neural ensemble recording in the visual cortex of awake mouse

Authors: *X. LI, H. ZHANG, J. TSIEN;
Georgia Regents Univ., Augusta, GA

Abstract: The development of genetic tools for analyzing neural circuits promoted the mouse to be a potential powerful model for studying the neural mechanism of cognition and behavior. In order to study visual recognition, we investigated the mouse visual cortex in awake condition and did neural ensemble recording. The first step we trained the mouse to keep sitting quietly with seldom eye movement, this helped us to investigate the basic characters of the visual neurons. Equiped with the drivable microelectrode arrays which could be fixed on mouse head for chronic recording, about 50 firing units could be obtained simultaneously with one 64 channels array in stereotrode mode. In the primary visual cortex of awake mouse, we found that the receptive fields of mouse visual neurons were very large and with long response latency. The receptive fields of neurons belonging to a local range (D = 0.8 mm) were in non- uniform distribution. Most neurons had strong orientation and spatial frequency selectivity. Less than half had strong temporal and direction selectivity. These suggested that more mouse V1 neurons could tell shape than motion. The neurons with similar response characters (preferred orientation, simple or complex cell) were not clustered, but in a salt and pepper arrangement.

Title: Differential wakening effects on inhibitory and excitatory neurons in visual cortex, revealed by *In vivo* two-photon functional imaging

Authors: *R. KIMURA[1], K. SOHYA[1], M.-S. SAFARI[1], T. EBINA[1], Y. YANAGAWA[2], T. TSUMOTO[1];
[1]RIKEN BSI, Wako, Saitama, Japan; [2]Gunma Univ. Grad. Sch. of Med., Maebashi, Japan

Abstract: In attempts to understand neural circuit mechanisms underlying visual perception and cognition, most of the previous works were carried out in anesthetized animals. To fully understand such neural mechanisms, however, it is necessary to record and analyze activities of visual cortical neurons in awakening animals. Also it is important to identify recorded neurons as inhibitory or excitatory because inhibitory interneurons play characteristic, specified roles in the operation of neuronal circuits in the visual cortex.

To address these issues, we directly compared visual response properties of the same cortical neurons between in the awakening and anesthetized states by applying the two-photon calcium imaging method to the transgenic rodents, in which inhibitory and excitatory neurons are identified in vivo. Functional imaging of cortical neurons was carried out by injecting a calcium indicator (fura 2-AM) and an astrocyte marker (SR101) into layer 2/3 of the primary visual cortex of adult VGAT-Venus transgenic rats, in which GABAergic neurons were identified with Venus fluorescence. Comparing the visual responses between the two states (monitored by EEG activity), we found that GABAergic neurons increased the magnitude of visual responses whereas excitatory neurons did not. Furthermore the decay time of excitatory neurons became faster so that their visual responses were shorter-lasting in the awake state than in the anesthetized state.
Previously it was suggested that acetylcholine (ACh) may be involved in the brain state-dependent changes in activities of cortical neurons through the basal forebrain projection from the nucleus basalis (NB). However, it is not clear whether this cholinergic modulation operates in a differentiated manner between GABAergic and excitatory neurons. To address this issue, we activated NB neurons through the optogenetic method in addition to the conventional electrical stimulation method. The changes in visual responses induced by activation of NB were compared with the results obtained with awakening animals.

Allen Institute for Brain Science

Title: Cell-type specific organization of functional circuits in mouse visual cortex

Authors: *H. ZENG, L. LI;
Allen Inst. For Brain Sci., SEATTLE, WA

Abstract: Cortex consists of many types of neurons with various morphological, physiological and genetic properties, but the cell-type specific role in cortical (micro)circuit construction and

neural information computation remains largely unknown. Morphological, physiological and genetic properties of different types of neurons need to be characterized in order to address these questions. Along with others at the Allen Institute for Brain Science, we have set up a Cell Types program aimed at understanding these properties of genetically defined cell types in mouse visual system. To reveal how different types of neurons are inter-connected and assembled into microcircuits for neural information processing, we are employing two-photon targeted whole-cell recording in vivo in transgenic mice in which individual types of neurons are fluorescently labeled. We will characterize physiological properties of neuronal types and integrate data with information of gene expression patterns and morphology generated from separate efforts at the Allen Institute.

Title: Functional maps in V1 of D1 and D2 dopamine receptors knockout mice

Authors: *B. O. SOUZA[1], S. THOMAS[1], J. M. BEAULIEU[2], C. CASANOVA[1];
[1]École d'Optométrie, École D'Optométrie, Univ. De Montréal, Montréal, QC, Canada; [2]Ctr. de recherche, Inst. universitaire de santé mentale de Québec, Québec, QC, Canada

Abstract: Dopamine (DA) is a neurotransmitter that plays an important role in the processing of the visual information in the retina. In addition to their implication in retinal function, DAergic receptors are also found in the visual cortex. However, the functional impact of these receptors on the structure and function of the visual cortex remains poorly understood. The aim of the present study is to determine the impact of the deletion of dopamine D1 and D2 receptors (D1-KO and D2-KO) on cortical organization and visual processing in V1. Adult mutant and wild-type mice (D1R-KO : n=2, D1R-WT : n=3, D2R-KO : n=3, D2R-WT : n=3) were placed in a stereotaxic apparatus under urethane anesthesia (2g/Kg). Activity in V1 was measured by optical imaging of intrinsic signals under a 630 nm illumination. Using a periodic stimulation paradigm (Kalatsky and Stryker, 2003), visuotopic maps were analyzed to measure structural parameters such as V1 shape, cortical magnification factor, scatter, binocularity and ocular dominance. Contrast sensitivity, spatial frequency selectivity and cortical acuity were evaluated using

dynamic sinusoidal gratings of different contrasts (6, 12, 25, 50 and 100% of contrast at 0.02 cpd) or spatial frequencies (0.005, 0.01, 0.02, 0.04, 0.8, 0.16, 0.32, 0.64 cpd at 100% contrast). Contrast sensitivity was reduced in both D1 and D2-KO mice. Indeed, the contrast value necessary to induce 50 % of the maximal response was increased by 70 % for D1-KO ($p<0.01$) and 55 % for D2-KO mice ($p<0.05$) when compared to their WT littermates. Furthermore, our preliminary results suggest a decreased cortical acuity for D1-KO compared to control littermates (0.09 ± 0.002 cpd vs 0.14 ± 0.002 cpd). This effect was not observed in D2-KO mice. Surprisingly, the various structural parameters extracted from V1 visuotopic maps were unaffected by the loss of expression of either D1 or D2 receptors. In conclusion, our preliminary data indicate that contrast sensitivity was reduced in both D1-KO and D2-KO mice. Our data also suggest that visual acuity is modulated by DA, through a D1R-specific signaling pathway. The lack of structural alteration in V1 maps of D1 and D2-KO mice suggests that DA receptors do not play a crucial role in the development of the mouse primary visual cortex.

Title: Functional organization of clonally related neurons in mouse visual cortex during development

Authors: *G. OHTSUKI[1], C. LOIS[2], K. OHKI[1];
[1]Mol. Physiol., Kyushu University, Grad Sch. of Med., Fukuoka, Japan; [2]Neurobio., Univ. of Massachusetts Med. Sch., Worcester, MA

Abstract: Recently, it was revealed that orientation preference among clonally related cells is more similar than among unrelated cells (Li et al., 2012; Ohtsuki et al., 2012). However, not all clonally related cells share response selectivity in adult mice (P49-62), suggesting that cell lineage is not the only determinant of response selectivity (Ohtsuki et al., 2012). In this study, we tested three hypotheses. First, the similarity of preferred orientation between clonal neurons may be strong just after eye opening (Li et al., 2012) and may be reduced in adult in the course of maturation of the cortical circuit. Second, the vertically aligned clonal cells in the cortex may have higher similarity in orientation preference. Third, the functional similarity of clonal cells

may be moderate from the eye opening to matured state, and it may be moderate even among vertically aligned clonal cells. By using the combination of *in vivo* two-photon Ca^{2+} imaging and a transgenic mouse which labels all the progeny derived from single cortical progenitor cells, we examined orientation, direction and spatial frequency selectivity of clonal and other cells at time points of the eye opening, 3-10 days later and matured. We also examined whether functional similarity among clonally related cells depends on the positional relation among those cells in each developmental stage, and analyzed proportion of difference in preferred orientation angle in vertically aligned cell population among all cells or clonal sisters.

Title: Spontaneous neuronal ensemble evoked by visual stimulation in awake mice

Authors: *J.-E. MILLER, I. AYZENSHTAT, R. YUSTE;
Dept Biol., Columbia Univ., New York, NY

Abstract: The cortical microcircuit is dominated by recurrent excitatory connections, and it has been long suggested that this could enable ongoing reverberating activity. To better understand the dynamics of neuronal activity present in neocortex, we performed two-photon calcium imaging of populations of layer 2/3 cortical neurons in mouse primary visual cortex in vivo in

anesthetized and awake mice, positioned on a floating trackball. We characterized the spatiotemporal dynamics of cortical activity in the presence or absence of visual inputs, using either drifting gratings or a natural movie to evoke population activity or a black screen to measure spontaneous activity.
We find that, under all conditions (gratings, natural movie, and spontaneous), most neurons become active as part of an ensemble, i.e. a group of neurons responding together forming coactive spatial patterns. There appears no appreciable difference in coactive pattern properties or dynamics according to different brain states (i.e. anesthetized or awake) or stimulus conditions. Different coactivations repeat significantly, involving many of the same neurons, although coactive groups are flexible and the same neurons can be part of different coactivations. Repeated coactive patterns are more frequent in awake animals although they are also present under anesthesia. Finally, the spontaneous coactive groups of neurons can be triggered also by specific visual stimulation. These overlapped coactive patterns during both spontaneous and visually evoked activities are statistically significant in awake mice, but not in anesthetized ones. Our results indicate that cortical activity mostly occurs in coactive patterns, and that, in the awake brain, sensory evoked activity is built out of a vocabulary of patterns that are already present in the spontaneous ongoing activity. These coactive patterns could represent emergent functional circuit states.

Title: Receptive fields and orientation tuning of thalamic excitation onto single neurons of the mouse's visual cortex

Authors: *A. D. LIEN[1], M. SCANZIANI[2];
[1]UCSD, La Jolla, CA; [2]UCSD, HHMI, La Jolla, CA

Abstract: A fundamental feature of cortical organization is that sensory information reaches the neocortex via excitatory synaptic input from the thalamus. Yet the specific sensory information

represented by the thalamic excitation received by a single cortical neuron are unknown. This is due to the difficulty in distinguishing thalamic excitation from that produced by intracortical excitatory inputs. Here we isolate thalamic excitation onto mouse L4 visual cortical neurons by performing in vivo whole-cell recordings while silencing intracortical excitation via optogenetic activation of inhibitory interneurons. We mapped the ON and OFF receptive fields of thalamic excitation using small black or white squares presented at various locations in the mouse's field of view. We find that the receptive field of thalamic excitation is organized into overlapping ON and OFF subfields with spatially offset peaks. The offset between ON and OFF subfields is a potential mechanism by which thalamic excitation can be selective for the orientation of a stimulus in visual space. Consistent with this hypothesis, we find that in response to drifting gratings, the F1 modulation (or peak) of thalamic excitation is tuned to the orientation of the grating. Furthermore, the relative position of the ON and OFF peaks is predictive of the preferred orientation. In contrast, the total excitatory charge (or average excitation) across the grating duration is poorly tuned, suggesting that recently described orientation and direction-selective thalamic neurons do not contribute to the tuning of thalamic excitation onto L4 neurons. In conclusion, we demonstrate that thalamic excitation is tuned for orientation and that its receptive field structure, namely the separation of ON and OFF subfields in visual space, likely forms the basis for this tuning.

Title: Inhibition of inhibition in visual cortex: The logic of connections between molecularly distinct gabaergic neurons

Authors: *C. PFEFFER[1,2], M. XUE[1], M. HE[3], Z. HUANG[3], M. SCANZIANI[1,2];
[1]Div. of Biol. Sci., UCSD, La Jolla, CA; [2]HHMI, La Jolla, CA; [3]Cold Spring Harbor Lab., Cold Spring Harbor, NY

Abstract: Cortical inhibitory neurons contact each other to form a network of inhibitory synaptic connections. Our knowledge of the connectivity pattern underlying this inhibitory network is, however, still incomplete. Here we address the interaction between the three largest classes of molecularly distinct inhibitory neurons in mouse visual cortex: the Parvalbumin (PV), the Somatostatin (SOM) and the Vasoactive Intestinal Peptide (VIP) expressing inhibitory neurons. We use conditional expression of Channelhodopsin in specific Cre-driver lines to photoactivate the three distinct classes of inhibitory neurons in acute cortical slices. We record the postsynaptic inhibition in GABAergic interneurons which we identify post-hoc using single-cell rtPCR expression profiling. We discover a simple and complementary interaction scheme between the inhibitory neuron populations. PV expressing interneurons strongly inhibit one another but, surprisingly, provide little inhibition to other populations. In contrast, SOM expressing interneurons avoid inhibiting one another, yet strongly inhibit all other populations. Finally, VIP expressing interneurons preferentially inhibit SOM interneurons. This scheme occurs in supra- and infra-granular layers, suggesting that inhibitory networks operate similarly at the input and output of visual cortex. Thus, as the specificity of connections between excitatory neurons forms the basis for the cortical canonical circuit, the scheme described here outlines a standard connectivity pattern among cortical inhibitory neurons.

Title: Role of thalamocortical input to mouse primary visual cortex in maintenance of excited states

Authors: *K. REINHOLD, M. SCANZIANI;
Neurosciences, Univ. of California At San Diego, San Diego, CA

Abstract: The principal feedforward sensory input to the primary visual cortex (V1) is the thalamus, yet thalamocortical synapses comprise a small fraction of the total synapses in V1. Local recurrent circuits account for the majority of these synapses, potentially supporting cortical activity in the absence of ongoing feedforward drive from the thalamus. For how long can a visually evoked representation in V1 last without this ongoing feedforward drive? To test this, we require a way to rapidly and reversibly remove thalamic input to the neocortex *in vivo* and measure the effects on an ongoing cortical representation. We have developed an optogenetic method to do this in the visual system of mice by activating inhibitory inputs from the GABAergic reticular thalamic nucleus onto relay cells of the dorsal lateral geniculate (dLGN) and lateral posterior (LP) nuclei, while recording unit activity across layers of V1. Our optogenetic approach is able to silence the thalamus within a few milliseconds, enabling us to measure the time course of activity decay intrinsic to the V1 circuit. We find that a visually evoked response in V1 decays within 40 ms of removal of the feedforward thalamic input. We also discover that spontaneous activity under anesthesia does not require the thalamus, while spontaneous activity in the *awake* mouse includes a large thalamus-dependent component. Finally, we investigate circuit mechanisms underlying the ability of the cortex to precisely follow feedforward thalamic input yet sustain its own intrinsic activity in the absence of this feedforward drive. These results explain how V1 can encode changes in the external world with such a high temporal fidelity yet exhibit waves of spontaneous activity in certain states such as sleep.

Title: Cell-type specific homeostatic mechanisms in mouse visual cortex

Authors: *M. XUE, M. SCANZIANI;
Div. of Biol. Sci., UCSD, La Jolla, CA

Abstract: The activity of cortical neurons critically depends on the relationship between the levels of synaptic excitation and inhibition that they receive. One prominent feature of the cortical synaptic organization is that the locally generated inhibition is proportional to the local or incoming excitation. This proportionality between excitation and inhibition is thought to be fundamental to the functional properties of cortical neurons such as receptive field structure, timing, gain, and so on. Disruption of the proper excitation and inhibition relationship often leads to neurological disorders. The mechanisms that establish the exact relationship between the two opposing synaptic conductances are, however, still poorly understood. Similarly, whether this relationship is individually regulated in each cortical neuron is unknown. We found that individual layer 2/3 pyramidal neurons in the mouse primary visual cortex exhibited highly heterogeneous spiking activity in vivo. Slice experiments showed those layer 2/3 pyramidal neurons that responded to visual stimuli more robustly in vivo received larger glutamatergic excitation from their main afferents, layer 4 projection neurons and concurrently larger GABAergic inhibition from parvalbumin-expressing (PV) cells than the ones that responded less robustly, thus maintaining the excitation to inhibition ratios across neurons despite their different firing rates. Furthermore, we found that suppression of layer 2/3 pyramidal neuron activity selectively decreased PV cell-mediated inhibition without affecting layer 4-mediated excitation. These results indicate that individual layer 2/3 pyramidal neurons autonomously adjust their levels of inhibition in an activity-dependent manner by selectively modulating PV cell-mediated inhibition, which provides a mechanism for cortical circuit to maintain the proper excitation to inhibition ratio at the single-neuron level.

Title: Neural circuits for the cortical control of the optokinetic reflex

Authors: *B. LIU, A. HUBERMAN, M. SCANZIANI;
UCSD, La Jolla, CA

Abstract: The optokinetic reflex (OKR) is an involuntary eye movement that allows the eyes to track a moving visual stimulus and thus to stabilize images on the retina. While mediated by the phylogenetically old accessory optic system (AOS) in the midbrain, interestingly, the performance of this innate behavior in mammals can also be modulated by the visual areas of the neocortex. However the circuit mechanisms by which the cortex exerts its modulatory roles on the OKR remain rather elusive. To investigate this question, we optogenetically silenced the mouse visual cortex during the OKR elicited by drifting gratings on a virtual drum and monitored by infrared video-oculography. We observed that transient cortical silencing significantly reduced the gain of the OKR by 10-30%, depending on visual stimulus parameters. Consistently, following the inactivation of the visual cortex, visually evoked activity in the AOS nucleus decreased. Moreover, with retrograde tracing and slice electrophysiology, we showed that a small portion of layer 5 neurons in the mouse visual cortex form functional synaptic connections onto AOS neurons. These results suggest that the visual cortex influences the OKR behavior, at least in part, through the direct corticofugal projection to the AOS system.

Title: A virtual foraging task for studying vision in mice

Authors: *S. R. OLSEN, M. SCANZIANI;
UCSD/HHMI, San Diego, CA

Abstract: Cognition and behavior are mediated by dynamic activity in cortical circuits. To study the mechanisms of cortical dynamics during behavior, we developed a paradigm in which mice use their vision to navigate along a linear track. In this task a mouse runs on a circular treadmill in order to move objects across a computer monitor. Over the course of several weeks of training, mice learn to collect rewards by running to and stopping on target objects, while running past unrewarded distractor objects. Using this paradigm we trained mice on an orientation discrimination task. Mice can learn to discriminate orientation differences less than 10 degrees. Optogenetic silencing of the visual cortex during the task severely disrupted performance, suggesting this behavior is cortex-dependent. In addition, the time course of learning and specificity of fine orientation discrimination is consistent with perceptual learning. This task (virtual foraging task) should be useful for studying various aspects of visual behavior ranging from stimulus detection/discrimination to spatial attention.

Title: Topological organization of spatial frequency in mouse primary visual cortex

Authors: *X. ZHANG, X. AN, J. PENG, S. CAI, W. WANG, Y. YANG;
Lab. of Plasticity of Sensory Syst. Develop., Anhui, China

Abstract: Summary:
Visual acuity, reflected as spatial discrimination and represented in spatial frequency (SF) tuning of neurons in V1, is of particular importance for animal survival. Although columnar organization of neurons with similar response properties is a salient feature in mammalian V1, the functional organization of neurons in rodent V1 processing different SFs remains unknown. Here, by combining intrinsic optical imaging and single-unit recordings, we revealed the topological organization of SF tuning in mouse V1 to accommodate different spatial discrimination tasks in lower and upper visual space. Firstly, we found that in both monocular and binocular zones, neurons in the anterior cortical area representing lower visual field

preferred low SF, whereas neurons in the posterior part representing upper visual field were apt to possess high spatial acuity. Secondly, we showed that the cutoff SF maps changed in a continuous manner along vertical visual field. Thirdly, we demonstrated that this specific structured map emerged from eye opening and was preserved into adulthood. Finally, we established that although the development of visual acuity was delayed in dark-reared animals, the topological organization of SF maps was similar to that in normal reared animals, suggesting that the functional organization of SF preference is inherent and independent of visual experience. Taken together, our findings provide new insights into the origin of SF columns in higher mammalian, and underscore the significance of SF maps for mice survival by avoiding predators' attack from the upper space.

Title: The assembly and function of PV microcircuits in the primary visual cortex

Authors: *A. BAOHAN[1], P. GOLSHANI[2], J. T. TRACHTENBERG[1];
[1]Dept. of Neurobio., [2]Dept. of Neurol., UCLA, Los Angeles, CA

Abstract: The emergent properties of cortical function are predicated on the dynamic and intricate balance of excitation and inhibition. Cortical inhibition is supplied by a diverse group of neurons with distinct structural, molecular, electrophysiological and likely, functional properties. Parvalbumin-expressing (PV), fast-spiking inhibitory neurons account for the majority of neocortical inhibitory neurons, yet little is known about how PV microcircuits are assembled and what function they serve in cortical computation. We find that phosphatase and tensin homolog (PTEN) regulates the assembly of neocortical PV-pyramidal microcircuits via the AKT signaling pathway. We generated a transgenic mouse with a PV-specific single copy deletion of *PTEN*

starting after the first postnatal week (PV-PTEN$^{+/-}$). Since PTEN negatively regulates the AKT signaling pathway, loss of PTEN activity results in increased AKT pathway activity. While these PV-PTEN$^{+/-}$ mice show normal cortical lamination and PV intrinsic properties, we find that they display an aberration in PV-pyramidal microcircuitry. Specifically, paired PV-pyramidal recordings in layer 2/3 of the primary visual cortex (V1) in acute slices reveal a significant unilateral decrease in PV to pyramidal connectivity, while reciprocal pyramidal to PV connections are preserved. The strength and short-term plasticity of the remaining PV to pyramidal connections are normal, which suggests that the decrease in PV to pyramidal connectivity is due to a decrease in the number of functional PV to pyramidal synapses, not a decrease in presynaptic GABA release probability. The 32% reduction in PV-mediated inhibition results in increased excitability of local pyramidal neurons, which cannot be attributed to intrinsic changes. We are currently working on interlaminar circuitry as well as intralaminar input-output transformation *in vivo* in awake mice with population Ca^{2+} imaging, using V1 as a model circuit. The elucidation of a novel role for the AKT signaling pathway in PV microcircuits may shed light on the mechanisms of neuropsychiatric disorders such as autism spectrum disorders, as many of the candidate genes for these disorders converge on the AKT signaling pathway.

Title: Phase-dependent coding in cortical ensembles during attentional tracking

Authors: *G. H. MULLIKEN[1], R. DESIMONE[2];
[1]McGovern Inst., MIT, CAMBRIDGE, MA; [2]McGovern Inst., MIT, Cambridge, MA

Abstract: We investigated how cortical neurons encode a moving object during attentional tracking. Monkeys were trained to covertly track a moving dot along an isoeccentric trajectory that passed through the receptive field (RF) of a neuron(s). Our analyses sought to characterize both signal encoding as well as noise suppression properties of V4 and LIP neurons by

quantifying the relationships between spike timing and the phase of the local field potential (LFP). We first evaluated the baseline state of neural activity. In the absence of a visual stimulus, a neuron's likelihood of firing was enhanced during the depolarized phase of the LFP (i.e., the trough) for low and high frequency bands of the LFP (e.g., theta, 4-6 Hz, and gamma, 30-70 Hz). This finding indicates that, by default, neuronal spiking correlates with depolarized net synaptic activity reflected in the extracellular LFP, irrespective of its constituent frequency. During stimulus presentation, we found that the probability of neurons to fire at the depolarized phase of the gamma-LFP was preserved, and even enhanced, while spike timing became desynchronized to the theta-LFP.
It has been suggested that the low frequency LFP may largely constitute a common mode noisy synaptic input into early visual processing areas, which is unrelated to a stimulus and interferes with neurons' ability to encode a signal. If true, then spikes generated during the peak of the theta-LFP should be less impacted by common-mode noise. We quantified a neuron's phase-dependent encoding strength by computing the mutual information between a neuronal spike train and the time-varying stimulus position for intervals coinciding with different phases of the theta LFP. Spikes that fired on the peak of the theta-LFP tended to encode more information about the stimulus position than spikes occurring during the trough of the theta-LFP. In addition, we assessed whether the theta-LFP phase might impact population coding by computing the pairwise spike count correlation between neurons with overlapping RFs. Interestingly, we found that pairwise correlations were also larger during the peak of the theta rhythm. In summary, these data provide evidence that neuronal populations suppress low-frequency common-mode noise, effectively reducing the in-band noise floor and enabling higher fidelity signal encoding of position. Lastly, the effects of attention on these phase-dependent coding schemes will also be presented.

Title: A two-stage cascade model of BOLD responses in human visual cortex

Authors: *K. N. KAY, J. WINAWER, A. ROKEM, A. MEZER, B. A. WANDELL;
Stanford Univ., Stanford, CA

Abstract: Visual neuroscientists have discovered fundamental properties of neural representation through careful analysis of responses to controlled stimuli. Typically, different properties are studied and modeled separately. To integrate our knowledge, it is necessary to build general models that begin with an input image and predict responses to a wide range of stimuli. In this study, we develop a model that accepts an arbitrary band-pass grayscale image as input and predicts blood oxygenation level dependent (BOLD) responses in early visual cortex as output. The model has a cascade architecture, consisting of two stages of linear and nonlinear operations. The first stage involves well-established computations--local oriented filters and divisive normalization--whereas the second stage involves novel computations--compressive spatial summation (a form of normalization) and a variance-like nonlinearity that generates selectivity for second-order contrast. The parameters of the model, which are estimated from BOLD data, vary systematically across visual field maps: compared to primary visual cortex, extrastriate maps generally have larger receptive field size, stronger levels of normalization, and increased selectivity for second-order contrast. Our results provide insight into how stimuli are encoded and transformed in successive stages of visual processing.

Title: Effects of rest on V4 network coding in perceptual learning

Authors: *S. L. EAGLEMAN, M. MULAS, J. FERNANDEZ-LEON, V. DRAGOI;
Neurobio. and Anat., Univ. of Texas-Houston Med. Sch., HOUSTON, TX

Abstract: It is widely documented that behavioral performance in perceptual tasks is improved following a brief rest. However, the changes in neural network dynamics and coding underlying the behavioral improvement are unclear. In addition, the changes induced by rest in individual neuron and network responses are unknown. We devised a study that had two goals: 1. to determine whether the behavioral performance improvement observed following a period of rest is correlated with an improvement in neuronal discrimination and coding of stimuli, and 2. to employ a battery of analyses during the rest period to identify patterns of neuronal activity during rest (e.g., the presence of replay events and/or pronounced low frequency activity in local field potential responses) that correlate with the improvement in behavioral performance. To accomplish these goals we trained two monkeys to perform a visual same/different task in which successive natural images were judged to have been presented at the same or slightly different orientation. While animals performed the task, we simultaneously recorded the responses of multiple neurons in visual cortex area V4 using custom-made electrode arrays and laminar probes. Each session consisted of a block of trials in which monkeys performed the task followed by a 20-min rest in a dark, quiet room. During this time monkeys were observed to have their eyes closed and jaw-slack (indicative of sleep). Monkeys then performed a second block of trials after rest. We assessed behavioral performance by determining the percentage of correct trials at the monkeys' discrimination thresholds. Following rest, we found a significant increase in the percentage of correct trials. These improvements were correlated with the amount of time animals had their eyes closed during the nap period (Pearson Correlation, r =0.0365, $P < 0.05$). Subsequently, we found improvements in individual neural coding assessed using d' as well as a decrease in the trial by trial correlated variability in firing rate (noise correlation, 20%, Wilcoxon signed rank, $P < 0.001$) which has been previously associated with impoverished stimulus coding. Preliminary results indicate correlative relationships between activity observed during rest and subsequent neural and behavioral improvement. Collectively, our results provide evidence that neural populations exhibit changes in their coding properties that improve network performance following a brief nap.

Title: Attention can adaptively increase or decrease interneuronal correlations in V4

Authors: R. CHANG, D. A. RUFF, *M. R. COHEN;
Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Correlations between the trial-to-trial fluctuations in the responses of pairs of neurons (spike count correlations) can increase, decrease, or have no effect on the amount of information encoded by a neuronal population depending on how information from many neurons is combined. An influential model of perceptual decision-making (Shadlen et al, 1996), predicts that positive correlations among neurons whose responses provide evidence in favor of the same choice are harmful. They reduce the benefit of averaging the responses of many neurons because shared variability cannot be averaged out. In contrast, positive correlations between neurons whose responses provide evidence for opposite choices are helpful because their shared variability can be subtracted out.

Visual attention has long been known to improve perception of an attended location or feature and also to increase the average responses of neurons in visual cortex whose tuning matches the attended location or feature. Recent studies have demonstrated that attention also decreases spike count correlations (Cohen and Maunsell, 2009, 2011; Mitchell et al, 2009; Thiele et al, 2012). In all of these studies, the responses of all of the neurons provide evidence for the same choice, so the correlation decrease could in principle contribute to attention-related improvements in perception. These results are therefore consistent with either of two hypotheses: 1) Attention always decreases correlations or 2) Attention can either increase or decrease correlations, depending on which is more advantageous for encoding sensory information.

To differentiate between these hypotheses, we recorded from groups of neurons in area V4 while monkeys performed a contrast discrimination task. The monkeys viewed two pairs of Gabor stimuli, one pair in each hemifield. In blocks of trials, the monkeys were instructed to indicate which stimulus in the attended hemifield had higher contrast and ignore the other pair of stimuli. We then compared neuronal responses on trials in which the stimuli in the neurons' receptive fields were to be discriminated (and therefore attended) or ignored.

Consistent with previous studies, we found that attention increased average firing rates and decreased correlations among pairs of neurons whose responses contribute to the same perceptual choice. However, we found that attention increased correlations between pairs of neurons that contribute to different choices. Our results show that attention can either increase or decrease correlations and suggest that the effects of attention may depend flexibly on what would benefit the ability of the population to encode sensory information.

Title: Effects of task difficulty on neuronal populations in visual area V4

Authors: *D. A. RUFF, R. CHANG, M. R. COHEN;
Dept. of Neurosci., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cognitive factors such as concentration and spatial and feature-based attention are known to affect both performance on psychophysical tasks and also to modulate the responses of individual neurons in visual cortex. Recent studies have made progress understanding the effects of visual attention on measures of population activity. In contrast, our understanding of the effects of global factors like concentration, motivation, or arousal on performance and neuronal populations is much more rudimentary.

Global factors are potentially much easier to manipulate experimentally than other cognitive factors, which makes it useful to know whether they share neuronal mechanisms with processes like attention. If they do, studying whichever cognitive factor is most experimentally accessible would yield general insights. Furthermore, a subject's concentration is likely to fluctuate naturally, which may affect the psychophysical and physiological results of any study of perception or cognition.

We manipulated global cognitive factors by changing the average difficulty of a visual task in blocks of trials. We trained monkeys to indicate which of a pair of Gabor stimuli was of higher contrast. We used three pairs of contrasts, which corresponded to easy, medium, and hard discriminations. We grouped the discriminations in blocks of trials that consisted either of easy and medium discriminations or medium and hard discriminations. Performance on the medium discriminations improved in the context of the difficult blocks, suggesting that the animals

concentrated more when the overall difficulty increased.
Consistent with a previous study (Boudreau et al, 2006), we found that the responses of individual V4 neurons to the medium difficulty stimuli tended to be higher in the hard than the easy blocks of trials. Like spatial attention, increasing the task difficulty also led to a decrease in the correlations between the trial-to-trial fluctuations in the responses of pairs of pairs of neurons. Correlations decreased regardless of whether the stimuli were in the neurons' receptive fields, highlighting the non-spatial nature of this manipulation. We also used the responses of groups of V4 neurons to estimate the animal's concentration on each trial. Fluctuations in concentration affected performance in ways that were predictable but qualitatively different than fluctuations in attention. Our results are consistent with the hypotheses that similar neuronal mechanisms underlie many cognitive factors and that uncontrolled fluctuations in global factors affect the psychophysical and physiological results of many studies, regardless of whether they focus on these factors.

Title: Natural texture selectivity of macaque V4 neurons examined by adaptive sampling

Authors: *G. OKAZAWA[1], S. TAJIMA[2], H. KOMATSU[1,3];
[1]Natl. Inst. For Physiol Sci., Okazaki, Japan; [2]Sci. and Technol. Res. Labs., NHK, Tokyo, Japan; [3]SOKENDAI, Okazaki, Japan

Abstract: Many natural materials are characterized by specific textures that consist of complex combinations of low-level image features such as local contrasts, spatial frequencies and orientations. It has been shown that neurons in ventral higher areas selectively respond to material textures (Köteles et al. 2008: Arcizet et al. 2008), but how the texture selectivity is formed is not known. In this study, in an attempt to understand how the low-level image features are integrated to form selectivity to natural textures, we systematically mapped responses of macaque V4 neurons in a high-dimensional texture parameter space. Texture images were selected from more than 10000 naturalistic textures of 8 materials that were synthesized by an algorithm of Portilla and Simoncelli (2000). Dimension of Portilla-Simoncelli texture synthesis

parameters was reduced by Fisher linear discriminant analysis and the texture images were characterized in 7 dimensional parameter space. To efficiently sample textures that evoke stronger neuronal responses, we introduced an adaptive sampling procedure (Yamane et al. 2008). In the experiment, we first recorded neuronal responses to 50 randomly selected textures, and subsequently we selected other 50 textures such that neighbors of the preferred textures will be more densely sampled. By repeating this procedure, we obtained responses of each neuron to 250 - 500 textures. We were successfully able to fit the observed neuronal responses in the 7 dimensional parameter space and found that the tuning peaks of neurons were widely distributed within the parameter space. Control experiments showed that responses tended to change when the phases of individual Fourier components were randomized but did not change for different textures generated using the same synthesis parameters. The response tunings were largely invariant to the changes in image sizes and positions. These results indicate that neural selectivity to material textures in the ventral higher areas can be understood in terms of the selectivity to higher order image statistics and provide hint on how the low-level image features are combined to form the neural selectivity to natural textures along the ventral visual pathway.

Title: Variance in population firing rate as a measure of slow time-scale correlation

Authors: *M. J. MORAIS[1,2], A. C. SNYDER[1,3], M. A. SMITH[1,3,2];
[1]Ophthalmology, [2]Bioengineering, [3]Ctr. for the Neural Basis of Cognition, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Correlation among the spiking responses of pairs of neurons, also known as spike count correlation, is a key indicator of functional connectivity and a critical factor in population coding. Importantly, such correlations are not fixed, but are dynamically modulated by the perceptual and cognitive context, underscoring the importance of correlation as a dependent measure for cognitive neuroscience research. Although the context may vary from moment to moment, correlation must by definition be calculated over multiple trials. This property undermines its utility as a dependent measure for investigations of cognitive processes such as selective attention, which have been shown to affect correlation when considered over an entire experimental session, but which presumably fluctuate on a trial-to-trial basis. To investigate the single-trial dynamics of functional connectivity of populations of spiking neurons, it is necessary to identify a measure that can be assayed on a moment-to-moment basis. Here, we introduce the measure of population variance in normalized firing rate for this purpose. We show using simulations and in vivo data how population variance in normalized firing rate is inversely related to the latent correlation in the population, and how this measure can be used to reliably classify trials from different ecologically typical correlation conditions, even when firing rate is held constant. We discuss the potential advantages for using population variance in normalized firing rate as a dependent measure for both basic and applied neuroscience research.

Title: The amplitude and phase of EEG oscillations index the spiking correlation of underlying brain areas

Authors: *A. C. SNYDER[1,2], C. M. WILLIS[1], M. A. SMITH[1,2,3];
[1]Dept. of Ophthalmology, [2]Ctr. for the Neural Basis of Cognition, [3]Dept. of Bioengineering, Univ. of Pittsburgh, Pittsburgh, PA

Abstract: An understanding of neuronal communication, both within and between regions of the brain, is fundamental to explaining perception and behavior. Communication among neurons has been studied at a variety of scales, from the relatively coarse resolution afforded by scalp electroencephalography (EEG) to the fine resolution achieved in extracellular microelectrode recordings of pairs of neurons. Measures of functional connectivity such as synchronization of EEG oscillations on a large scale, and correlation of spiking activity among small groups of neurons on a small scale, have each been separately linked to a variety of cognitive and perceptual processes. Although the knowledge gained to date by these parallel efforts has been invaluable, a detailed understanding of neuronal communication will ultimately need to bridge these scales so that the relationships between individual neurons can be understood in the context of the interactions of large-scale brain regions, and vice versa. Here we take the first steps toward this goal with the use of simultaneous EEG and single unit recordings in alert macaque monkeys. Since EEG signals are generally considered to be manifestations of coherent local field potentials (LFPs) generated in cortex, and coherent LFPs would reflect common inputs to that region of cortex, we reasoned that EEG oscillations would be related to the correlation in spiking activity between pairs of neurons in the underlying cortical area. To test this prediction, we recorded population spiking activity from microelectrode arrays chronically implanted in visual area V4 of awake, behaving macaques simultaneously with signals from EEG electrodes on the scalps of the animals. Consistent with our predictions, we found that the amplitude and phase of EEG oscillations indexed the correlation of the underlying spiking activity. Interestingly, we found this relationship between EEG oscillations and spiking correlation to be frequency-specific, which may be related to important functional distinctions between different EEG frequency bands. This is a crucial development that directly links EEG signals to physiological processes with clear computational consequences, and opens an avenue for understanding spiking correlations in terms of the interaction among large-scale brain networks.

Title: Noise covariations weakly reduce spike ensemble decoding of object content in macaque inferior temporal cortex

Authors: *Y.-P. CHEN[1], C.-P. LIN[1], C. P. HUNG[2];
[1]Inst. of Neurosci. and Brain Res. Ctr., Natl. Yang-Ming Univ., Taipei, Taiwan; [2]Dept. of Neurosci., Georgetown Univ., DC, WA

Abstract: To understand object recognition, it is necessary to characterize the format of the neural code in the inferior temporal (IT) cortex, the last stage of the ventral visual pathway. Are objects encoded by the precise timing of spiking ensembles in inferior temporal cortex, and do slow firing rate covariations (noise covariations) have a strong impact on information coding? Previous studies addressed this issue by examining the entropy of single spike trains, by pooling responses across independent spike trains, or by examining pairwise coincident spiking. However, it remains unclear whether simultaneous measurements of spiking ensembles contains more information than independent recordings of the same neurons. Specifically, we focus on the issue of whether slow trial-to-trial variations are coupled across neurons in an IT ensemble, and the effect of such coupling on object decoding. We recorded simultaneously from local ensembles of ~64 neurons at the lateral surface of macaque anterior IT and compared their synchronous versus asynchronous (trial-shuffled) object category content via a linear support vector machine classifier. The classifier was trained and tested on independent object stimuli, based on spiking responses across a range of ensemble sizes, bin sizes, and analysis windows. As control, we simulated (via spike jittering) the effect of slow covariations in firing rate. Trial-shuffling slightly improved, by less than 10%, category decoding performance across a range of jitter window sizes. These results suggest that simultaneous measurements do not improve decoding based on ensemble firing rates, and that noise covariations in an ensemble only weakly reduce object category content. We speculate that the tuning decorrelation of nearby IT neurons also reduces the impact of noise correlations, and that downstream neurons may further improve decoding by compensating for trial-to-trial firing rate variations in local IT ensembles.

Title: Visual selectivity and attentional modulation in V4, IT and the posterior lateral pulvinar

Authors: *E. M. MEYERS[1], R. J. SCHAFER[2], Y. ZHANG[2], T. POGGIO[3], R. DESIMONE[2]; [1]Brain & Cognitive Sci., MIT, CAMBRIDGE, MA; [2]McGovern Inst. for Brain Res., [3]Brain and Cognitive Sciences, McGovern Inst., MIT, Cambridge, MA

Abstract: The neural processing that underlies visual object recognition in primates occurs in the ventral visual pathway, and it is widely believed that this pathway operates in a feed-forward manner where information is passed from one cortical region to the next. It is also known that the pulvinar nucleus of the thalamus is interconnected with visual brain regions, and studies have suggested that all visual cortical regions that have direct anatomical connections also have a connection that passes through the pulvinar. However, it is still unclear what role the pulvinar plays in visual processing, or even how the pulvinar's visual selectivity and attention modulation compares to that of visual cortical areas. To address these questions we recorded neurons in visual cortical areas V4 and the inferior temporal cortex (IT), and from the lateral pulvinar which is interconnected with these regions, while monkeys engaged in a visual attention task. Our results revealed that the population of neurons in the pulvinar was almost as visually selective as populations in V4 and IT, and that the pulvinar contains information in a position invariant format. Additionally, we observed that the magnitude of attention effects in the pulvinar were similar to those seen in V4 and IT. From these findings it appears that the pulvinar inherits its selectivity from the cortical regions it is connected to, and that it might be part of a second pathway that relays visual information between cortical regions.

Title: Decoding spiking activity in V4, but not V1, correlates with behaviour in perceptual learning

Authors: *S. C. LOWE[1,2], X. CHEN[3], M. VAN ROSSUM[2], S. PANZERI[4], A. THIELE[3]; [2]Sch. of Informatics, [1]Univ. of Edinburgh, Edinburgh, United Kingdom; [3]Inst. of Neurosci., Newcastle Univ., Newcastle, United Kingdom; [4]Inst. of Neurosci. and Psychology, Univ. of Glasgow, Glasgow, United Kingdom

Abstract: When an individual repeatedly performs a simple sensory task, such as discrimination between similar visual stimuli, performance gradually increases, a phenomenon known as perceptual learning. However the neural correlates of this process are not well understood. Here we consider the results of an experiment in perceptual learning of visual contrast discrimination in cortical areas V1 and V4.

In the experiment, a Gabor (V4 recordings) or sinusoidal (V1 recordings) stimulus, with a contrast chosen at random from a set of 14 possibilities, was presented to a macaque monkey. Recordings were made using chronically implanted electrodes in a multi-unit array. The animal was tasked with determining whether the contrast was higher or lower than a control stimulus of 30% contrast; a correct response was met with a water reward. Experimentation continued until performance saturated, after around 20 days.

Using a population-wide linear-discriminant decoding technique based on the mean firing rates during 500ms of stimulus presentation from ~20 channels in V4, we achieved similar levels of performance for the discrimination task, and a similar rate of improvement in performance, as in the monkey's behavioural responses. However, using the same analysis in V1, decoder performance was constant throughout the learning process, despite the animal's improvement in performance. This suggests contrast information present in V1 is invariant throughout learning, whilst V4 improves in its ability to read information from V1.

The trial-to-trial response agreement for the behavioural and decoding responses was statistically significant for V4 (but not V1) when compared with a null hypothesis of independent response generating processes.

By shuffling the neural responses for individual channels across trials with the same stimulus and applying the decoder to this data, the effect of noise correlations on decoder performance was investigated. Although noise correlations do reduce the performance of the decoder, this

reduction does not vary throughout training. Consequently, it is unlikely that perceptual learning for this task is mediated by a reduction in noise correlations in sensory regions.

Title: Neurons in macaque area CIP visually encode the 3D pose of objects

Authors: *A. ROSENBERG, D. E. ANGELAKI;
Neurosci., Baylor Col. of Med., Houston, TX

Abstract: Interacting with an object in three-dimensional (3D) space often requires the brain to determine the object's 3D spatial pose (i.e., position and orientation) based on visual information. We recently showed that individual neurons in the caudal intraparietal area (CIP) of the macaque monkey visually encode the 3D orientation of a planar surface, and that all orientations are equally represented across the population (Rosenberg, Cowan, & Angelaki; SfN 2012). Because the planar surfaces were always centered on the fixation point in those experiments, it remains unknown whether CIP neurons also encode object position. In the present study, we measure joint tuning curves for the position and orientation of planar surfaces in order to determine if CIP neurons encode 3D object pose.
Position-orientation tuning curves were measured using single-unit extracellular recordings. Stimulus position was varied along left-right, up-down, or forward-backward axes of space, with the central stimulus centered on the fixation point 30 cm in front of the monkey. The translation magnitude ranged between 2.5 and 10 cm. Orientation was varied about either a slant (rotation in depth) or tilt (parallel to the line-of-sight) axis. The planar surfaces were rendered with both checkerboard texture and binocular disparity cues on an LCD screen using red-green anaglyphs. Fixation was maintained within 2 degree version and 1 degree vergence windows. Based on von Mises function fits (average r = 0.93, N=161), orientation preference was largely invariant to position. The average change in orientation preference between fixation centered and displaced object positions was -2±24 degrees standard deviation (N=97 comparisons), and the direction of change was not systematically related to the position (sign test, $p>0.17$). This suggests position

and orientation have multiplicatively separable effects on CIP firing rates, which was tested using singular value decomposition to create a separable model of each position-orientation tuning curve. On average, 86% of the variance in the data (N=63) was accounted for by this model, confirming that position and orientation have largely independent effects on the responses of CIP neurons. Using maximum likelihood decoding, we lastly demonstrate that the position and orientation of a planar surface can be jointly decoded from CIP population activity. Thus, the present results show that CIP can answer two fundamental questions faced whenever it is necessary to interact with an object: Where is it? and How is it oriented?

Title: Choice-related activity in area CIP during slant discrimination

Authors: *L. C. ELMORE[1], A. ROSENBERG[1], G. C. DEANGELIS[2], D. E. ANGELAKI[1]; [1]Neurosci., Baylor Col. of Med., Houston, TX; [2]Brain & Cognitive Sci., Univ. of Rochester, Rochester, NY

Abstract: The ability to construct accurate 3D representations of the world from 2D retinal projections is fundamental to many visually guided behaviors including reaching, grasping, and navigation. A critical step in this process is the precise judgment of the 3D spatial orientation of objects. Recent work in our laboratory has shown that neurons in the caudal intraparietal area (CIP) are tuned for 3D surface orientation. These neurons are jointly tuned for two angles describing 3D surface orientation: tilt (orientation within the frontoparallel plane) and slant (orientation in depth).

To examine the contribution of CIP neurons to slant perception, we recorded extracellular single-unit responses while a rhesus monkey performed a fine slant discrimination task. Stimuli were rendered as random dot stereograms using red-green anaglyphs. Planar slant was defined solely by binocular disparity cues. In a two-alternative forced-choice task, the monkey reported whether a plane was slanted forward or backward by making a saccade to one of two targets. The monkey's mean psychophysical threshold was 3.56°.

We assessed the neural sensitivity of a sample of CIP neurons from one monkey using ROC

analysis. Neurometric functions were plotted for each neuron, and the geometric mean of the neuronal threshold was 26.97±4.57 SD. The average ratio of neurometric to psychometric threshold was roughly 8:1, indicating that single neurons were generally much less sensitive than the animal. We computed choice probabilities to assess the relationship between trial-to-trial variability in neural responses and the animal's choices. The majority of neurons had significant choice probabilities with a mean value (0.58±0.12 SD) that was significantly greater than chance ($p = 0.03$). Also, there was a significant negative correlation between neural threshold and choice probability ($r = -0.48$, $p = 0.05$), such that more sensitive neurons tended to have larger choice probabilities. This relationship between threshold and choice probability is consistent with the hypothesis that perception relies more heavily on the most sensitive neurons. Our findings provide the first evidence of neural activity correlated with the perception of slant, and suggest that area CIP contributes to perception of 3D surface orientation.

Title: Joint tuning for direction of motion and binocular disparity may reveal local map structure in MT

Authors: A. SMOLYANSKAYA, D. A. RUFF, *R. T. BORN;
Harvard Med. Sch., BOSTON, MA

Abstract: Neurons in sensory cortical areas are tuned to multiple dimensions, or features, of their sensory space. Exactly how single neurons achieve the representation of multiple features is of interest for understanding where specific transformations occur along the visual hierarchy as well as for determining the decoding algorithms appropriate for extracting information from a population of neurons. We investigated the joint tuning of individual MT neurons for two visual features: direction of motion and binocular disparity, an important depth cue. In total we recorded from 92 well-isolated MT neurons in three awake macaque monkeys while they fixed

their gaze on a central point on a computer screen. All combinations of 8 stimulus directions and 7 binocular disparities (-1.2° to +1.2° in 0.4° steps) were presented to two animals, with 15-20 repetitions of each stimulus. The third animal was presented with more finely spaced steps that depended on the preferences of each neuron.

We found that a separable, multiplicative combination of tuning for direction of motion and binocular disparity accounted for more than 95% of the variance in the joint tuning function for over 93% of MT neurons. The separable encoding of these two features indicates that 1) each feature can be read out independently from MT by simply averaging across the population without regard to the other feature and 2) the inseparable representations seen in subsequent areas, such as MST, must be computed beyond MT.

Intriguingly, we found that the remaining non-separable component of the joint tuning function often manifested as small, but *systematic* changes in the neurons' preferences for one feature as the other one was varied. For example, a surprising number of neurons showed a pattern consisting of a counterclockwise rotation of the preferred direction as the binocular disparity was changed from near to far. To determine how frequently such orderly rotations of the preferred direction occurred by chance, we developed a resampling procedure that permuted the disparity information across direction tuning curves while accounting for changes in overall gain that occurred as binocular disparity was varied. This test revealed significant, systematic rotations of the preferred direction as binocular disparity was changed for 34 of the 78 MT neurons for which we had sufficient data to perform the test. We speculate that these non-random rotations reflect the functional organization for direction and binocular disparity in MT and suggest a "like-to-like" local connectivity with respect to both features. If this is correct, joint tuning may provide a new tool with which to probe the local structure of cortical maps.

Title: Longitudinal investigation of IT cortex: Delayed emergence of learning-induced plasticity

Authors: *D. A. LEOPOLD[1], A. P. JONES[2], D. B. T. MCMAHON[3];
[1]NIMH, BETHESDA, MD; [2]Univ. of Maryland, College Park, MD; [3]Lab. of Neuropsychology, Natl. Inst. of Mental Hlth., Bethesda, MD

Abstract: We recently developed a technique for obtaining longitudinal single unit recordings across days (McMahon et al 2013). As demonstrated by the results presented in the accompanying presentations (Jones et al 2013, Elnaiem et al 2013), visual responses in inferotemporal (IT) cortex are largely stable from day to day in the absence of explicit learning pressure. This observation must be reconciled with evidence that the responses of neurons in IT cortex are shaped by various types of visual experience. For example, norm-based theories of visual function suggest that IT cortex responses are continually recalibrated to reflect the statistical properties of the visual world, at least for specific categories of visual stimuli such as faces. With the goal of understanding how long-term plasticity in IT contributes to acquisition of perceptual expertise, we developed two behavioral paradigms to longitudinally study the effects of learning on single neuron responses in IT. In the first paradigm, monkeys learned to categorize 48 images as "good" or "bad" over the course of less than one hour. In the second paradigm, the animals gradually gained perceptual expertise in discriminating low identity values of morphed human, monkey, and artificial face stimuli. During the course of eight longitudinal experiments conducted in two monkeys in the first paradigm, neurons were tracked from 12 to 37 days. We found that neurons changed their response strength following learning. Changes were not immediate, but generally appeared 1-2 days following the behavioral signs of learning, and were selective for particular stimuli. Changes were sometimes expressed as a scaling up or down of the action potential firing rate and in other cases as an abrupt decrease in response latency. In a few cases, training resulted in neurons gaining new responses to stimuli to which they had previously been unresponsive. The delayed emergence of these experience-induced neuronal changes indicates that visual response plasticity in IT cortex is secondary to learning, but cannot be the causal drivers of learning. We will report these results from the first paradigm along with preliminary data from the second paradigm, which focuses on the acquisition and refinement of perceptual expertise for faces.

Title: Longitudinal investigation of IT cortex: Impact of stimulus repetition across days

Authors: *D. B. MCMAHON[1], I. V. BONDAR[2], D. A. LEOPOLD[3];
[1]Lab. of Neuropsychology, Natl. Inst. of Mental Health, NIH, Bethesda, MD; [2]Inst. of Higher Nervous Activity and Neurophysiol., Moscow, Russian Federation; [3]Lab. of Neuropsychology, Natl. Instiute of Mental Hlth., Bethesda, MD

Abstract: Repeated presentations of the same stimuli are commonly associated with improvements in behavioral performance. At the level of single neurons, stimulus repetitions are also associated with reduced spiking responses in monkey inferotemporal (IT) cortex. These findings run contrary to the intuitive expectation that stronger neuronal activity should give rise to faster and better behavioral responses. One hypothesis proposes that the repetition suppression commonly observed over the course of a single recording session contributes to long-lasting decreases in responses to highly familiar stimuli (Li, Miller and Desimone 1993). Since conventional physiological methods typically preclude following activity from the same neurons for more than a few hours, it has not been possible to test this idea experimentally. We recently developed a drivable, MRI-compatible chronic recording technique suitable for longitudinal single unit recording. We first use this technique to demonstrate that the selectivity profile of neurons IT cortex is remarkably stable from day to day, and in some cases across many months. In recordings from two monkeys trained to fixate while the stimuli were presented sequentially, the spiking responses of many neurons (N = 46) decreased strongly over the course of the first seven stimulus presentations (mean reduction = 85%, inter-quartile range = 64%-99%). However, repetition suppression that was observed over the course of a single session did not carry over to the following day. This patten of within-day suppression and across-day recovery to the initial response strength produced a reliable sawtooth pattern in the activity of neurons followed over the course of one month. In the gamma frequency range of the local field potential, the inverse pattern was observed: The amplitude of rectified, band-limited responses in the gamma range increased over repeated trials within a day and returned to low baseline levels overnight. In contrast to the spiking and gamma responses, the broadband evoked field potential did show signs of accumulated changes across days. In particular, the N170 component of the evoked potential decreased in amplitude from 45 microVolts on day one to 23 microVolts on day thirteen. These results show that long-term firing rate reductions as stimuli become more familiar are not an obligatory consequence of repetition suppression observed over shorter, within-session time scales. They instead support the idea that the (presumably deleterious) impact of reduced visual response strength on the fidelity of feature representations might be offset by compensatory changes reflected by the increase in gamma power.

Title: Longitudinal investigation of IT cortex: Probing category selectivity with 10,000 stimuli

Authors: *A. P. JONES[1,2], D. A. LEOPOLD[2], D. B. T. MCMAHON[2];
[1]Biol., Univ. of Maryland, College Park, MD; [2]Lab. of Neuropsychology, NIMH/NIH, Bethesda, MD

Abstract: In high-level visual areas such as IT cortex, neurons commonly show complex patterns of stimulus selectivity that cannot be readily accounted for by set of simple feature parameters. Response properties of such neurons evidently reflect specialization within a high-dimensional feature space in which the relevant parameters are largely unknown. Our ability to probe the organizing principles of the brain's representational scheme ultimately depends on the number of trials it is possible to obtain for a single neuron. Extending the range of a single experiment to encompass multiple days could therefore shed new light on the principles underlying neuronal specialization. We recently developed a drivable, MRI-compatible chronic recording technique suitable for longitudinal single unit recording. We used this approach to collect responses from neurons in the temporal lobe face patch AF to 10,000 stimuli. Images were drawn from ten object categories that included human faces and body parts, monkey faces and body parts, birds, butterflies, plants, inanimate objects, scenes and Fourier descriptor patterns. Eight trials per stimulus were collected over the course of twelve recording sessions (eighteen days). Consistency in responses to individual stimuli was assessed by a split-halves correlation analysis between odd and even trials ($r = 0.86$). This analysis indicated that the responses obtained were highly reliable despite the fact that they were collected on different sessions spanning more than two weeks. Neurons that gave excitatory responses to human or monkey faces tended to show suppressive responses to whole bodies and body parts, and visa versa. Face cells also responded selectively, albeit more sparsely, to images from non-face categories. Within the face category, AF neurons were selective for identity, face viewpoint, and image scale. Selectivity patterns of nearby neurons (< 1mm apart) tended to carry largely independent signals, as reflected by low correlations across neurons (mean $r = 0.03$, inter-quartile range = -0.04 to 0.11). The independence of neuronal signals in AF was further indicated by principle components analysis, which revealed that the first fourteen principle components only accounted for 85% of the variance across responses. These results demonstrate that longitudinal

recordings have the sensitivity to uncover complex features of neuronal specialization within massive, multi-dimensional feature spaces.

Title: Longitudinal investigation of IT cortex: Responses to naturalistic movie stimuli

Authors: *H. D. ELNAIEM, D. B. T. MCMAHON, B. E. RUSS, D. A. LEOPOLD;
Lab. of Neuropsychology, Natl. Inst. of Mental Health, NIH, Bethesda, MD

Abstract: The primate temporal lobe visual system contains specialized regions for processing categories of stimuli that are likely to be of particular importance, such as faces and bodies. Under ecological conditions, the visual world is in constant motion and the dynamic properties of animals and objects are an integral aspect of the sensory environment. In this study, we exploited the ability of chronically implanted microwire electrodes to track cells across days. We used this approach to obtain longitudinal recordings from multiple electrodes while the subjects watched movies showing clips of humans, monkeys, and other animals in naturalistic settings. Chronic electrodes were implanted in the superior temporal sulcus region of inferotemporal (IT) cortex in three monkeys, including one bundle of 64 microwires in face patch AF. Sixty-six neurons from the three animals were strongly modulated by movie content. Individual neurons responded with patterns that were highly consistent across different runs, as well as across days ($r = 0.75$). Correlations between simultaneously recorded neurons located within 1 mm showed weaker, but still significant, correlations ($r = 0.15$). Thus neurons in close proximity (i.e., contained within a single voxel or cortical column) carry largely independent signals. Although neurons outside of face patches responded with a high degree of consistency and selectivity for specific movie content, their responses could not be accounted for by any obvious trigger features. In contrast, the population of neurons in face patch AF responded particularly strongly to scenes showing close-ups of monkey faces. Despite this shared preference for face stimuli, correlations between neurons within AF were no stronger than correlations between neurons from non-face-selective regions. To investigate the underlying dimensions of the neuronal response space, we computed the principle components across a population of 45 simultaneously

recorded spiking responses. The first six principle components together accounted for 85% of the variance across neurons, suggesting a relatively compact dimensionality of feature space. Taken together, these results provide a framework for investigating the specialization of the ventral visual system using a rich, relatively unconstrained regime of visual stimulation.

Title: Transcranial electrical stimulation mitigates motion adaption in V1, MT, and MST neurons of awake, behaving macaques

Authors: *K. KAR, J. DUIJNHOUWER, B. KREKELBERG;
Rutgers Univ., Newark, NJ

Abstract: Transcranial electrical stimulation (tES) is used in the clinic to treat depression, expedite recovery from stroke, and has been used to augment human cognition. Moreover, it is finding increasing use in behavioral neuroscience as a tool to modulate brain activity noninvasively. Its widespread use notwithstanding, the mechanisms by which the externally applied electric fields modulate brain and behavior are still poorly understood. Previously we have reported that tES (10 Hz, 0.5 mA) over hMT+ reduces adaptation in human subjects. This led us to hypothesize that subthreshold rhythmic membrane voltage modulations produced by tES reduce adaptation in motion selective neurons. Here we test this hypothesis with single unit recordings in V1, MT, and MST of the macaque monkey.
We recorded from adapted and unadapted cells with and without tES. The tES electrodes were placed extra-cranially on either side of the recording chamber (over area MT). In the adaptation condition, we presented the adapter stimulus (dots moving coherently in the cell's preferred direction) for 3 s. This was followed by a 300 ms blank period and a 300 ms test phase during which we presented a random dot stimulus moving coherently in one of eight directions. In the stimulation condition the visual adapter stimulus was accompanied by tES (10 Hz, 1.0 mA). In

unadapted control trials, the adapter stimulus was replaced by a noise stimulus consisting of dots moving in random directions.
We measured changes in tuning amplitude and tuning width of the cells and the evoked LFP responses. tES diminished the effects of adaptation on motion selective cells. Notably, whenever adaptation decreased (or increased) tuning amplitude of a neuron, the concurrent application of tES with adaptation reduced this suppression (or facilitation). Similarly when adaptation sharpened (or broadened) the tuning width of a cell, application of tES during adaptation reduced this sharpening (or broadening). Similar mitigation of adaptation was found in the evoked LFP. These results provide novel insight into how tES interacts with neural activity and establishes the awake, behaving macaque as a model to study the mechanisms of tES in-vivo.

Title: Effects of luminance contrast on the color selective responses in monkey inferior temporal cortex

Authors: *H. KOMATSU[1,2], T. NAMIMA[1,2], M. YASUDA[3], T. BANNO[4];
[1]Div. of Sensory and Cognitive Information, Natl. Inst. Physiol Sci., Aichi, Japan; [2]The Grad. Univ. for Advanced Studies (SOKENDAI), Okazaki, Japan; [3]Natl. Eye Inst., Bethesda, MD; [4]Natl. Inst. of Neurosci., Kodaira, Japan

Abstract: Luminance contrast of a color stimulus may cause significant influence on the color perception. Although the relationship between color and luminance signals is an important problem in visual perception, relatively little is known about how the luminance contrast affects the responses of color selective neurons.
In the present study, we examined this problem in the monkey inferior temporal (IT) cortex by comparing the responses of color selective neurons at two different luminance contrasts.
Single neuron activities were recorded from the anterior and posterior color selective regions in IT cortex (AITC and PITC) identified in previous studies (Yasuda et al. 2010, Banno et al. 2011)

where color selective neurons are accumulated. Color stimuli (15 bright stimuli and 15 dark stimuli) consisted of 28 stimuli that evenly distribute across the gamut of the CRT display defined on the CIE -xy chromaticity diagram at two different luminance levels (5 cd/m2 or 20 cd/m2) and 2 stimuli at white points. The background was maintained at 10 cd/m2 gray.
We found that the effect of luminance contrast on the color selectivity was markedly different between AITC and PITC. When we examined the correlation between the responses to the bright stimuli and those to the dark stimuli with the same chromaticity coordinates, most AITC neurons exhibited high correlation whereas many PITC neurons showed no correlation or only weak correlation regardless of sharpness of color selectivity. In PITC, the effect was specifically large for neutral colors (white, gray, black) and for colors with low saturation.
These results indicate that the effect of luminance contrast on the color selective responses differs between AITC and PITC. These results suggest that AITC and PITC play different roles in color perception: PITC neurons may play important roles in the distinction between white/black or orange/brown in our color perception, while AITC may do so in the perception of hue across different luminance contrasts.

Title: Effects of luminance contrast on the color selective responses in monkey visual area V4

Authors: *T. NAMIMA[1,2], G. OKAZAWA[1], H. KOMATSU[1,2];
[1]Natl. Inst. For Physiological Sci., Okazaki, Japan; [2]The Grad. Univ. for Advanced Studies (SOKENDAI), Okazaki, Japan

Abstract: It is well established that there exist color selective neurons in the monkey visual area V4. It has been reported that the responses of many color selective neurons in V4 exhibit selectivity that is invariant to the luminance contrast of the color stimuli (Conway et al, 2009), whereas some neurons are affected by the luminance contrast (Bushnell et al, 2011). However, no attempt has been made to quantitatively compare the responses across the entire range of

gamut including colors with low saturation between stimuli with different luminance contrasts. In the present study, we systematically examined the effect of luminance contrast on the color selectivity of V4 neurons using stimuli that covered the entire range of the gamut.
Color stimuli (15 bright stimuli: 20cd/m^2 and 15 dark stimuli: 5cd/m^2) consisted of 28 stimuli that evenly distributed across the gamut of the CRT display defined on the CIE -xy chromaticity diagram and 2 stimuli at white points. The background was maintained at 10 cd/m^2 gray. Single neuron activities were recorded from the prelunate gyrus in visual area V4 of monkeys performing a visual fixation task.
We found that the effect of luminance contrast varies across V4 neurons and in general responses of V4 neurons were affected by the luminance contrast of color stimuli. When we analyzed the correlation between the responses of the population of color selective V4 neurons to the bright stimulus and those to the dark stimulus having the same chromaticity, we found that the variation in the effect of luminance contrast across colors was large for sharply color selective neurons but small for broadly color selective neurons. In the former, a large effect was stably observed for colors with low saturation.
These results indicate that the luminance contrast significantly affects the neural coding of colors especially for colors with low saturation. The present results are similar to those obtained in PIT cortex in some aspects but different in other aspects (Komatsu, Namima, Yasuda, Banno, this meeting), suggesting that some transformation of color signals takes place between V4 and PIT.

Title: Sensitization of developing cutaneous nociceptors during peripheral inflammation

Authors: *M. P. JANKOWSKI[1,2], J. L. ROSS[1], J. WEBER[1], A. T. SHANK[1], R. C. HUDGINS[1];
[1]Dept Anesthesia, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Dept. Pediatrics, Univ. of Cincinnati, Cincinnati, OH

Abstract: We have previously found that cutaneous polymodal nociceptors (CPM) are sensitized to heat stimuli in adult mice during inflammation of the hairy skin. We also have found that there is an apparent recruitment of mechanically insensitive, heat sensitive C-fibers (CH). In order to

determine if a similar pattern of sensory neuron sensitization occurred during postnatal development in response to peripheral inflammation, we examined the response properties of cutaneous afferents one day after injection of 3% carrageenan into the hairy hindpaw skin at postnatal days seven and 14. Electrophysiological recordings were performed in male Swiss Webster mice using an *ex vivo* hairy skin-saphenous nerve-DRG-spinal cord preparation. We found that fast conducting sensory neurons had significantly increased firing to both mechanical and heat stimulation of the skin one day after P7 inflammation relative to age-matched naives. We also detected a significant decrease in heat threshold in these fibers at this age. Conversely, one day after P14 inflammation, we did not observe any changes in the fast conducting afferents, but we did detect increased firing to mechanical and heat stimuli in the slowest conducting sensory neurons. In addition, we also observed decreased thresholds to mechanical deformation of the skin in these slowly conducting cutaneous fibers at this age. No changes in fiber distribution were observed at any age at these acute time points. The age-related changes in afferent sensitization correlated with specific upregulation of mechanically and thermally sensitive receptors/channels in the DRGs at distinct ages. For example, while P2Y1, ASIC3, and TRPM3 were upregulated in the DRGs after P7 inflammation, during P14 inflammation, ASIC1, Piezo2 and TRPV1 were uniquely upregulated. These results suggest that sensitization of cutaneous afferents during peripheral inflammation differs depending on the postnatal stage of development. Mechanisms of hypersensitivity to peripheral stimuli may therefore be regulated through different subsets of cutaneous nociceptors and receptors/channels in an age-dependent manner.

Title: Sensitization of group III and IV muscle afferents after ischemia and reperfusion injury

Authors: *J. L. ROSS[1], E. R. COHEN[1], R. C. HUDGINS[1], A. T. SHANK[1], M. P. JANKOWSKI[1,2];

[1]Anesthesia, Cincinnati Children's Hosp. Med. Ctr., Cincinnati, OH; [2]Pediatrics, Univ. of Cincinnati, Cincinnati, OH

Abstract: Previous data has shown that inflammation of the muscles alters group III and IV muscle afferent responses to thermal and mechanical stimuli with corresponding changes in gene expression in the affected DRGs. In order to determine if similar changes in response properties and gene expression occur in these afferents during chronic and transient ischemia of the muscles, we surgically occluded the right brachial artery (BAO) of adult male Swiss Webster mice and either maintained the BAO for 24hr or removed the occlusion after 6hr, allowing for 18 hours of reperfusion (I/R). Differences in mechanical, thermal, and chemical sensitivity in muscle afferents were then examined between these two injury states using an *ex vivo* forepaw muscle-median and ulnar nerve-DRG-spinal cord recording preparation. Compared to age-matched naïves, both injury models increased the prevalence of polymodal afferents. Specifically, both chronic BAO and transient BAO with reperfusion induced a significant increase in the number of cells that responded to both non-noxious (low lactic acid and ATP concentrations; pH 7.0) and noxious (high lactic acid and ATP concentrations, pH 6.6) chemical stimulation of the muscles. However, each injury model also induced a unique set of changes in afferent response properties. Chronic BAO induced an increase in firing to heat stimuli in group III and IV muscle afferents that was not detected after I/R. In addition, transient ischemia with reperfusion decreased mechanical threshold and enhanced firing rates to mechanical stimuli, whereas BAO did not differ from the naïve condition in regards to both mechanical threshold and firing. Corresponding with these functional changes in the afferents, each injury state caused upregulation of specific receptors/channels in the DRGs when compared to the naïve condition. Although both conditions showed a significant increase in ASIC3 mRNA, BAO also caused a significant increase in P2X5 and P2Y1, whereas I/R exhibited significant increases in P2X3 and ASIC1, but a significant decrease in P2Y1. Together, these data suggest that ischemic muscle pain may be generated by different mechanisms during chronic ischemia compared to transient ischemia with reperfusion.

Title: Firing properties of cutaneous nocieptors in response to natural and optical stimulation in ChR2 transgenic mice

Authors: *K. M. BAUMBAUER, J. J. DEBERRY, B. M. DAVIS, H. R. KOERBER;
Dept. of Neurobio., Univ. of Pittsburgh, Pittsburgh, PA

Abstract: Cutaneous nociceptive fibers are a heterogeneous population comprising many distinct subsets whose individual influence on nociception and/or sensory information processing cannot be easily assessed using naturalistic (e.g. mechanical, thermal, etc.) stimulation. However, with the recent availability of mice modified to express channelrhodopsin, we can now begin to explore the contribution of distinct populations of sensory neurons to nociceptive processing independent of natural transduction mechanisms. The first step in the development of these models is to determine whether light-induced neuronal responses are similar to those evoked by natural stimuli. Transgenic mice expressing channelrhodopsin-2 driven by the Rosa-26 promoter (ChR2-EYFP) were crossed with peripherin-cre or advillin-cre mice. The EYFP tag allowed for visualization of cell bodies and fibers within the DRG and central projections within the spinal cord. When light-induced tail-flick responses were assessed, all mice demonstrated robust responses to as little as a 30 ms flash of light. We next utilized an *ex vivo* skin/nerve/DRG/spinal cord preparation to explore response properties of cutaneous neurons expressing ChR2. Responses were characterized from multiple classes of nociceptors from both strains of mice. Cells were characterized based on their conduction velocities and response to mechanical and thermal stimuli. Once receptive fields were localized, responses to 473 nm laser light transmitted through a 200m diameter optical fiber, were assessed. Nociceptors responded to flashes ranging from 10-5000 ms (39.2 mW/mm^2) and as little as 3.2 mW/mm^2 (1000 ms pulse) of power. Responses to light and naturalistic stimulation were analyzed in mechanically sensitive cells. Suprathreshold light stimulation resulted in tonic firing over the duration of the stimulus while suprathreshold mechanical stimulation evoked a more phasic response. Latency to first response to mechanical and light stimulation were similar. However, peak instantaneous frequencies were significantly higher for suprathreshold mechanical stimulation, averaging 33.9 Hz *vs* 5.4 Hz for optical stimulation (39.2 mW/mm2). These responses were not the result of activation of heat sensitive afferents as the temperature measured at the skin only increased 1°C in response to laser stimulation. These results demonstrate that optical stimulation of the skin in ChR2 mice can activate cutaneous nociceptors, but that optical and naturalistic stimuli are not equivalent. Ongoing experiments are exploring the impact of sensitization on neuronal responses in ChR2 mice.

Title: Channelrhodopsin-activation of bladder afferents is sufficient to initiate the visceromotor reflex

Authors: J. J. DEBERRY, H. R. KOERBER, K. M. ALBERS, K. M. BAUMBAUER, *B. M. DAVIS;
Dept. of Med., Univ. of Pittsburgh, PITTSBURGH, PA

Abstract: Sensory innervation of the bladder is comprised of heterogeneous neuronal subpopulations of lightly myelinated and unmyelinated peripheral fibers (A[[Unsupported Character - Symbol Font ]]- and C-fibers, respectively) that convey information about multiple processes, including homeostasis (metaboreceptors) and detection of potentially damaging stimuli (nociceptors). Channelrhodopsin (ChR2) is a light-gated ion channel that allows light activation of neurons. We used Cre-recombinase technology to express ChR2 fused to enhanced-YFP (ChR2-EYFP) in bladder afferents that normally express peripherin or TRPV1 (Per/ChR2; TRPV1/ChR2, respectively). Visualization of the ChR2-EYFP revealed that peripherin-expressing bladder afferents make up the majority of fibers seen in bladder nerve bundles. Fine ChR2-EYFP-positive fibers could be seen leaving the larger nerves and coursing through all bladder layers including the urothelium. In addition, postganglionic neurons in the pelvic ganglion also expressed ChR2-EYFP. TRPV1 promoter-driven ChR2-EYFP fibers were also found throughout the bladder including numerous fine fibers that penetrated the urothelium at regular intervals, perpendicular to the bladder lumen. Using a 473nm laser generating 8-25 mW/mm^2, we were able to induce a foot withdrawal reflex in lightly anesthetized Per/ChR2 mice (1.0% isoflurane). Separate studies (see SfN abstract by Baumbauer et al.) showed that this reflex could be induced with 30ms light pulses, that were only slightly longer than that needed to activate individual nociceptors. This was not a heat-evoked response; thermistor measurements showed that skin temperature did not increase more than 1.0 ^oC upon exposure to the laser. A

laparotomy was then performed to expose the bladder for laser stimulation. A 10 sec stimulation produced a viseromotor reflex that was equivalent to 30-50 mm Hg bladder distention. The reflex onset occurred within the 1.5 sec of laser stimulation (similar to that seen with distension) and continued for the remaining 8.5 seconds. After discharges were also seen occasionally, similar to that observed following bladder distension in the noxious range. These studies show that sufficient ChR2 expression was driven by the peripherin promoter in bladder afferents to evoke bladder reflexes upon light activation. Further, these studies provide proof-of-concept that increases (using ChR2) or decreases (using halorhodopsin) in bladder afferent activity could be effected by selective expression of light-activated molecules and serve as potential treatments for bladder dysfunction.

Title: Transgenic expression of endogenous calcium indicator GCaMP3 allows visualization of somatic and visceral sensory neurons *In vivo*

Authors: B. M. DAVIS[1], *J. DEBERRY[1], K. SMITH[2], C. J. WOODBURY[2];
[1]Med., Univ. of Pittsburgh, Pittsburgh, PA; [2]Zoology and Physiol., Univ. of Wyoming, Laramie, WY

Abstract: Both somatic and visceral structures are innervated by numerous types of sensory fibers that are functionally distinct and highly plastic in response to injury and disease. Two central questions in sensory biology are whether disease/injury alter which populations of sensory fibers respond to a given stimulus and the extent to which neurons that were previously silent become functional. To address these questions we crossed mice expressing GCaMP3 (an endogenous calcium indicator) downstream of a loxP-flanked CAG promoter with an EIIa-Cre line in order to induced GCaMP3 expression in all DRG neurons. When dissociated GCaMP3-expressing DRG neurons were examined in culture, low levels of GCaMP3 fluorescence were

detected at rest. When stimulated with 50mM K^+ to induce depolarization and allow Ca^{2+} influx, virtually every cell exhibited a strong Ca^{2+} signal with a αF twice that of Fura-2, but with a longer decay constant ($t_{1/2}$). Stimulation with K^+ could be repeated multiple times (1/min for 20 mins) with no obvious decrease in signal. To determine if GCaMP3 could be used to report activity in somatic and visceral afferents *in vivo*, optical recordings were made in L6 and S1 spinal ganglia in a decorticate preparation. Bipolar electrodes implanted in the base of the tail were driven with stimulus frequencies of 1, 10 and 100 Hz at two different stimulus durations (100 and 500μs). A 100μs pulse was required to elicit a GCaMP3 signal. A GCaMP3 signal was observed at all frequencies with increasing number of cells responding at higher frequencies and the intensity of the GCaMP3 signal increased in individual cells with increased frequency of stimulation. GCaMP3 signals could also be elicited with light brushing, pinch and radiant heat applied to the tail. Light brushing of the tail produced reproducibly strong signals in S1 neurons with large diameter somata. Heating of the tail and perianal region elicited a GCaMP3 signal from neurons with small somata in both L6 and S1 DRG. Both ramp distension (0-60 mmHg over 20 sec) and stepwise square-wave distension (at 20, 40, and 60 mmHg for 20 sec) of the bladder were able to produce GCaMP3 signals. DRG neurons responding to bladder distension exhibited both low (<40 mmHG) and high (>40mmHg) thresholds. Bladder afferents that responded throughout all distension pressures were also observed. These results demonstrate that genetically engineered GCaMP3-expression can be used for population studies of sensory neurons *in vivo*, allowing relatively high throughput analysis of new pain therapies.

Title: Built to sense: Protein, lipid, and carbohydrate composition of isolated murine dorsal root ganglia neurons

Authors: *M.-E. A. BARABAS[1], E. C. MATTSON[2], C. J. HIRSCHMUGL[2], C. L. STUCKY[1]; [1]Cell biology, Neurobio. & Anat., Med. Col. of Wisonsin, Milwaukee, WI; [2]Physics, UW-Milwaukee, Milwaukee, WI

Abstract: Dorsal root ganglia (DRG) neurons are specialized to detect sensory stimuli such as heat, cold and mechanical force. Sensory neurons are heterogeneous, and specific subpopulations are activated by noxious stimuli, leading to the perception of pain. The identification and characterization of nociceptive subpopulations and their sensory transduction molecules may lead to development of novel pain therapeutics. Chemical components of the neuronal plasma membrane, such as lipids and carbohydrates, may modulate properties of channels and may be used to distinguish subpopulations. In order to study the relevant chemical features of sensory neurons, we conducted infrared (IR) spectromicroscopy on isolated murine DRG neurons. The IR measurements were performed at the Synchrotron Radiation Center (SRC, Madison, WI) with the infrared environmental imaging (IRENI) beamline(1). This approach allows for imaging of chemical functional groups (protein, lipid, carbohydrate) at diffraction-limited resolution on live, unfixed sensory neurons without the use of antibodies or dyes.
We compared IR spectra and chemical images generated from IR absorption of proteins, lipids, and carbohydrates of small-diameter neurons, which are typically nociceptive, with those of large-diameter neurons. The analysis of subcellular localization of chemical features of DRG neurons indicated that some neurons have a lipid- or carbohydrate-dense ring around the perimeter of the somata and the presence of these rings is mainly among large-diameter neurons. It is possible that these rings might provide enhanced sensitivity to large-diameter neurons for activation by innocuous stimuli. We also compared the relative quantities of protein secondary structures throughout isolated neurons and found elevated concentrations of beta-sheet proteins at the soma periphery relative to the interior in both large- and small-diameter neurons. The organization of these protein types may play a vital role in sensory specialization of DRG neurons.
IR spectromicroscopy has not been previously used to study relationships between chemistry, morphology and function in sensory neurons at the single-cell level. Our study demonstrates the potential of this technique to determine relationships between chemical composition and specialized functions of sensory neurons, as well as to potentially identify novel molecular epitopes to define subpopulations of sensory neurons and their transduction moieties.

Title: A subclass of cutaneous polymodal nociceptive C fiber afferents in non human primates responds to β-alanine

Authors: *M. RINGKAMP[1], M. WOOTEN[1], J. BORZAN[2], A. H. KLEIN[1], T. V. HARTKE[1], R. A. MEYER[1];
[1]Dept Neurosurg., [2]Dept Anesthesiol. and Critical Care Med., Johns Hopkins Univ., BALTIMORE, MD

Abstract: Two types of heat responses are observed in cutaneous polymodal nociceptive C-fibers when their receptive fields (RF) are exposed to a stepped heat stimulus (49°C, 3s): a quick response (QCs) or a slow response (SCs). We have previously shown that QCs exhibit a greater response to the pruritogen cowhage, whereas the heat response of SCs sensitizes more following a mild burn injury. Others have shown that β-alanine produces itch in humans, and that it activates non-peptidergic, MrgprD positive C fibers in mice. To test if QC and SC afferents differ in their response to β-alanine, we recorded from unmyelinated C fibers innervating the hairy skin in anaesthetized, non human primates using standard teased fiber techniques. After locating the RF, the sensitivity of the afferent fiber to noxious heat was assessed using a contact free, temperature controlled CO2 laser system. A series of 10 µl injections was then administered at the RF: extracellular fluid (ECF), histamine (HIS,10 µg) and β-alanine (ALA, 90 µg). The order of HIS and ALA injections was randomized. Following each injection, neuronal activity was recorded for at least 5 minutes after which recordings were aborted if activity was absent in 3 consecutive minutes. A total of 31 C fibers was tested, 14 of which were classified as QC and the remaining 17 as SC. Responses to ECF were negligible and did not differ between QC and SC afferents. HIS evoked activity did not significantly differ between SC and QC afferents. In contrast, ALA evoked a 4.5-fold larger response in QC than SC afferents. In addition, all QC fibers were activated by β-alanine, but only about one third of SC fibers responded. These results suggest that QC fibers are more sensitive to β-alanine than SC fibers and that QCs may encode the itch associated with β-alanine. The response to a stepped heat stimulus allows identification of β-alanine responsive afferents.

Title: Single-cell labeling of mammalian non-peptidergic nociceptors reveals differences in central projection morphology between axial- and limb-innervating levels

Authors: *W. P. OLSON, J. NIU, A. VYSOCHAN, W. LUO;
Dept. of Neurosci., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Nociceptors are primary pain-sensing neurons located in the dorsal root and trigeminal ganglia. Each nociceptor has one axonal branch elaborating a terminal arbor in the periphery and one central axonal branch innervating the spinal cord. The structure of the peripheral and central arbors of nociceptors defines key aspects of pain sensation (receptive field size, spinal cord connectivity, etc.). Although previous work has revealed the single-cell morphology of some mammalian somatosensory neurons, a systematic characterization of the morphology and development of a defined nociceptor population has not been carried out. To fill this gap, our lab generated a novel inducible Cre mouse line (*MrgD*^{CreERT2}) that allows us to sparsely label non-peptidergic-type nociceptors. When crossed to an alkaline phosphatase reporter mouse line (*Rosa*^{iAP}), AP staining of whole mount skin and spinal cord tissue reveals the morphology of individual peripheral and central terminal arbors of non-peptidergic nociceptors. Interestingly, while the peripheral arbors of this population show a surprising uniformity between body regions, we found clear morphological differences in the central terminal morphology of axial- vs. limb and extremity- innervating neurons. Non-peptidergic nociceptors innervating the trunk have exclusively long and thin central terminals covering ~0.4 segments of the thoracic spinal cord. In contrast, those that innervate limbs, head, and tail display rounded central terminals covering ~0.2 segments of the medial cervical enlargement, medial lumbar enlargement, medulla, and sacral spinal cord. We are currently studying the potential functional relevance of these differences by comparing the postsynaptic partners of these two morphological classes. This work will reveal fascinating novel insights into the neural circuits underlying region-specific functions of the mammalian nociceptors.

Title: Purinergic modulation of type II cochlear afferents: Sensing trauma in the ear

Authors: *C. LIU[1], E. GLOWATZKI[2], P. A. FUCHS[2];
[1]Dept. of Neurosci., [2]Dept. of Otolaryngology- Head and Neck Surgery, Johns Hopkins Univ. Sch. of Med., BALTIMORE, MD

Abstract: The mammalian cochlea is innervated by two groups of cochlear afferents - type I afferents form synapses with inner hair cells, and are well known for transmitting acoustic information with high fidelity and efficiency. In contrast, the function of type II afferents has remained mysterious for decades. Despite being postsynaptic to multiple outer hair cells (OHCs), they are found to be 'insensitive' to sound, due at least in part to low probability transmitter release from outer hair cells. In the present study, we asked whether type II afferents also may be driven by purines and pyrimidines released from damaged tissue, as might occur during acoustic trauma. To answer this question, we recorded from type II afferents near their terminal arbors under OHCs in excised cochlear turns from young rats (P7 - P9). 50μM ATP strongly depolarized all tested afferents. ATP-evoked currents reversed at 0mV and could be blocked by PPADS, suggesting the opening of ionotropic P2X receptors. On the other hand, 100μM UTP (a P2Y2 and P2Y4 receptor agonist) also depolarized all the tested afferents, but through a conductance decrease mechanism: the UTP response reversed at -70mV (equilibrium potential for potassium). UTP-evoked current could be antagonized by XE-991, an inhibitor of KCNQ channels, suggesting that UTP activates metabotropic P2Y receptors to close KCNQ channels through second messenger mediated pathways. Although UTP depolarized the type II fibers less potently than did ATP, its closure of KCNQ channels increased membrane resistance, and thus lowered the action potential threshold to enhance excitability. Finally, in order to examine the effect of cell damage, we developed a method that allows us record from type II afferents while OHCs are acutely ablated with a sharp electrode. Strikingly, upon hair cell rupture, a large inward current was recorded from type II afferents, and a slower component of that current was blocked by PPADS, revealing the role of purines as a nociceptive signal. Our results therefore suggest that type II cochlear afferents could sense trauma caused by noxious levels of sound, via their purinergic receptors. The mechanism involves both ATP, the common mediator of tissue damage, and UTP, a sensitizing factor that could lead to hypersensitivity. Our work could have important implications for the pathology of diseases such as tinnitus and hyperacusis, where peripheral damage is thought to lead to central synaptic changes.

Title: Cholinergic neurotransmission links nasal solitary chemosensory cells to the immune system

Authors: *C. J. SAUNDERS[1,2], M. CHRISTENSEN[1,3], T. E. FINGER[1,2], M. TIZZANO[1]; [1]Dept. of Cell and Developmental Biology, Mail Stop 8108, [2]Neurosci. Program, Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [3]Dept. of Biosci., Aarhus Univ., Aarhus, Denmark

Abstract: The nasal epithelium houses a population of Solitary Chemosensory Cells (SCCs) that respond to “bitter” substances and bacterial metabolites via the canonical taste transduction cascade (T2Rs, Gα-gustducin and TRPM5). SCCs release a hitherto unidentified neurotransmitter onto peptidergic (substance P+) trigeminal nerve endings to evoke protective respiratory reflexes. Until now the possibility that SCCs might also trigger neurogenic inflammation has gone unexplored. In the current study, we developed assays for measuring indicators of inflammation: edema, assayed as plasma leakage, and activation of the innate immune system, assayed as mast cell degranulation (MCD). To measure plasma extravasation (PE), we injected mice i.v. with Alexa555-conjugated albumin, then applied an irritant to the nose. To measure MCD, we stained the respiratory epithelium with acidified toluidine blue, which stains mast cell granules. In both experimental paradigms, mice were stimulated with Denatonium benzoate (Den, 10mM), which stimulates SCC, or with capsaicin (Cap, 2uM), which directly activates trigeminal nocipcetors. Both Den and Cap elevated PE and MCD in normal mice, but only Caps did so in gustducin-/- or TRPM5-/- mice which inactivate SCC transduction. Thus for Den, SCC activation is required for induction of inflammation. Next, we tested mice whose TrpV1-expressing pain fibers had been ablated by resiniferatoxin. In those mice, both Den and Cap fail to evoke PE or MCD, indicating that trigeminal nociceptors are required for these effects. In the lower airways, brush cells, which are similar to SCCs in many respects, utilize acetylcholine (ACh) to signal to nerve fibers. To test whether SCCs too, which like brush cells express choline acetyltransferase, utilize ACh to activate pain fibers, prior to

stimulation, we treated mice with the nicotinic ACh receptor (nAChR) blocker Mecamylamine (Mec). In mice treated with Mec, Den failed to induce PE or MCD, but Caps still evoked normal responses, indicating that nAChR's are required for SCCs to activate trigeminal fibers. Finally, to test the hypothesis that Substance P release from trigeminal fibers triggers PE and MCD regardless of irritant, we treated mice with L732138, an inhibitor of the substance P receptor, neurokinin1. In mice treated with L732138, no significant PE or MCD occured, indicating that activation of NK1 triggers these effects. In summary, we have outlined the pathway by which SCCs trigger neurogenic inflammation in the nasal epithelium first via ACh acting on nAChRs and downstream by release of substance P which acts on NK1 receptors on blood vessels and mast cells.

Title: Squid have nociceptors that display widespread long-term sensitization and spontaneous activity after bodily injury

Authors: *R. CROOK[1], R. T. HANLON[2], E. T. WALTERS[1];
[1]Dept. of Integrative Biol. and Pharmacol., Univ. of Texas Hlth. Sci. Ctr. At Houston, Houston, TX; [2]Program in Sensory Physiol. and Behavior, Marine Biol. Lab., Woods Hole, MA

Abstract: Bodily injury in mammals often produces persistent pain that is driven at least in part by long-lasting sensitization and spontaneous activity (SA) in peripheral branches of primary nociceptors near sites of injury. While nociceptors have been described in lower vertebrates and invertebrates, outside of mammals there is limited evidence for peripheral sensitization of primary afferent neurons, and there are no reports of persistent SA being induced in primary afferents by noxious stimulation. Cephalopod molluscs are the most neurally and behaviorally complex invertebrates, with brains rivaling those of some vertebrates in size and complexity. This has fostered the opinion that cephalopods may experience pain, leading some governments

to include cephalopods under animal welfare laws despite minimal evidence for affective states in any invertebrate. It is not known if cephalopods possess nociceptors, or whether their somatic sensory neurons exhibit nociceptive sensitization after noxious stimulation or bodily injury. Previous studies have shown that minor injury to one arm in the squid *Doryteuthis (Loligo) pealeii* promotes a generalized hypervigilant state that persists for days after injury, potentially offsetting the heightened risk of predation that is associated with the presence of injury.
Using extracellular recordings from the fin nerve of the squid, before, during and after a crush injury to the excised fin, we show that squid possess nociceptors that selectively encode noxious mechanical but not heat stimuli, and show long-lasting peripheral sensitization to mechanical stimuli after minor injury to fin tissue. As in mammals, injury in squid can cause persistent SA in peripheral afferents. Unlike in mammals, the afferent sensitization and SA are not restricted to the proximity of the wound site, but are almost as prominent on the contralateral side of the body as they are near an injury. Similar increases in mechanical sensitivity and SA were obtained from squid that had experienced minor injuries inflicted by conspecifics prior to testing.
This distributed sensitization of sensory afferents parallels previous behavioral studies showing increased responses to touch all over the body after a focal injury, and supports previous observations of an absence of directed wound-tending behaviors in squid. Thus, while squid exhibit peripheral alterations in afferent neurons similar to those that drive persistent pain in mammals, robust changes far from sites of injury in squid suggest that persistently enhanced afferent activity provides much less information about the location of an injury in cephalopods than it does in mammals.

Title: Architecture of lumbar spinal cord immediate early gene expression in nociception

Authors: *O. BOJOVIC, D. PANJA, C. R. BRAMHAM, A. TJØLSEN;
Dept. of Biomedicine, Neurosci. research group, Univ. of Bergen, Norway, Bergen, Norway

Abstract: The study's objective: Long-term facilitation (LTF) of C-fiber-evoked firing of wide dynamic range neurons in the spinal dorsal horn after conditioning stimulation (CS) of afferent fibers represents a model of spinal nociceptive sensitization and synaptic plasticity. Arc has been

shown to play a role in synaptic plasticity in the hippocampus. Here we wanted to investigate the expression of Arc, C-fos and Egr-1 after a CS which has been shown to elicit LTF.
Methods used: An electrical CS (10 trains of 1 s duration, 10 s intervals, 100 Hz, 1 ms square pulses) delivered to a peripheral nerve has been used in an experimental model of LTF in the spinal cord. Here we examined the effects of this CS of the sciatic nerve in anesthetized female Sprague-Dawley rats on the formation and localization of Arc, C- fos and Egr-1 protein in the lumbar dorsal horn at different time points up to 12 hours post stimulation. The presence of immediate gene proteins after the conditioning stimulation was evaluated by immunohistochemical analysis as well as by western blotting. The detailed location of immediate early gene proteins was examined by fluorescent imaging techniques while cell counting was semi-automatically conducted by FIJI- freeware software.
Results: The numbers of superficially located (laminae I and II) dorsal horn neurons positive for Arc, C- fos and Egr-1 were sharply elevated after the CS compared to the contralateral unstimulated side, and to unstimulated control subjects. Western blotting showed the presence of a band representing increased Arc protein localization at the stimulated side of the spinal cord. The amount of Arc protein seems to be decreasing with time from 1 to 12 hours after CS.
Conclusion: Stimulation of afferent fibers creating LTF increased the number of Arc, C-fos and Egr-1 positive cells in the dorsal horn on the stimulated side of the rat spinal cord. Western blotting showed increased amount of Arc protein on the stimulated side of the spinal cord dorsal horn.

Title: Cutaneous NGF injection in rat: Electrophysiological effects on C-nociceptors revealed by microneurography

Authors: SUMALLA, C. GIAS, R. SOLA, E. GARCIA, M. JONES, J. SERRA;
Neurosci. Technologies, Barcelona, Spain

Abstract: There is growing evidence that spontaneous impulse generation in hyperexcitable peripheral nociceptors is an important phenomenon in the pathogenesis of neuropathic pain. These abnormally generated ectopic impulses contribute a direct afferent input into the central

nervous system, evoking a sensation of pain, and may set up a state of altered central sensitization that could further amplify the effect of this abnormal input. The intimate mechanisms by which nociceptors may become hyperexcitable are still unclear, but there is growing evidence that NGF may be a key player.
In the present work we have studied the electrophysiological abnormalities induced by NGF in identified subclasses of peripheral C-nociceptors, as a possible surrogate animal model of spontaneous activity in C-nociceptors. We studied the effects of intracutaneous administration of NGF (2 and 5 μg) in the plant of Sprague-Dawley male rats (200-250 g). Microneurographic recordings were obtained at 4 different times: 120 minutes (n=24), 24 hours (n=13), 48 hours (n=15), and 5 days (n=13), in 2 different groups: saline (n=25) vs. NGF (n=40). Activity from individual C-nociceptors was recorded with microneurography, using tungsten microelectrodes inserted into the sciatic nerve trunk.
We recorded from a total of 369 C-nociceptors in the NGF treated group and 302 C-nociceptors in the saline group. Globally, we observed spontaneous activity in 9/302 (3%) of the C-nociceptors of the saline group vs. 74/369 (20.1%) in the NGF treated group. We also observed multispike responses in 5/302 (1%) of the C-nociceptors of the saline group vs. 86/369 (23.3%) in the NGF treated group. The percentage of spontaneous C-nociceptors increased over time from an initial 10.5% at 120 min to 28.9% at 24 h, 22.9% at 48 hours and 22.6% at 5 days. Similarly, there was an increase over time of the frequency of multispike responses from an initial 8% at 120 min to 36% at 24 h, 28.2% at 48 h and 25.8% at 5 days.
In summary, we observed an increased proportion of C-nociceptors displaying spontaneous activity and presence of multispikes due to unidirectional blocks at branching points following NGF treatment in the rat. This experimental paradigm may constitute an excellent surrogate animal model to test the efficacy of new compounds aimed at reducing pathological nociceptor hyperexcitability.

Title: Neurotrophic factors regulate scratching behavior and responses of sensory neurons to pruritogens

Authors: *S. DAVIDSON[1], M. V. VALTCHEVA[2], J. P. GOLDEN[2], R. W. GEREAU, IV[2]; [1]Anesthesiol., Washington Univ. Sch. of Med., St Louis, MO; [2]Anesthesiol., Washington Univ. Sch. of Med., Saint Louis, MO

Abstract: Nerve growth factor is increased in the skin of patients with pruritic skin conditions such as atopic dermatitis and is likely involved in concomitant hyperinnervation of the epidermis. Less is known about the potential roles of the Ret activating glial-derived neurotrophic factors in pruritus. We hypothesized that neurotrophic factors modulate scratching behavior and act directly on pruriceptive neurons. This was tested by pretreating mouse cheek skin with a neurotrophic factor (NGF, GDNF, Artemin, or Neurturin) and subsequently recording site-directed scratching behavior evoked by histamine and non-histaminergic pruritogens. NGF increased scratching to histamine, and artemin increased scratching to chloroquine with little increase in cheek wiping, suggesting that neurotrophic factors can increase itch sensation without inducing ongoing pain. The retrograde tracer DiI was injected into the cheeks of mice with eGFP knocked into the Ret locus for identification of Ret+ versus Ret- neurons that innervate the skin. Cultured trigeminal ganglion neurons with identified projection targets to the skin were analyzed in calcium imaging experiments to determine whether neurotrophic factors directly modulate the expression and function of pruritic receptors. Two-thirds of histamine-responsive trigeminal neurons were Ret+. Pre-incubation of cultured neurons with NGF increased the proportion of neurons responsive to histamine. Our results show that neurotrophic factors in the skin can enhance scratching in response to histaminergic and non-histaminergic pruritogens and that neurotrophic factors can act directly on sensory neurons to increase responses to pruritogens.

Title: Physiological and behavioral responses to pruritogens in the absence of Protein Kinase-Cδ

Authors: *M. V. VALTCHEVA[1], S. DAVIDSON[1], C. ZHAO[1], M. LEITGES[2], R. W. GEREAU, IV[1];
[1]Pain Ctr. and Dept. of Anesthesiol., Washington Univ. Sch. of Med., Saint Louis, MO; [2]Biotech. Ctr. of Oslo, Univ. of Oslo, Oslo, Norway

Abstract: Itch is an unpleasant sensation that elicits the urge to scratch and can present as a debilitating symptom of various dermatological, neurological, and systemic diseases. Itch-producing compounds known as pruritogens stimulate receptors located on C-fibers that innervate the skin and mucous membranes. Most currently known pruritogen receptors are G_q-Protein Coupled Receptors (G_qPCR), which activate the canonical Phospholipase C (PLC) pathway, generating IP_3 and Diacylglycerol (DAG). The specific isoform PLCβ3 is coupled to the histamine H1-receptor, but little is known about the intracellular signaling molecules further downstream and at other pruriceptors. Here, we investigated the role of Protein Kinase-Cδ (PKCδ) as an intracellular mediator of itch signaling in response to various pruritogens. We previously examined PKCδ-knock out (KO) mice in acute tests of mechanical and heat nociception and found no significant change from wild type controls. Immunohistochemistry (IHC) was used to characterize the distribution of PKCδ in mouse dorsal root ganglion (DRG) cells and co-expression with markers for peptidergic and nonpeptidergic neurons. PKCδ expression was restricted to small diameter cells and half of PKCδ-positive cells co-stained for IB4, while a smaller number expressed CGRP. We are currently using *in vivo* and *in vitro* techniques to characterize the effects of genetic deletion and pharmacological inhibition of PKCδ on itch.

Title: Mutual information analysis of spinal and supraspinal responses to graded electrical stimulations

Authors: *F. G. ARGUISSAIN, J. BIURRUN MANRESA, C. D. MØRCH, O. K. ANDERSEN;
Aalborg Universitet, Aalborg, Denmark

Abstract: Aim: to determine the amount of information carried by single-trial response features extracted from electromyographic (EMG) and electroencephalographic (EEG) signals in response to nociceptive and non-nociceptive electrical stimulation.
Methods: sixteen male subjects participated in a single experimental session, in which they received repeated electrical stimuli to the arch of the foot in order to elicit the nociceptive withdrawal reflex (NWR). Six stimulation intensities (0.5x, 0.75x, 1.0x, 1.25x, 1.5x and 2.0x) multiples of the NWR threshold (i.e. the minimum intensity necessary to elicit the reflex) where applied. NWR features (root-mean-squared amplitude, interval peak z-score, latency and duration) were quantified from EMG signals recorded from the tibialis anterior muscle. EEG features were defined as the amplitudes and latencies extracted from the characteristic peaks (N1, P1, N2 and P2) of the somatosensory-evoked potentials recorded at the vertex. The Information Theory framework was applied to quantify the amount of mutual information (MI) contained in these features with respect to the stimulus. MI is expressed in bits, where zero can be interpreted as a completely random stimulus-response relation and the theoretical maximal value is given by the entropy or self-information of the stimulus (2.58 bits in the present study). Mutual information quantities were calculated on an individual basis and for a subset of combinations of these features.
Results: median MI values of all selected response features from both modalities were informative in regard to the stimulus when considered individually. Significant differences were found among the median MI values of the response features (Kruskall-Wallis test, $P \leq 0.001$). Specifically, the information carried by the EMG features (0.39 bits in average) was significantly higher than information contained in the EEG features (0.11 bits in average) (Dunn's test, p0.05). A preliminary analysis showed that the combination of response features might be more informative than their individual values; however, an overall redundant effect was observed. In most of the combinations, the observed redundancy was small, which might indicate that the stimulus-related information carried by each feature is mainly independent from each other.
Conclusion: these results provide evidence that supports the importance of assessing and interpreting both SEPs and NWR when studying the nociceptive system. The current study presents an alternative approach that allows the quantification of stimulus-signal and signal-signal relationships at single-trial level without linearity and gaussianity constraints.

Title: μ-Opioid receptor mediated short-term inhibition of Ca2+ signaling and long-term frequency dependent inhibition of action potentials in CGRP nociceptive fibres

Authors: L. D. BAILLIE, *S. J. MULLIGAN;
Physiol., Univ. of Saskatchewan, Saskatoon, SK, Canada

Abstract: μ-Opioid receptor agonists are potent analgesics but potential adverse side effects secondary to their central nervous system actions present substantial barriers to their clinical use. Recent studies suggest that peripheral μ-opioid receptors may also be important effectors of systemic opioids in alleviating pain, however, the peripheral cellular mechanisms remain to be established. We have recently introduced an optical microfluorometric imaging approach to directly study physiological functioning within selectively identified, individual nociceptive fibre free nerve endings in a mouse *ex vivo* meningeal preparation (Baillie *et al*. 2011). Calcitonin gene-related peptide (CGRP) pain fibres that originate from the trigeminal ganglion densely innervate the intracranial meninges. We find high density punctate μ-opioid immunoreactive co-localized labeling in the CGRP terminating nociceptive fibres suggesting a peripheral site of action for μ-opioid agonists. Indeed, application of the selective μ-opioid agonist damgo (1 μM) caused a rapid, reversible short-term inhibition in the amplitude of single action potential evoked Ca^{2+} transients that could be blocked with pre-application of the opioid antagonist naloxone (1 μM). After recovery from temporary Ca^{2+} inhibition, we found that μ-opioid receptor activation from localized application of damgo caused long-term failure of action potential propagation. The μ-opioid receptor mediated action potential inhibition is frequency dependent. Short interval action potential firing (for example; 0.25Hz) in control conditions that can be evoked reliably and continuously for extended periods of time, fail in the presence of damgo (1 μM). The short interval action potential firing occurs reliably and continuously with naloxone block of μ-opioid receptor activation. Action potential failures do not occur in the presence of damgo during longer inter-spike intervals (for example; 0.15Hz) demonstrating the frequency dependent inhibition. We find the same effects with the peripherally restricted μ-opioid receptor agonist loperamide. Our research suggests that attacking pain at its source with peripherally restricted opioids may represent a valid therapeutic strategy to achieve potent analgesia while avoiding undesirable central side effects.

Title: Fibromyalgia is a neurological disorder of abnormal central processing mechanisms

Authors: *B. T. SHAHANI[1], R. S. KATZ[2];
[1]Neurol. & Rehabil., UIC Col. Med., Chicago, IL; [2]Rush Univ. Med. Ctr., Chicago, IL

Abstract: Fibromyalgia is usually associated with central pain processing abnormalities, including central sensitization. In addition, we have recently demonstrated that approximately one-third of patients with fibromyalgia syndrome (FMS) also have evidence of peripheral nerve dysfunction, which may contribute to pain, paresthesias, numbness, and fatigue. In this study, we describe three patients, two females (41 and 48 years old) and one male (49 years old) who had no evidence of peripheral neuropathy on detailed electrophysiological studies. Each individual patient described a different sensory perception to the same controlled stimulus, suggesting abnormalities of central processing mechanisms.

Detailed electrophysiological studies including motor sensory nerve conduction as well as late response studies were performed using a TECA EMG machine. Patients were asked to report the sensation they felt when electrical stimulation was delivered to peripheral nerves. The stimulus consisted of single electrical pulses of 0.1to 0.5 msec. duration. The stimulus intensity was adjusted to deliver a supramaximal stimulation.

Motor and sensory nerve conduction as well as late response studies were within normal limits, suggesting that none of these patients had any evidence of peripheral neuropathy.

Supramaximal electrical stimulation of peripheral nerves at the level of the ankles of the lower limbs in the first patient produced a “burning” pain in the feet, which was so intense that she could not control crying during the study.

In the second patient, a single electrical stimulus delivered to the peroneal and tibial nerves produced a ticklish feeling, which elicited uncontrollable laughter on the part of the patient.

In the third patient, electrical studies of median and ulnar nerves produced a dull tapping sensation without any discomfort or dysesthesias.

Electrical stimulation of mixed peripheral nerves produced a distinctly different sensory response in each of these three patients FMS. The stimulus parameter used for this study activated only myelinated fibers; small unmyelinated nerve fibers (C-fibers) were not stimulated. The different types of sensations, including burning and a ticklish sensation experienced by our patients, therefore must have resulted from activation of large and small diameter myelinated nerve fibers. Since the peripheral nervous system was intact in these patients, the perception of burning,

tickling, and the dull tapping feeling must be related to abnormalities of central processing mechanisms.

Title: A magnetoencephalography study of early versus late encoding of pain anticipation

Authors: *R. GOPALAKRISHNAN[1], J. C. MOSHER[2], R. C. BURGESS[2], A. G. MACHADO[1];
[1]Ctr. for Neurolog. Restoration, [2]Epilepsy Ctr., Cleveland Clin., Cleveland, OH

Abstract: Central pain syndrome may occur after thalamic strokes or lesions, with contra-lateral numbness or numbness in the body. Not purely a somatosensory experience, chronic pain has significant affective components, including anticipatory phenomena (Melzack 1990). Evaluation of the neural mechanisms underlying pain anticipatory phenomena may be important for understanding pain conditioning and perception. In this study we evaluated for the first time, with magnetoencephalography (MEG), the evolution of electrophysiological activity of underlying neural networks during pain anticipation from the naïve state to the conditioned state. Testing was performed with 5 normal adults seated upright in a 306 channel MEG array (Elekta AB). The paradigm consisted of 4 blocks of 60 randomized trials of distinct visual cues signaling the arrival of a painful stimulus (60% chance) or of no stimulus. Each trial was 9s long with 1s of baseline, 3s of pre-stimulus countdown and 5s post-stimulus period. A contact heat stimulator (Medoc Ltd.) was used to induce pain. The trials were sorted and labeled in four phases as early, mid-early, mid-late and late, the early being naïve and late being conditioned state. The 3s pre-stimulus countdown was pre-processed to the frequency of interest, anomalies rejected and baselined. Minimum-norm source estimation was performed on a tessellated cortex of the brain that was anatomically parcellated. The average time series from each parcel was subjected to a complex Morlet wavelet analysis. The average power estimates were then Z-scored to compute evoked activity. Left pre-frontal cortex showed significant gamma band oscillation to incoming painful stimuli during “early” phase and disappeared thereafter. Interestingly, the visual cortex picked up the gamma activity in the later phases, indicating that the visual cortex gained

encoding independence from frontal areas. The results are indicative of visual cortex initially interacting with higher cortical areas involved in the contextual learning of pain and affective experiences, before becoming independent.

Title: Pre-attentive cognitive processing as indexed by the mismatch negativity (MMN) in tonic experimental pain

Authors: Y. XU, J.-Y. WANG, *F. LUO;
Key Lab. Mental Hlth., Inst. Psychology, Chinese Acad of Sci., Beijing, China

Abstract: Previous studies have shown that pain has modulatory effect on cognitive processes, such as attention. Although the brain mechanisms underlying the interaction between pain and

attention have been explored by numerous cognitive studies, few studies have clarified whether and how pre-attentive processing is influenced in the pain condition. The mismatch negativity (MMN) is an early cognitive component that reflects the automatic detection of a change in a sequence of repeating stimuli, e.g., sounds, and is considered an attention independent process. In the present study, auditory-MMN was recorded in healthy human subjects to investigate the pre-attentive processing under experimentally evoked pain. Cold pressor test (5 ℃ water) was used to produce tonic pain. MMN was elicited using a passive oddball paradigm by frequency changes in sounds consisting of 100-ms tones (standard stimuli: 1000Hz, deviant stimuli: 900/1100Hz). A total of thirty-two healthy subjects participated in the experiment. The MMN was recorded in three conditions (pre-, during, and post-pain), and the amplitude and latency of MMN were compared within subjects. Independent component analysis (ICA) and standard low-resolution tomography algorithms (sLORETA) were employed and combined to analyze the spatiotemporal dynamics of MMN cerebral sources. The results showed that, the MMN which was recorded during pain (when subjects put their hands in the cold water) from the frontal electrode (Fz) was remarkably enhanced compared with the other two conditions. In contrast, positive mismatch potentials of decreased magnitude were detected from the mastoid electrodes (M1 and M2). Moreover, both above measures were correlated with the subjects' pain ratings. ICA and sLORETA analysis revealed that the MMN-related components were located within the temporal and frontal areas which have distinct temporal distribution. Further more, the frontal components were enhanced while the temporal components were reduced during the hand immersion in cold water. These findings raise the possibility that the ongoing pain experience has different influences on the frontal and temporal generators of auditory MMN.

Abstract: The simple act of writing about traumatic experiences (Written Emotional Disclosure, WED) has been shown to result in long-term improvements in health. Individuals with chronic pain, characterized by heightened pain sensitization, have also benefited from WED. Our laboratory recently showed that multiple sessions of WED produce a short-term increase in pain sensitization followed by a long-term decrease in women with trauma history. Although the mechanisms of multi-session WED are beginning to be understood, the acute effects remain understudied. Here we examined the acute effects of WED after a single session of writing on suprathreshold heat (Experiment 1) and on capsaicin-induced spontaneous pain (Experiment 2). Prior studies indicated that WED induces short-term increases in negative affect and arousal leading to our hypothesis of heightened pain following trauma writing. Contrary to our hypothesis, following one session of writing about their most traumatic experience,women reported reduced pain intensity ($F(1,80) = 4.958$, $p < .05$) and unpleasantness ($F(1,69) = 3.7$, $p < .05$) in response to suprathreshold heat as well as reduced ratings of capsaicin-induced spontaneous pain intensity ($F(1, 26) = 4.517$, $p < .05$) and unpleasantness ($F(1, 26) = 4.096$, $p < .05$) compared to participants in a neutral control condition. Data will also be presented on WED's impact on peripheral and central sensitization assessed through neurogenic flare and mechanical secondary hyperalgesia.

Title: The effects of fear conditioning on the psychophysiological responses to pain

Authors: *V. TAYLOR[1,3], M. ROY[4], P. RAINVILLE[1,2,5,3,6];
[1]Psychology, [2]Stomatology, Univ. de Montréal, Montreal, QC, Canada; [3]Ctr. de recherche en

neuropsychologie et cognition (CERNEC), Montreal, QC, Canada; [4]Univ. of Colorado Boulder, Boulder, CO; [5]Ctr. de recherche de l'Institut universitaire de gériatrie de Montréal (CRIUGM), Montreal, QC, Canada; [6]Groupe de recherche sur le système nerveux central (GRSNC), Montreal, QC, Canada

Abstract: Animal studies have shown that a fear conditioned stimulus (CS+) can induce conditioned analgesia mediated by CS-induced amygdala activation sending descending inhibitory signals to the spinal cord. This human psychophysiological study examined whether learning, determined by skin conductance responses (SCR) to the CS+, would alter cortical and spinal responses to a noxious electrical shock (US), assessed respectively with subjective pain ratings and the nociception flexion reflex (NFR). The delay fear conditioning paradigm involved two blocks of acquisition, two blocks of reversal and one block of extinction. In the acquisition phase, two coloured fractal images were presented for 2 sec, one which co-terminated with the shock on 50% of trials (CS+) while the other was never paired with the shock (CS-). In this acquisition phase, 40 CS-, 20 CS+ paired and 20 CS+ unpaired were presented. The reversal phase involved the switching of the CS+ and CS- images. Shocks to the right sural nerve were adjusted individually with an intensity set at 135% of the NFR threshold. NFR was recorded through electromyographic (EMG) recording of the right biceps femoris muscle. Electrodermal activity was recorded on the palmar surface of the left hand. A repeated measures ANOVA revealed a significant PHASE X CS interaction on SCR measures ($F=12.08$, $p=0.0001$). Consistent with the theory of conditioned analgesia, between-subjects correlations revealed significant negative associations between the differential SCR (CS+ vs CS-) and pain ratings to the US in the Acquisition and Reversal blocks (rs between -0.39 and -0.28; ps between .019 and .070). A similar pattern of results was found for the NFR only in the first Acquisition and the second Reversal blocks ($r=-0.31$, $p=0.05$; $r=-0.60$, $p=0.0001$), while the opposite effect was found in the first Reversal block suggesting a facilitation of spinal processes in subjects with faster reversal learning ($r=0.54$, $p=0.0001$). These results are generally consistent with previous studies demonstrating conditioned analgesia but they demonstrate a partial dissociation between spinal and cortical responses suggesting the involvement of at least two separate mechanisms.

Title: Associations between chronic stress and pain processing in healthy adults

Authors: B. SHAHIDI[1], M. L. LAUDENSLAGER[2], *K. S. MALUF[1];
[1]Physical Med. & Rehabil., [2]Dept. of Psychiatry, Univ. of Colorado Anschutz Med. Campus, Aurora, CO

Abstract: Chronic pain disorders have a high comorbidity with stress-related somatic symptoms and have been associated with dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis. Although acute stress is known to suppress pain sensitivity in both healthy and clinical populations, the effects of chronic stress on pain processing are not well understood. Measurement of hair cortisol has recently been proposed as an index of chronic stress over several months duration. The purpose of this study was to investigate relationships between objective and subjective measures of chronic stress and quantitative assessments of pain sensitivity and central pain processing in healthy individuals. Seventy four healthy adults participated in this study. Hair samples were obtained, and the first 3cm were analyzed for cortisol content as an indicator of chronic stress over the previous 3 months. The Perceived Stress Scale (PSS) was administered as a subjective assessment of chronic stress. Central pain processing was assessed by measuring conditioned pain modulation using a cold pressor test as the conditioning stimulus, and pressure algometry over the upper trapezius (UT) muscle as the test stimulus. This method is thought to elicit endogenous pain inhibitory responses through diffuse noxious inhibitory controls (DNIC). Pressure-pain sensitivity was measured as the threshold for detection of pain during pressure algometry over the UT applied at 1kg*F/sec, and cold-pain sensitivity was measured as the threshold for detection of pain during submersion of the hand in a 38 degree water bath. Hair cortisol levels ranged from 1.07 to 43.73 pg/mg, PSS scores ranged from 3 to 26 points, and DNIC levels ranged from -31.16 to 120.33%. Pressure-pain thresholds ranged from 1.38 to 9.06 kg*F and cold-pain thresholds ranged from 2 to 93 seconds. Results demonstrated no significant associations between hair cortisol and DNIC (r^2=0.0, p=0.88), pressure pain thresholds (r^2=0.0, p=0.99), or cold pain thresholds (r^2=0.02, p=0.27). PSS scores were also found to have no correlation with measures of pain processing($p \geq 0.36$), however, PSS scores were significantly correlated with hair cortisol (r^2=0.11, p=0.004). These results suggest that in healthy individuals, neither objective nor subjective measures of chronic stress are related to pain processing or sensitivity. Further research is needed to investigate the effect of chronic
stress on pain processing in individuals with chronic pain conditions.

Title: Interaction effects between active treatment and treatment expectation on pain in humans

Authors: *L. A. SCHENK, C. SPRENGER, S. GEUTER, C. BÜCHEL;
Insitute of Systems Neurosci., Univ. Med. Ctr. Hamburg-Eppendorf, Hamburg, Germany

Abstract: Pain relief after administration of an analgesic drug does not merely reflect a pure pharmacological effect - it also depends on contextual factors such as expectation, hope or beliefs about the treatment. The relationship between specific drug and contextual factors is of high theoretical and clinical interest. However, the precise interplay of these factors is currently debated and is still insufficiently understood.
The aim of our study was to investigate possible interaction effects between an active analgesic treatment and treatment expectation at the behavioral and neuronal level. We combined topical lidocaine-prilocaine cream with an expectancy manipulation in a 2x2 within-subject design (open treatment, hidden treatment, placebo, control). 32 healthy subjects received heat pain stimuli on capsaicin pretreated skin and rated their experienced pain during a functional magnetic resonance imaging experiment. Conditions were counterbalanced across subjects. Our design allowed us to separate drug-related and expectancy-related effects at the behavioral and neuronal level and to test whether they interact during the processing of painful stimuli.
Pain ratings revealed a significant main effect of active treatment and a significant interaction between active treatment and treatment expectation. The expectation effect was significantly larger in the treatment conditions (open treatment versus hidden treatment) compared to the no-treatment conditions (placebo versus control). Active treatment was associated with reduced activity in the anterior insular cortex. The interaction was related to signal changes in several placebo-associated brain areas, including the anterior insular cortex, the anterior cingulate cortex and the ventral striatum.
In conclusion, this study shows that synergistic effects between active treatment and treatment expectation are found in behavioral pain ratings and are associated with responses in placebo-related brain regions. Our results are relevant for clinical studies where additive effects of drug and context are presumed, as well as for clinical practice, which could benefit from a better understanding of synergistic effects between therapy and context.

Title: Deficient modulation of pain by a positive emotional context in fibromyalgia patients

Authors: *H. FLOR, I. C. BOMBA, E. DIESCH, S. KAMPING;
Dept. of Cognitive and Clin. Neuroscience, CIMH, Heidelberg Univ., Mannheim, Germany

Abstract:
Fibromyalgia syndrome (FMS) is marked by chronic widespread pain and is accompanied by additional symptoms ranging from fatigue, stiffness, sleep disturbances, to depressive symptoms. Lang's motivational priming hypothesis (Lang PJ, Bradley MM, Cuthbert BN. (1990) *Psychol Rev.* 97:377-398) suggests that an organism's motivational state will modify its responses to stimuli, with enhanced pain perception to negative and decreased pain perception to positive picture stimuli. We aimed to investigate the modulating effects of emotional context on pain perception in 16 patients with FMS and 16 healthy control (HC) subjects. An infrared laser was used to apply individually adapted painful stimuli to the dorsum of the left hand. The emotional background of the painful stimuli was modulated by concurrent presentations of negative, neutral, and positive picture stimuli selected from the International Affective Picture System. As control conditions, painful stimuli and the pictures were also presented by themselves. During each of the five laser-picture trials, subjects received 10 painful stimuli and were asked to rate the average intensity and unpleasantness of the experienced pain. Functional magnetic resonance images were obtained, using a T2* sensitive echo planar sequence. HC subjects showed a linear increase in pain intensity and unpleasantness ratings when painful stimuli where presented during positive, neutral, and negative pictures. In contrast, FMS patients showed a quadratic trend for pain intensity ratings indicating a lack of pain reduction by the positive pictures. In addition, the FMS patients showed less activation in secondary somatosensory cortex, insula, orbitofrontal cortex, and anterior cingulate cortex during the positive picture pain trials. Our results suggest that fibromyalgia patients are less efficient in modulating pain by positive affect and may benefit less from appetitive events than healthy controls. In light of our results we propose that therapeutic approaches for the treatment of FMS should place a stronger emphasis

on emotional processes and try to normalize the disrupted affective modulation.

Title: Effects of a personal music-enhanced conditioning paradigm on heat pain analgesia

Authors: C. HSIEH[1], J. KONG[2], *R. L. GOLLUB[2];
[1]Hlth. Sci. and Technol., MIT, Cambridge, MA; [2]Dept. of Psychiatric Neuroimaging, Massachusetts Gen. Hosp., Charlestown, MA

Abstract: Introduction
The experience of pain has both sensory and affective elements, and can be modulated with cognitive distractions as well as emotional manipulation. Placebo analgesia studies have shown an effect from verbal expectancy manipulation, which can be additionally boosted through covert conditioning. More recently, there have been a number of demonstrations of music's analgesic capabilities in experimental settings. Music has been shown to both reduce anxiety and activate reward circuitry; because both factors are part of the neural pathways modulating pain perception, it is conceivable that music could access one or both pathways as an analgesic vehicle.
Materials and Methods
A two-session experiment was performed with 48 healthy, pain experiment-naïve subjects (age 27.1 ± 7.1, 15 males). The first 36 were randomized into one of 3 treatment groups, including music conditioning, sound conditioning, and no-treatment routine pain calibration. A second music conditioning group of 12 subjects was completed after the first cohort. Primary outcome measures included the difference (pre- minus post-treatment) in subjective pain rating to calibrated experimental noxious heat stimuli. We also collected treatment expectations using an Expectancy of Relief Scale (ERS).

Results

Expectations for the sound sample remained significantly lower throughout the study in the calibration group (Fig. 1a), but were increased in the sound conditioning group by verbal suggestion. Music expectations were not increased above calibration level by verbal suggestion but were increased by conditioning, however conditioning did not further increase analgesia induced by music (Fig. 1b). Conditioned sound did not reduce pain intensity, but sound reduced pain unpleasantness.

Conclusion

The results here suggest a non-additive interaction between personal music's analgesic capacity and that from expectancy-based conditioning. Strongly personal stimuli may invoke a ceiling effect rendering conditioning ineffective at enhancing analgesia.

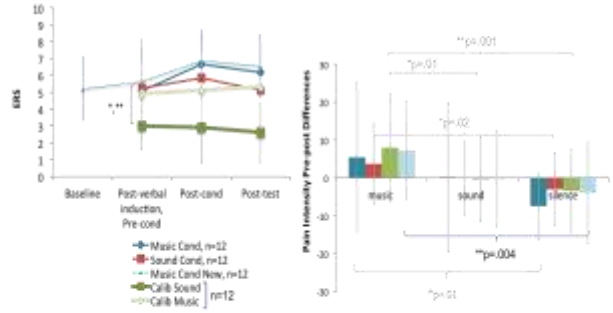

Fig. 1a: Expectancy differed significantly within the calibration group between expectations for music and that for the sound sample (**p<.001). This difference was seen at all time points the ERS was assessed, with a slightly less significant difference after testing. The verbal induction boosts expectations significantly higher (*p=.03) in the sound conditioning group, to the level of music expectations. In the new music conditioning group, an additional assessment of ERS at a completely naive baseline in this group shows that verbal induction did not significantly raise expectations for music. We also see a replication of pre-conditioning ERS scores for music conditioning.

Fig. 1b: Within the calibration group (green bars), music reduced pain intensity significantly more than sound and silence. In the sound conditioning group (red bars), only unconditioned music reduced pain, as compared to silence. In the original music conditioning group (turquoise), only music reduced pain as compared to silence, with neither magnitude or significance greater than that seen in the calibration group. In the second music conditioning group (light turquoise), music again reduced pain as compared to silence, with a slight increase in significance compared to the original music conditioning group.

Title: Cool adaptation reduces the pain of the thermal grill illusion

Authors: *D. E. HARPER, M. HOLLINS;
Psychology, Univ. of North Carolina, Chapel Hill, NC

Abstract: The thermal grill illusion (TGI), a phenomenon in which interlaced warm and cool bars produce a painful sensation, is not completely understood. The present study used thermal adaptation as a tool to elucidate the relative contributions of warm and cool signals to the illusion. Each subject (n=24; 14 female) underwent three experimental runs, in counterbalanced order. Two runs tested the effects of pre-adapting the subject to either cool bars (18°C) or warm bars (42°C), interlaced with neutral bars (32°C), for a period of 3min. Following pre-adaptation, the neutral bars were warmed or cooled to produce a canonical thermal grill (i.e. 42°C bars interlaced with 18°C bars). Both sets of bars were held at the neutral temperature during the pre-adaptation phase of the remaining run, to measure baseline sensitivity to the TGI. Subjects rated thermal sensations and pain at various times during each run using computerized visual analogue scales (VAS). Thermal ratings during pre-adaptation revealed significant thermal adaptation, with warm/cool sensations gradually weakening over the course of 3 min. There were no differences in the perceived intensity of these warm and cool sensations, or in the amounts by which they declined. A repeated-measures ANOVA showed a significant difference in the painfulness of the TGI across runs. Compared to the pain of the TGI during the baseline run (M=29.9), cool adaptation significantly reduced pain (M=13.6) while warm adaptation was without effect (M=26.4). This result indicates that the grill's cool bars have a selective role in supplying the pain of the TGI. Most subjects perceived the TGI in the baseline condition to be hotter than the grill's warm bars alone; following warm adaptation, however, a majority instead rated the TGI as cool or cold. The subjects who found the TGI to be cool or cold following warm adaptation also found it to be significantly less painful, following both warm and neutral pre-adaptation, than did those who perceived it as hot. In fact, the more often a subject reported feeling cool or cold from the TGI across all runs, the less pain he or she reported from the TGI. Several studies have shown that there is a great degree of variability in susceptibility to the painfulness of the TGI and some researchers have even questioned whether the TGI is actually painful. The present study provides a possible explanation for this variability - cool's susceptibility to be masked by warmth (a mechanism of the TGI proposed by Craig and Bushnell, 1994) might differ across individuals, shielding some from the painful burn of the TGI.

Title: Brain indoleamine 2,3-dioxygenas regulates nociceptive and depresion- like behavior in genetically predisposed depression-like behavior rats

Authors: *H. KIM[1], M. MCCABE[2], G. LIM[3], L. CHEN[3], J. MAO[3];
[1]Anesthesia, MGH, CHARLESTOWN, MA; [2]MGH, boston, MA; [3]MGH, Boston, MA

Abstract: We demonstrasted that persistant nociception induces both depression-like behavior and upregulation of brain indoleamine 2, 3-dioxygenase (IDO), a rate-limiting enzyme in tryptophan metabolism. Here, we demonstrate that brain indoleamine 2,3 dioxygenase 1 (IDO1) expression was elevated in genetically predisposed depression-like behavior rats (WKY rats). As compared with Wistar rats at the basal level, WKY rats showed 1) an increased immobility time in FST, 2) an increased hippocampal IDO expression and 4) an increased kynurenine/tryptophan ratio but a decreased serotonin/tryptophan ratio in the hippocampus. Moreover, WKY rats exhibited a lower baseline nociceptive threshold in both mechanical and thermal tests as compared with Wistar rats.
Predisposed depressive behavior in WKY rats exacerbated mechanical allodynia, thermal hyperalgesia, and depressive behavior following the CFA injection into the right tibio-tarsal joint as compared with sham controls. Moreover, the hippocampal IDO expression was further upregulated in WKY rats with arthritis which resulted in a further elevated kynurenine/tryptophan ratio and a further reduced serotonin/tryptophan ratio in the hippocampus of these WKY rats. These results, together with the data from Wistar rats, demonstrate a reciprocal relationship between pain and depression that is linked through IDO expression and activity in the hippocampus.

Title: Cannabinoids differentially modulate behavioral responses to nociceptive vs non-nociceptive stimuli

Authors: *T. L. RASMUSSEN, B. D. BURRELL;
Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: The endocannabinoid system is thought to play a role in modulating nociception, making it a potential therapeutic target for treating pain. The anti-nociceptive effects of endocannabinoids appear to be due, at least in part, to a depression of excitatory synaptic transmission within pain neural circuits. However, conflicting results from both clinical and laboratory-based studies have found that endocannabinoids can also pro-nociceptive effects, contributing to pain-related sensitization (e.g. mechanical hyperalgesia or allodynia) due to disinhibition of synapses from primary afferents. Using the medicinal leech as a model system, our lab has observed that while endocannabinoids differentially modulate somatosensory signaling; depressing nociceptive afferent synapses, but potentiating non-nociceptive afferent synapses (Yuan & Burrell *J. Neurophysiol.* 104: 2766, 2010; Higgins et al. *Molec. Pain* under review). In the present study, we examined cannabinoid treatment had a similar differential effect on behavioral responses to nociceptive vs. non-nociceptive stimuli. Leeches were injected with either the synthetic cannabinoid CP 55940 (0.11 mg/g) or the endocannabinoid 2-arachidonoylglycerol (2-AG; 0.28mg/g). Responses to non-nociceptive stimuli were monitored by measuring the threshold for eliciting sucker withdrawal in response to von Fray fiber stimulation. Responses to nociceptive stimuli were tested by applying capsaicin to the posterior sucker and observing latency to move away from the treatment area and duration of this nocifensive locomotion. Both CP 55940 and 2-AG significantly sensitized the animals to non-nociceptive stimuli, indicated by a decrease in the response threshold to von Frey fiber stimulation. Simultaneously, 2-AG and CP 55940 decreased responses to nociceptive stimuli, i.e. increased latency to move after capsaicin application and decreased the duration of nocifensive locomotion. Additional studies are currently underway to examine the duration of these effects and if both forms of cannabinoid-elicited modulation are mediated by central Transient Receptor Potential (TRP) channels. These findings provided behavioral support for the hypothesis that the pro- and anti-nociceptive effects of cannabinoids are due to differentiation modulation of nociceptive vs. non-nociceptive signaling.

Title: Differential effects of GABA in modulating nociceptive vs. non-nociceptive synapses

Authors: Y. WANG, B. D. BURRELL;
Basic Biomed. Sci., Univ. of South Dakota, Vermillion, SD

Abstract: Treatment of pain is a major health concern in the United States and there is considerable interest in developing new analgesic therapies. Cannabinoid-based treatments represent one potential approach, but results from both laboratory and clinical studies have observed both pro- and anti-nociceptive effects of cannabinoids. How can the cannabinoids have these opposing effects? Using the leech as a model system, our lab has observed that endocannabinoids can depress synapses from nociceptive neurons, but increase synaptic transmission by non-nociceptive neurons, potentially recruiting these cells into the nociceptive circuitry (Yuan & Burrell J. Neurophysiol. 104: 2766, 2010; Higgins et al. Molec Pain under review). These increases in synaptic signaling appear to be due to endocannabinoids causing a decrease in inhibitory GABAergic signaling (disinhibition). However, this leads to the question of why nociceptive synapses are not potentiated/ disinhibited by endocannabinoids as well. These opposing effects may be due to differences in effects of normally inhibitory neurotransmitter GABA.

We have observed that GABA can hyperpolarize/inhibit non-nociceptive sensory neurons, but depolarize/excite nociceptive neurons (Higgins et al. Molec Pain under review). GABA's effects are dependent on the levels of intracellular Cl-, which is controlled by two Cl- transporters: Na-K-Cl co-transporter isoform 1 (NKCC1), which imports Cl- and K-Cl co-transporter isoform 2 (KCC2), which exports Cl-. GABA-induced depolarization of the nociceptive afferent was reduced by the NKCC1 inhibitor bumetanide. The GABA-A receptor antagonist, bicuculline, depressed N-cell synaptic transmission, indicating that GABA-mediated depolarization was in fact excitatory. Bumetanide depressed N-cell synaptic transmission as well, consistent with the hypothesis that the excitatory effects of GABA on nociceptive synaptic signaling are the result of a depolarized Cl- equilibrium potential. GABA-induced hyperpolarization of the non-nociceptive afferent was reduced by the KCC2 inhibitor VU 0240551, which also caused a depolarizing shift in the chloride equilibrium potential. Bicuculline disinhibited non-nociceptive synapses and experiments are currently underway to determine if VU 0240551 can also affect these synapses. These findings suggest that the "sign" of GABAergic signaling plays a critical role in regulating the modulatory effects of endocannabinoids at the synaptic circuit level.

Title: Medial septum GABAergic mechanisms preferentially modulate formalin-induced moment-to-moment agitation and aversion

Authors: *S.-T. ANG[1,2], A. T. H. LEE[1,2], Z. M. ARIFFIN[1,2], L. NG[1,2], A. VIPIN[1,2], C.-M. LOW[1,3,4], S. KHANNA[1,2];
[2]Physiol., [3]Pharmacol., [4]Anaesthesia, [1]Natl. Univ. of Singapore, Singapore, Singapore

Abstract: The forebrain medial septum (MS) is implicated in nociception. Thus, hind paw injection of formalin in rat, a model of tonic inflammatory pain, excites septohippocampal neurons and lead to the generation of theta rhythm in the hippocampus which is also implicated in formalin nociception. Conversely, inactivation of the MS with the GABAA receptor agonist, muscimol, attenuated formalin-induced nociceptive licking and flinching and c-Fos induction in the spinal cord. Interestingly, the MS GABAergic neurons are implicated in the generation of the hippocampal theta rhythm that indirectly suggests that these are excited by noxious stimulation. Thus, the objective of the present study was to examine the role of MS GABAergic mechanisms in a spectrum of pain-induced behaviors, including (i) formalin-induced acute nociceptive behaviors and agitation, (ii) pain-induced associative learning in a contextual fear-conditioning task, (iii) pain-induced avoidance learning using the formalin-induced conditioned place avoidance (F-CPA) task, and (iv) the expression of peripheral hypersensitivity (PH) in the complete Freund's adjuvant model (CFA) of chronic inflammatory pain. The role of MS GABA in formalin-induced acute behaviors was assessed directly by microinjection of bicuculline and by selectively destroying the GABA neurons with the neurotoxin, kainic acid. The effect of GABAergic manipulations was compared with intraseptal microinjection of the NMDA receptor antagonist, AP5, in doses that attenuate septohippocampal theta activation. Subsequently, the influence of destruction of MS GABAergic neurons was assessed on fear-conditioning, F-CPA and CFA-induced PH.
In awake animals, intraseptal microinjection of bicuculline, in dose that attenuated theta activation in anaesthetized rat, and AP5 had no effect on formalin-induced nociceptive licking and flinching. However, these drugs enhanced the formalin-evoked agitation. Likewise destruction of GABAergic neurons (more than 70%) by kainic acid did not affect formalin-

induced nociceptive behaviors and PH in the CFA model, though a trend towards increased agitation was observed in the formalin test. The destruction of GABAergic neurons, however, attenuated freezing response in contextual fear conditioning and abolished avoidance behavior to the pain-paired compartment in the F-CPA task. Taken together, the study provides evidence that MS GABAergic mechanisms modulate pain-induced affect and sensorimotor integration. Moreover, the evidence suggests that MS mechanisms that modulate pain affect are functionally separate from those that underpin pain-induced acute nociceptive behaviors.

Title: Increase in spontaneous saphenous nerve activity after oxaliplatin administration: a possible index of spontaneous dysesthesia

Authors: *T. ANDOH, S. MIYAO, P. GAUCHAN, Y. KURAISHI;
Univ. Toyama, Toyama, Japan

Abstract: Oxaliplatin causes peripheral neuropathy, a dose-limiting side effect of anti-cancer drugs. Oxaliplatin-induced peripheral neuropathy is characterized by pain and dysesthesias, such as spontaneous electrification-like sensation and cold dysesthesia, in the hands and feet. Cold dysesthesia and mechanical allodynia have been studied in rodents, because they can be behaviorally assessed. However, spontaneous pain and dysesthesia are difficult to behaviorally examine in rodents. In this study, therefore, we examined whether spontaneous pain and dysesthesia associated with oxaliplatin-induced peripheral neuropathy can be electrophysiologically assessed in mice. Male C57BL/6 mice were used. A single intraperitoneal injection of oxaliplatin (3mg/kg) or vehicle (5% glucose) was administered. Recordings were made from the saphenous nerve that innervates the medial-dorsal hindpaw. Mechanical allodynia and cold dysesthesia were evaluated using a von Frey filament (0.69 mN) and acetone, respectively. Spontaneous saphenous nerve activity significantly increased on days 3, 10, and 32 after oxaliplatin injection, peaking on day 10. Licking, a pain-related behavior, of the hindpaws did not increase on day 3, 10, and 32. Mechanical allodynia and cold dysesthesia peaked on day 10 and day 3 after oxaliplatin injection, respectively, and almost subsided on day 32. The

response of the saphenous nerve to von Frey filament stimulation increased on days 3, 10, and 32 after oxaliplatin injection, peaking on day 10. Saphenous nerve response to acetone stimulation increased on days 3 and 10 after oxaliplatin injection, peaking on day 3. We found for the first time that spontaneous saphenous nerve activity increased after oxaliplatin administration. Although further studies are needed, the present results raise the possibility that increased spontaneous activity of the saphenous nerve is associated with oxaliplatin-induced spontaneous dysesthesia, including electrification-like sensation.

Title: Bidirectional virally-mediated optogenetic control of pain

Authors: *S. M. IYER, K. L. MONTGOMERY, C. L. TOWNE, S. Y. LEE, C. RAMAKRISHNAN, K. DEISSEROTH, S. L. DELP;
Bioengineering, Stanford Univ., Stanford, CA

Abstract: Optogenetic control of primary nociceptors could potentially have great translational and basic research value. Here, we demonstrate bidirectional optogenetic control over pain perception in non-transgenic, virally injected, freely moving mice, through non-invasive illumination of the mouse environment. We use injection of wild-type mice with adeno-associated virus to express opsins in unmyelinated nociceptors. We show that blue light illumination of the feet of mice injected with AAV6-ChR2 (channelrhodopsin-2) is aversive, and appears to result in characteristic pain-like behavior. Interestingly, we also find that low intensities of blue light that are insufficient to induce outward signs of pain can still induce place aversion, and sensitize mice to mechanical and thermal stimuli. We demonstrate that the same viral system can be used to deliver halorhodopsin (NpHR) to unmyelinated nociceptors, and

show that yellow light illumination can significantly raise mechanical and thermal withdrawal thresholds in these mice.

Title: Optogenetic silencing of peripheral pain pathways in transgenic mice

Authors: *I. DAOU[1], A. R. ASE[1], J. S. WIESKOPF[2], J. S. MOGIL[2], P. SEGUELA[1]; [1]Montreal Neurolog. Institute, McGill Univ., Montreal, QC, Canada; [2]Dept. of Psychology, McGill Univ., Montreal, QC, Canada

Abstract: Nociceptors are primary afferent neurons activated by noxious stimuli. Their peripheral nerve endings are the sites of nociceptive transduction, therefore their selective activation and/or silencing can control pain perception. Using a tissue-restricted genetic strategy, we sought to generate an analgesic model in which pain is optically inhibited by silencing the activity of nociceptors using light-gated inhibitory opsins. This approach consisted of expressing the proton pump archeorhodopsin (ArchT) fused to EGFP in the Nav1.8+ nociceptors, using the Nav1.8-Cre recombinase driver line. Cellular distribution of the ArchT-EGFP construct was assessed in fluorescence in dorsal root ganglia (DRG), trigeminal ganglia, sciatic nerve, glabrous skin and dorsal horn of the spinal cord, and showed a strong and selective expression of ArchT in nociceptive soma and fibers. The strong labeling in laminae I and II of the dorsal horn and the glabrous skin demonstrated the efficient trafficking of ArchT from cell soma to the central and peripheral targets, making it a promising candidate for optical silencing of the peripheral pain

pathways. Electrophysiological recordings on cultured DRG neurons revealed significant outward photocurrents and hyperpolarizations in ArchT-expressing cells in response to yellow light (589 nm) stimulation. These light-evoked hyperpolarizations were sufficiently large to block electrically- as well as αβmeATP-induced action potentials. Behavioral analysis of the analgesic effects of yellow light in freely moving transgenic mice is in progress as sensory phenotyping is conducted under acute, inflammatory and neuropathic pain conditions, to determine whether ArchT activation can reduce/eliminate acute and/or chronic pain. The development of a model in which pain can be optically and remotely inhibited has the potential to lead to the discovery of novel optogenetic treatments for intractable chronic pain in humans.

Title: Neuropeptide FF receptor type 2 transgenic mice exhibit hyperreactivity to nociceptive stimulation

Authors: *Y.-T. LIN[1], H.-L. LIU[2], H.-Y. LI[3], J.-C. CHEN[1];
[1]Grad. Inst. of Biomed. Sci., [2]Med. Imaging and Radiological Sci., Chang Gung Univ., Kwei-Shan, Taiwan; [3]Sci., Oregon Inst. of Technol., Klamath Falls, OR

Abstract: Neuropeptide FF (NPFF) belongs to FMRF-NH2 peptide and was known as an opioid modulating peptide. Two NPFF receptor subtypes have been cloned, i.e. NPFFR1 and NPFFR2. According to receptor competition assay, NPFFR2 was suggested to be physiological receptor for NPFF. NPFF-NPFFR system regulates morphine-induced analgesia and involves in both pro-nociceptive and anti-nociceptive responses, however the cellular mechanism remained unclear. The aim of this study was to explore if pain modulating effect of NPFF would be mediated through NPFFR2, taking advantage of in-house made NPFFR2 transgenic (Tg) mice. Behaviorally, NPFFR2 Tg mice exhibit hyperreactivity to mechanical and thermal nociceptive stimulations as compared to wild type (WT) mice. After CFA- or carrageenan-induced hind paw

inflammation, NPFFR2 Tg mice displayed a more severe allodynia than WT mice. Consistent with these findings, we demonstrated levels of NPFF and NPFFR2 mRNA in the lambar dorsal spinal were up-regulated after injection of CFA or carrageenan cord of WT mice. Via immunohistochemical analysis, we found protein levels of CGRP were significant increased after CFA injection in the NPFFR2 Tg mice as compared to CFA-treated WT mice. Further, functional MRI with electrical stimulation was introduced to evaluate brain activity in these mice and results showed that both signal intensity and activated extents in various brain regions (sensory cortex, thalamus, PAG, etc.) were much greater in NPFFR2 Tg mice than in WT mice. We conclude that NPFFR2 over-expression enhances the nociceptive threshold, thus plays an important role on pain modulation.

Title: Validation of tonic painful EEG during cold pressor test

Authors: *M. GRAM, C. GRAVERSEN, S. S. OLESEN, A. E. OLESEN, A. M. DREWES; Medicinal Gastroenterology, Mech-Sense, Aalborg, Denmark

Abstract: Pain in experimental studies has traditionally been assessed by short stimuli to induce event-related potentials. The use of short stimuli however can be problematic, since they fail to accurately simulate clinical pain in the experimental setting. Tonic pain can be simulated using the cold pressor test and have been utilized both for induction of DNIC as well as EEG investigations of pain processing. Despite its growing use in EEG studies, no studies have so far investigated the inter-session reliability of EEG parameters during cold pressor pain. This study is aimed to investigate the reliability of EEG during the cold pressor test, and compare it to EEG during rest.
EEG was recorded from 40 healthy volunteers, on two separate days. Recordings were obtained both during rest and the cold pressor test using a 64-channel setup. The EEG signals were processed using the continuous wavelet transform to obtain the spectral distribution in 8 frequency bands, ranging from 1 to 70 Hz. Reliability between the two days was assessed using the coefficient of variation and the intra-class correlation.
The analysis showed excellent reliability for the resting EEG with intra-class correlation

coefficients above 0.8 and coefficients of variance below 15% for all frequency bands. Furthermore, the EEG during the cold pressor test proved to be comparable to the resting EEG with regards to reliability, with intra-class correlation coefficients above 0.9 and coefficients of variance below 15 % for all frequency bands.
This study found the inter-session reliability of EEG recorded both during rest and the cold pressor test to be excellent. This is an important validation step for previous and future EEG studies planning to utilize the cold pressor test for assessment of pain processing.

Title: Neuropathic pain and the PFC: Dysregulation of the intercellular signaling pathways regulating pyramidal neuron excitability

Authors: *B. HARLAN[1], H. HUGHES[1], R. WANG[2], T. SHIPPENBERG[3], A. RIEGEL[1]; [1]Med. Univ. of South Carolina, Charleston, SC; [2]IUPUI, Indianapolis, IN; [3]NIH, Bethesda, MD

Abstract: In MRI studies of humans with neuropathic pain, hyperexcitability in the dorsal medial Prefrontal Cortex (dmPFC) is correlated with a negative affective state. To better understand the cellular mechanisms that may drive this hyperexcitability, various behavioral, anatomical and electrophysiological measurements were employed at 3-30d following spared nerve injury (SNI). In behavioral tests, allodynia was maximal at 4d post-SNI. At >7d post-SNI, C-Fos expression in CaMKII positive, not GAD positive, dmPFC pyramidal cells was elevated and remained so thereafter. At 30d post-SNI, confocal analysis of L5 dmPFC pyramidal neuron dendrites labeled with the lipophilic dye (DiI) indicated an overall increase in the density of thin spines and filopodia , suggesting a persistent reorganization of dendritic structure and altered structural plasticity. In patch clamp recordings in brain slices from SNI animals, such neurons displayed a loss of the slow after-hyperpolarization (AHP) and a loss of inhibitory accommodation. This adaptation was most prominent in dmPFC neurons contralateral to the SNI limb and absent in surrounding brain regions. Accommodation could be restored to SNI tissue by: blockade of PKA with H89, depletion of intracellular Ca2+ with cyclopiazonic acid,

chelation of intracellular Ca2+ with BAPTA or bath application of retigabine, a stabilizer of KCNQ ion channels. In pharmacologically isolated voltage-clamp experiments, KCNQ currents activated by slow voltage ramps or depolarizing pulses rapidly inactivated via a mechanism involving excessive release of calcium from intracellular stores. Taken together these data suggest that SNI: (i) induces a persistent and rapid allodynia consistent with the sensory perception of pain, (ii) a slow to develop reorganization of structural plasticity and (iii) increases in neuronal excitability in specific dmPFC neurons via Ca2+ mediated-changes in the signaling of KCNQ ion channels.

Title: Electrophysiological characterisation of projection neurons in naive and nerve-injured rats

Authors: *D. ROBERTS, H. REES;
Pfizer Neusentis, Great Abington, United Kingdom

Abstract: Quantitative sensory testing (QST) is an established and clinically relevant tool used to diagnose the changes in somatosensory function underlying chronic pain conditions. QST protocols can assess and quantify both the sensory loss (negative) and sensory gain (positive) symptoms that characterise neuropathic pain. One such protocol developed by the German Research Network on Neuropathic Pain (DNFS) uses a mechanism-based system that is well characterized and with good test-retest and interobserver reliability.
Preclinical studies in animal models of nerve injury typically only study positive symptoms such as tactile allodynia. In contrast, extensive studies by the DFNS has revealed that neuropathic pain patients are just as likely to suffer from negative symptoms recording a lack of sensation. Using in vivo electrophysiology we aimed to study whether both the negative and positive sensory phenomena could be recorded in rats following nerve injury (spinal nerve ligation (SNL)). To do this we characterised the response properties of projection neurons in both naive and nerve-injured rats to avoid a selection bias. As far as possible the same stimuli used by the DFNS protocol were employed (i.e. cotton wool, brush, Von Frey hairs (2 - 60g), PinPrick stimulators (8 -512 mN), mechanical wind up (256 mN PinPrick stimulator) and thermal ramps (2°C, 42°C,

44°C, 46°C, 48°C and 50°C, Medoc TSA II).
Projection neurons were reliably identified using antidromic protocols. Preliminary data analysis also revealed that the majority of the identified projection neurons studied in naive and SNL rats responded only to high threshold stimuli. Strong mechanical stimuli were required such as Von Frey hairs (>15g), Pinprick stimulators, pinch and higher temperature stimuli (>48°C). A few neurones from SNL rats with ongoing baseline activity were also identified and studied. Studies detailing the characterisation of older rats as well as the pharmacology of projection neurons in SNL rats are also described.

Title: Application of Mdr1a/b-Bcrp knockout mice to evaluate role of CNS penetration to antinociceptive efficacy

Authors: *S. K. JOSHI, C. ZHU, L. LEWIS, C. ZHONG, D. GAUVIN, J. MIKUSA, C. ZHAN, C. KALVASS, A. BANNON;
Neurosci. Res., AbbVie Inc, North Chicago, IL

Abstract: In analgesic drug discovery an important consideration for any given target is the relevance of central nervous system (CNS) penetration for efficacy. The P-glycoproteins (Pgp) expressed in the endothelial cells of the blood brain barrier extrude drugs from the CNS thus limiting their CNS concentration. The Mdr1a/b-Bcrp triple knockout mice have targeted mutations of the major such P-glycoproteins. In the present experiments, we first tested whether the knockout mice exhibit a normal pain phenotype by performing testing in acute (thermal, mechanical), inflammatory (complete Freund's adjuvant, CFA) and neuropathic (spinal nerve ligation, SNL, and chronic constriction injury, CCI) pain models. We then evaluated efficacy of A-1048400, a Pgp-substrate in wild type (WT) and knockout (KO) mice.
In agreement with previous reports, the Pgp KO mice were viable and appeared normal as demonstrated by comparable body weight gain and locomotor activity compared to WT mice. The acute pain responses as well as development and maintenance of nociceptive hypersensitivity in CFA (thermal and mechanical) and SNL (mechanical) models were comparable in the WT and KO mice. In WT mice A-1048400 produced efficacy at 30 and 100

mg/kg in the CCI model. In KO mice, A-1048400 produced significant antinociceptive effects at a lower dose of 10 mg/kg. In WT mice mean brain levels at the 10 mg/kg dose were 10 ± 3 ng/g while in KO mice mean brain levels were 110 ± 14 ng/g. These data provide evidence that CNS penetration can enhance the efficacy of A-1048400. Overall, these data highlight the utility of using Mdr1a/b-Bcrp triple knockout mice as a tool for assessing the role of CNS penetration for contributing to effects of novel compounds.

Title: Characterising the role of Langerhans cells in models of chronic pain conditions

Authors: *M. THAKUR, F. DENK, S. MCMAHON;
King's Col. London, London, United Kingdom

Abstract: Langerhans cells are a self-sustaining epidermal population of dendritic cells with functions including the phagocytosis of antigens in the epidermis and maintenance of immune tolerance. There is circumstantial evidence that they are involved in the pathogenesis of certain chronic pain disorders.
We have used a knock-in mouse expressing human diphtheria toxin receptor in langerin-expressing cells to probe interactions between Langerhans cells and peripheral nerve in a number of models of chronic pain conditions. We find that epidermal Langerhans cells cannot be detected in sections of hindpaw skin for at least 18 days following two i.p doses of 1µg

diphtheria toxin.
In pilot studies we assessed how ablation of Langerhans cell ablation affects the pathophysiology of the Seltzer model of traumatic nerve injury-induced pain. Epidermal C-fibre terminals were found to be cleared less rapidly after nerve injury in Langerhans-depleted mice, suggesting a novel role for these cells in axonal phagocytosis during Wallerian degeneration.

Title: Modulation of pain by wnt signaling molecules in an experimental neuropathic pain model

Authors: J.-A. YOON, K. SUNG, *S. LEE;
Dept Physiol, Col. Med., Hanyang Univ., Seoul, Korea, Republic of

Abstract: Wnt signaling molecules are important in development and differentiation of nervous tissues. Recently, a few studies have suggested that wnt signaling might contribute to development and maintenance of pathological chronic pain. However, direct evidences that enhancement of wnt signals might actually induce painful behavior are very limited. This study was designed to examine that stimulation or inhibition of wnt signaling could modulate pain behaviors in experimental animals. Pain was assessed by mechanical threshold evoking withdrawal response (PWT) or paw withdrawal latency (PWL) to thermal stimuli. Agonists or antagonist of wnt signaling were injected into the spinal cavity of normal or neuropathic rats through intrathecal catheters, and their PWT or PWL were measured before and after the injections. Intrathecal injection of a wnt agonist elicited hyperalgesic signs, the reduction of PWT, indicating that increase of Wnt signaling might be to develop hyperalgesic signs. The hyperalgesic effect was completely blocked by peremptive antagonist injection. Intrathecal injection of a Wnt3 antagonist increased PWT of rats suffering neuropathic pain, induced by L5 & 6 spinal nerve transection. These results suggest that increase of wnt signaling might be one of the factors which change the spinal plasticity, leading the hypersensitivity to stimuli. However, the mechanisms of pain modulation of wnt signaling are still obscure.

Title: Modulation of neuronal hyperactivity in ventral posterolateral nucleus by electrical stimulation of anterior cingulate cortex in neuropathic pain model rats

Authors: *S. RYU[1], J. CHOI[1], J. KIM[2], C. IM[3], J. CHANG[2], H.-C. SHIN[3], K. KIM[1]; [1]Biomediecal Engin., Yonsei Univ., Wonju, Kangwon, Korea, Republic of; [2]Dept. of Neurosurg. and Brain Res. Inst., Yonsei Univ. Col. of Med., Seoul, Korea, Republic of; [3]Dept. of Physiol., Col. of Medicine, Hallym Univ., Chuncheon, Korea, Republic of

Abstract: Electrical stimulation to a specific area in the brain has been widely used to treat neurological disorders such as Parkinson's disease. It has been recently reported that electrical stimulation to anterior cingulate cortex (ACC) is effective to relieve symptoms of neuropathic pain. To understand its mechanism, it is necessary to observe how neuronal activities in the pain-related area are affected by the stimulation. In this study, we investigated pain-related characteristics of neuronal activities in ventral posterolateral nucleus (VPL) of thalamus and analyzed how they are affected by ACC electrical stimulation. Spared nerve injury rats (200-300 g) were used as models of neuropathic pain.Singe unit activities and local field potentials (LFPs) were recorded from the VPL. Press stimulus was applied to the hind paw. Biphasic electrical pulse was applied to an electrode placed in the ACC (pulse amplitude: 100 μA, pulse duration: 60 μS, frequencies of 10-130 Hz). In single unit activities, firing rate was increased during the press stimulation both in normal and neuropathic pain model rats. However, firing rate was increased significantly higher and lasted much longer (after-discharge) in neuropathic pain model than in the normal rats. According to the press stimulus, spectral power of LFPs was increased in high gamma band (80-150 Hz) and decreased in low frequency band (1-10 Hz). Similarly to the single unit activities, changes in LFPs also were sustained longer in neuropathic pain model than in the normal rats. By the electrical stimulation of the ACC, the hyperactivity in

single unit activities including the after-discharge was suppressed. The duration of increased/decreased LFP spectral powers were also reduced to near-normal levels by the ACC stimulation. The ACC stimulation became effective when the stimulation frequency was higher than 50 Hz. Our results suggest that the abnormal singe unit activities and LFPs are distinctive features of neuropathic pain, and high frequency electrical stimulation of the ACC is an effective way to reduce these pain-specific features.

Title: Pharmacological characterization using Ca2+ imaging in *Ex vivi* spinal cord slices during inflammatory or multiple sclerosis pain

Authors: *S. DOOLEN[1], G. CORDER[1], T. IANNITTI[2], B. K. TAYLOR[1];
[1]Univ. of Kentucky, Lexington, KY; [2]Univ. of Leeds, Leeds, United Kingdom

Abstract: We recently reported successful imaging of multiple neurons in adult spinal cord slices, and found that SNI increases glutamate-evoked Ca2+ mobilization. Here we extend this characterization to pharmacological studies in animal models of inflammation and multiple sclerosis (MS).
To test the hypothesis that Ca2+-dependent central sensitization is maintained not only during but also after the resolution of inflammatory hyperalgesia, we used live-cell Ca2+ imaging in adult mouse spinal cord slices. von Frey (vF) measures of tactile sensitivity were assessed at 3 d, 7 d or 21 d after CFA (5 ul, intraplantar). Transverse lumbar spinal cord slices (450 um) were bulk loaded with 10 uM fura-2 AM for ratiometric Ca2+ imaging. Glutamate-evoked [Ca2+]i in

lamina II dorsal horn neurons was potentiated at 3 d after CFA ($p<0.05$) and then resolved by day 21; this coincides with the temporal onset and resolution of inflammatory hyperalgesia. Perfusion of either the selective mu antagonist, CTOP or the non-selective opioid receptor antagonist NTX markedly increased glutamate-evoked [Ca2+]i in CFA 21d ($p<0.05$) but not sham slices. Similarly, opioid receptor blockade 21d post-CFA reinstated pain-like behavior. These data suggest endogenous opioids mask Ca2+-dependent central sensitization and pain-like behavior 21d after CFA-induced inflammation.
To test the hypothesis that the MS-induced pain is associated with glutamate-evoked Ca2+ responses, we evaluated the glutamate dose-response relationship of Ca2+ mobilization 7-10 days after induction of experimental autoimmune encephalomyelitis (EAE). EAE was induced in 24 d mice by injecting myelin oligodendrocyte glycoprotein 35-55 (MOG33-35; 300 ug) and again 6 d later. Pertussis toxin was administered (200 ng, i.p.) on days 0 and 2. Prior to (baseline) and up to 21 d post-injury, tactile (vF) and cold (acetone) hypersensitivity were assessed. EAE clinical scores and pain-like behavior were significantly greater compared to control animals by 7 d after EAE induction. EAE significantly increased Ca2+ responses to 0.3 and 1 mM glutamate ($p<0.05$). We next tested the hypothesis that FTY720, a sphingosine-1-phosphate ligand that is FDA approved for the motor dysfunction of MS, reduces the central sensitization that drives tactile and cold allodynia. FTY720 (1 mg/kg i.p.) daily beginning 6 days after the first MOG injection significantly reversed tactile and cold allodynia compared to saline-injected controls; and Ca2+ responses to 0.3 and 1 mM glutamate were also significantly lower ($p<0.05$). These data suggest a functional link between Ca2+ signaling in the dorsal horn and the maintenance of inflammatory and MS-induced pain.

Title: Characterization of nociceptive sensitization in larval Manduca sexta

Authors: *M. FUSE[1], E. MERCHASIN[1], M. MCMACKIN[1,2], K. IWASAKI[1,3], L. RAMOS[1], C. MOFFATT[1];
[1]Biol., San Francisco State Univ., SAN FRANCISCO, CA; [2]Molecular, Cell. and Integrative Physiol., UC Davis, Davis, CA; [3]Neurosci., Univ. of Michigan, Ann Arbor, MI

Abstract: Nociceptive sensitization results when an animal learns to strengthen its defensive response to a previously neutral or weak stimulus after the presentation of a noxious or painful stimulus such as a strong pinch or an electrical shock. This phenomenon has been observed in the hornworm, *Manduca sexta*, by testing the number of defensive strikes that occurs before and after a strong pinch (Walters et al., 2001). We have been developing a novel approach to quantifying nociceptive sensitization, while concurrently using Walter's method to assess the role that cGMP plays in this sensitization. Our new method assessed the force needed to generate a strike before and after the aversive stimulus, and our data indicated that larvae were sensitive to a lighter touch after presentation of the noxious stimulus, which lasted for over 18 hours. Our pharmacological study suggested that cGMP has an antinociceptive effect. Injection of 8-bromo-cGMP attenuated the sensitization induced by a strong pinch in a dose-dependent manner, as noted by a decreased number of strikes after cGMP application. In contrast, strike number increased after injection of methylene blue, a non-specific inhibitor of soluble guanylyl cyclase activity used to inhibit the production of cGMP, although no effect was noted with ODQ, an inhibitor of NO-sensitive cGMP activity. These data suggest that an alternate transduction pathway sensitizes the strike response, and cAMP is being assessed currently.

Title: Chronic administration of the cannabinoid agonist, WIN 55,212-2, reduces hyperalgesia and nociceptor sensitization produced by cisplatin

Authors: *M. L. UHELSKI[1], C. HARDING-ROSE[2], D. SIMONE[2];
[1]Univ. of Minnesota Twin Cities, Minneapolis, MN; [2]Univ. of Minnesota, Minneapolis, MN

Abstract: Painful chemotherapy-induced peripheral neuropathy (CIPN) is the major dose-limiting side effect of chemotherapy, which could impact the efficacy of therapy for patients who are unable to tolerate increasing doses. Many patients continue to experience neuropathic symptoms for months or years after treatment has ended. Neuropathic pain due to chemotherapy has been explored in animal models. The platinum compound cisplatin produces mechanical, heat, and cold hyperalgesia in rodents and is associated with damage to primary sensory neurons. Cisplatin has been shown to sensitize nociceptors, evidenced by an increase in spontaneous discharge among both Aδ- and C-fiber nociceptors and an increase in evoked responses. Cannabinoids have been shown to reduce neuropathic pain, including pain from CIPN. Here we examined the effects of chronic administration of the non-selective cannabinoid receptor agonist WIN 55,212-2 on hyperalgesia and sensitization of nociceptors produced by cisplatin. Mice received a daily injection of WIN 55,212-2 (2 mg/kg, ip) or vehicle with cisplatin (1 mg/kg, ip) for 7 consecutive days. We found that WIN 55,212-2 attenuated the development of mechanical and heat hyperalgesia associated with cisplatin administration. Twenty-five percent (2/8) of Aδ- and 76% (13/17) of C-fiber nociceptors exhibited ongoing spontaneous discharge in mice pretreated with vehicle, whereas only 15% (2/13) of Aδ-fibers and 38% (8/21) of C-fiber nociceptors were spontaneously active in mice given WIN 55,212-2. Nociceptors that were spontaneously active in the latter group had lower mean discharge rates for both Aδ- (0.3 ± 0.3 Hz vs 0.1 ± 0.1 Hz) and C-fibers (0.2 ± 0.0 vs. 0.1 ± 0.7 Hz). There was also a decrease in responses of Aδ-fibers evoked by a mechanical stimulus (von Frey monofilament with 147 mN force). Responses in mice given cisplatin with vehicle or WIN 55,212-2 were 91.9 ± 21.4 vs. 64.9 ± 14.3 impulses, respectively. Evoked responses of C-fiber nociceptors did not differ between the groups. These data demonstrate that daily administration of cannabinoids reduces hyperalgesia and nociceptor activity produced by cisplatin and may be useful to reduce pain from chemotherapy treatment.

Title: Vesicular Glutamate Transporter 2 and Aspartate Aminotransferase alterations in rat DRG neurons during adjuvant-induced arthritis

Authors: *B. BOLT, K. E. MILLER;
Anat. and Cell Biol., Oklahoma State Univ. Ctr. For Hlth. Sci., Tulsa, OK

Abstract: The sensory neurons of the dorsal root ganglia (DRG) are glutamatergic, utilizing glutaminase (GLS) and aspartate aminotransferase (AST) for glutamate synthesis (Miller et al., Pharmacol Ther 130:283, 2011). Following synthesis, glutamate is transported into synaptic vesicles by either vesicular glutamate transporter (VGLUT) 1 or 2 (Brumovsky et al., Neurosci 147:469, 2007). VGLUT2 is produced primarily in medium (400-800 μm2) to small sized (100-400μm2) DRG neurons, whereas large sized DRG neurons (>800 μm2) predominantly express VGLUT1. We previously demonstrated that glutamate metabolism (↑ GLS, AST, glutamate levels) is altered in the rat DRG, sciatic nerve and skin during adjuvant-induced arthritis (AIA). Additionally, we have determined that AST is elevated in nociceptive, calcitonin gene-related peptide (CGRP) containing DRG neurons during AIA. In the present study, we evaluated alterations of VGLUT2 in AST DRG neurons and AST in VGLUT2 DRG neurons during AIA. Complete Freund's adjuvant was injected into the rat right hindpaw to induce AIA and DRG's were analyzed at 1, 2, 4 and 8 days. Rats were anesthetized and transcardially perfused with fixative. AST and VGLUT2 colocalization was evaluated in L4 DRG's with immunohistochemistry, followed by quantitative image analysis with Image J. At 1, 2 and 8 days AIA, AST-immunoreactivity (ir) in VGLUT2-positive DRG neurons was elevated when compared to naïve controls. Furthermore, VGLUT2-ir in AST-positive neurons was elevated slightly at day 1 AIA, but at no other time points when compared with controls. These results suggest that part of the alteration of glutamate metabolism during peripheral inflammation is due an increase in VGLUT2 and AST levels in DRG neuronal cell bodies. The underlying mechanisms for these alterations could be due to retrograde transport of neurotrophic factors and/or modification of transcriptional, translational, or trafficking processes in the DRG neuronal cell body.

Title: Effects of distraction and suggestions with and without hypnotic induction on spinal-motor, autonomic and cortical pain-evoked responses

Authors: *A. STREFF[1,2], B. HOUZE[1,2], A. LEHMANN[1,4,2], M. PICHE[1,5], P. RAINVILLE[1,3]; [1]psychology, CRIUGM, Montreal, QC, Canada; [3]Stomatology, [2]Univ. de Montreal, Montreal, QC, Canada; [4]BRAMS, Montreal, QC, Canada; [5]Univ. de Trois-Rivieres, Trois-Rivieres, QC, Canada

Abstract: While the effects of hypnotic suggestions on pain are well-known, the specific contribution of "hypnotic states" in acute pain modulation is less described. At what level and how exactly hypnosis changes nociception? Using psychophysiological and electroencephalographic measures, this study examines a modulation of pain-related responses elicited by noxious electrical stimulation induced by four manipulated conditions: hypo- and hyperalgesic suggestions after induction, hypoalgesic suggestions without induction and a mental distraction task.

10 women and 10 men (age: Mn= 25±7 yrs.) participated in two sessions (hypnosis vs. non-hypnosis; duration 90-120 min.) with two experimental parts. Sessions and parts were counterbalanced with respect to order and gender. Noxious electrical shocks (30-ms train of 1-ms pulses at 333 Hz; ISI = 6-12s) were administered to the right sural nerve, at an intensity of 120% of the individual RIII-reflex threshold determined in a pre-experimental block. In each session, stimuli were administered in 3 blocks of 6 shocks after neutral suggestions and 2 blocks of 9 shocks after hypo- (with and without induction) and hyperalgesic suggestions or during the calculation task. After each block, participants rated pain intensity and unpleasantness. Electromyography (EMG) of the right biceps femoris, electrocardiographic activity (ECG) and skin conductance responses (SCR) were monitored continuously. Additionally, electroencephalographic activity (EEG) was recorded in order to investigate late SEPs (N150-P260 components) in each condition.

The four experimental conditions modulated pain intensity ratings ($p=0.001$) compared to the neutral condition. Hypoalgesic suggestions significantly decreased RIII-reflex amplitude with ($p<0.001$) and without induction ($p=0.009$) whereas hyperalgesic suggestions increased EMG activity ($p<0.001$). SCRs and heart rate were reduced after hypo- ($p=0.008$; $p=0.001$) and increased after hyperalgesic ($p= 0.004$; $p=0.006$) suggestions. The mental calculation task only accelerated the cardiac rhythm ($p<0.001$). P260 component was significantly reduced on Cz ($p=0.025$) and Pz ($p=0.008$) locations only after hypoalgesic suggestions preceded by hypnotic induction.

Hypoalgesic suggestions, after induction only, modulate pain ratings, motor, autonomous and cerebral responses. These results indicate that different psychological strategies used to modulate pain act through at least partly separable mechanisms. Further experiments should include BOLD measures to get a more detailed idea of the brain regions involved in the modulation of a spinal nociceptive reflex by hypnosis.

Title: Computational model of in-vitro sigh generation

Authors: *N. TOPORIKOVA[1], A. ZAIDI[2], M. THOBY-BRISSON[3];
[1]BIology, [2]Neurosci., Washington and Lee Univ., Lexington, VA; [3]Univ. Bordeaux, Bordeaux, France

Abstract: Eupneic breathing in mammals is periodically interrupted by spontaneous augmented breaths (sighs) that are characterized by a biphasic larger-amplitude inspiratory burst followed by post-sigh apnea. Previous in vitro studies in newborn rodents have demonstrated that the respiratory oscillator of the pre-Bötzinger complex (preBötC) can generate the distinct inspiratory-related motor patterns for both eupnea- and sigh-like activity. However it remains debated whether these two types of inspiratory activities are produced by the same neuronal population or by distinct sub-networks. In order to address this issue we developed two mathematical models to investigate possible mechanisms for sigh generation. One model proposes that sighs are generated by two distinct neural sub-networks, while the second model hypothesizes that sighs are generated within the same network, with sigh generation relying on calcium-dependent mechanisms in both cases (as suggested by Lieske et al., 2000; Pena et al., 2004 and Thoby-Brisson et al, unpublished). For each model we searched for parameters (such as synaptic strength, pacemaker properties, distribution on ionic currents) that allow reproducing experimental data obtained in vitro on mouse transverse brainstem slices isolating the preBötC. Although the low frequency dynamics of the sigh and its biphasic shape can be reproduced by both models, decoupling of the two components of a sigh event after blockade of glycinergic synapses (Lieske et al., 2000) was only achieved in the two sub-network model. This model also simulated the increase in sigh frequency in response to Gq-coupled neuromodulator (Tryba et al., 2008) and independence of the sigh frequency from the extracellular K+ concentration (Thoby-Brisson et al., unpublished) Overall, our data suggest that sigh generation mechanisms rely on the activity of a specific sub-population of neurons within the preBötC network.

Title: Astrocytes determine conditions for rhythmogenesis in a trigeminal sensori-motor circuit involved in mastication

Authors: *P. C. MORQUETTE[1], D. VERDIER[1], R. ROBITAILLE[1], A. KOLTA[2];
[1]Physiologie, [2]Stomatologie, Univ. De Montreal, Montreal, QC, Canada

Abstract: In trigeminal and spinal circuits thought to be involved in mastication and locomotion respectively, rhythmic neuronal bursting is enhanced and promoted when the extracellular concentration of calcium [Ca2+]e decreases. This study investigates the ability of astrocytes to modulate neuronal bursting by influencing the [Ca2+]e in the trigeminal main sensory nucleus (NVsnpr). In vitro, neurons of the dorsal NVsnpr fire rhythmic bursts spontaneously when Ca2+ is removed from the perfusing medium, or when a calcium chelator like BAPTA is applied locally next to the recorded cell. Under physiological [Ca2+]e (1.6mM), local applications of NMDA or repetitive stimulation of afferent inputs to NVsnpr can also elicit rhythmic bursting. We used Ca2+ -imaging and whole cell patch recordings to test whether astrocytes respond to these “burst inducing stimuli”. Both stimuli induced large depolarizations in recorded astrocytes. This activation was further confirmed for NMDA applications using Ca2+ -imaging with either intracellular or extracellular Ca2+ indicators. When the latter were used, NMDA application invariably caused activation of multiple cells. In dual recordings of pairs of neurons and astrocytes, the astrocytic depolarization occurred in parallel to rhythmic neuronal bursting. To determine the presence or absence of causality in this relationship, we took advantage of the fact that astrocytes connect through gap junctions to selectively prevent their activation by patching a single one with a pipette filled with BAPTA and letting the BAPTA diffuse. After allowing 30-50 min for BAPTA diffusion, the inactivation of the glial syncytium was confirmed by the extinction of Ca2+ responses in surrounding astrocytes. In paired recordings NMDA could no longer induce bursting in neurons recorded under this condition, despite maintaining its ability to depolarize them. However, inactivation of glial syncytium had no effects on the spontaneous rhythmic bursting of neurons recorded in calcium free ACSF. Thus direct decrease of [Ca2+]e seemed to bypass the astrocytic implication, suggesting that the effect of astrocytes is mediated through an effect on [Ca2+]e .

Interestingly S100β, a calcium binding protein that has been shown to be secreted from astrocytes could act as a Ca2+ chelator. Local application of S100β induces rhythmic bursting and pre-treatment of slices with an antibody against it prevents NMDA-induced bursting in 7/11 cases, whereas in 5/5 cases bursting was not prevented by use of an unspecific antibody. This work provides strong evidence that rhythmogenesis in a part of the masticatory CPG depends on neuron-astrocyte interaction.

Title: Stimulation of the trigeminal sensory tract causes bursting and calcium depletion in dorsal neurons of the trigeminal main sensory nucleus

Authors: *P. A. KADALA, D. VERDIER, A. KOLTA;
Dept. de Physiologie, Univ. De Montréal, Montréal, QC, Canada

Abstract: Central pattern generators (CPGs) underlie rhythmic movements like breathing, walking and chewing. For the latter, a subpopulation of neurons located dorsally in the trigeminal main sensory nucleus (NVsnpr), may be the core of the masticatory CPG. Previous investigations in rats have shown that artificially lowering the concentration of extracellular calcium promotes rhythmic bursting in these neurons. A stimulation of the afferent sensory tract to the NVsnpr or local application of N-Methyl-D-Aspartate (NMDA) can also cause them to switch from a tonic firing to a bursting pattern. The question remains (i) whether or not the extracellular calcium fluctuates during stimulation of afferent sensory fibers and if any, what is the extent of that fluctuation, (ii) what are the mechanisms underlying these changes in extracellular calcium concentrations. Parallel work from our laboratory suggests that astrocyte activation is essential to neuronal bursting. The protein S-100β is secreted to extracellular space by astrocytes and has been shown to play numerous roles in the brain, including chelation of calcium. As such, it might cause calcium fluctuations in extracellular space. In the present study, we used calcium-sensitive electrodes to monitor changes in extracellular calcium concentration

along with stimulations of the sensory tract in brainstem slices obtained from rats. We also investigated the effect of local application of S-100β and an anti-S100β antibody on both the extracellular calcium concentration and the firing pattern of NVsnpr neurons. After stimulation of the sensory tract, 30% of neurons switched from a tonic (singlets or doublets) to a bursting firing pattern. Most of these changes occurred conjointly with a decrease in extracellular calcium concentration. Calcium decreases exhibited two profiles: a transient calcium depletion that was paralleled by a complete inhibition of neuronal firing, and a slow long-lasting decrease which was accompanied by a switch to bursting firing pattern. Application of S-100β (50 or 129 μM) caused neurons to burst and decreased extracellular calcium by ~1mM. Similar effects were obtained with NMDA (1mM). Pretreatment of the slices with an anti-S-100β antibody but not with a non-specific antibody, prevented burst induction and calcium depletion with stimulation of the sensory tract and application of NMDA or S-100β. Together, these data show that stimulation of trigeminal sensory tract can trigger depletion in extracellular calcium along with burst discharges in trigeminal main sensory nucleus and these effects are mediated by release of the astrocyte protein S-100β.

Title: The effect of ectopic axonal spiking on synaptic dynamics

Authors: *N. DAUR[1,2], Y. ZHANG[3], F. NADIM[2,3], D. BUCHER[1,2];
[1]Univ. of Florida, Whitney Lab. For Marine Biosci., St Augustine, FL; [2]Dept. of Biol. Sci., NJIT and Rutgers Univ., Newark, NJ; [3]Dept. of Mathematical Sci., NJIT, Newark, NJ

Abstract: Information flow in neurons usually consists of synaptic integration and spike initiation in proximal compartments, and axonal propagation of signals to distal synaptic targets. However, distal (ectopic) axonal spike initiation has recently been shown to play a role in neural processing during specific network states in cortex and hippocampus.
We use an unmyelinated crustacean motor axon of the lobster stomatogastric nervous system,

and its postsynaptic muscle targets, to investigate the role of ectopic spikes in shaping postsynaptic responses. The rhythmically active Pyloric Dilator neurons send 4-5 cm long axons to different target muscles. We have previously shown that low concentrations of dopamine enhance I_h in these axons. The resulting depolarization can be sufficient to elicit ectopic peripheral spike initiation (Bucher et al., 2003; Ballo & Bucher, 2009, Ballo et al., 2010). The incidence of peripheral spike initiation depends on the level of centrally generated activity, as higher burst frequencies are sufficient to suppress peripheral spike initiation. Axonal stimulations with lower burst frequencies, as well as dampening of centrally generated activity by modulatory inputs lead to patterns of centrally generated bursts interleaved with a few peripherally generated spikes during the interburst intervals. These additional spikes have a "priming" effect on the postsynaptic muscle responses in that they enhance the compound depolarization in response to bursting input by 20-40 %. This is true even in muscle fibers that show no discernible direct response to the interburst spikes. Furthermore, the priming effect is not dependent on the overall spike numbers, but persists when overall spike rate is kept constant. The muscle responses appear largely passive, but current and voltage clamp recordings show some voltage-dependent non-linearity and occasional spike-like responses. However, the priming effect qualitatively persists when synaptic currents are measured. Therefore, the priming effect appears to be due to a mixture of short-term synaptic dynamics and active (threshold- or voltage-dependent) responses.
A mathematical decoding technique applied to these data indicates that a combination of fast depression and slow facilitation can account for the priming effect. However, when the same decoding process is applied to data from *Poisson*-like stimulations of the same muscle fiber, it suggests a different history dependence that fails to capture the priming effect. Together, these results confirm that the priming effect is not merely a history-dependent effect but also involves nonlinear voltage- or calcium-dependent processes.

Title: Modulatory masking: Activation of distinct currents in a single cell supports temporary reversals of response character in a multi-functional network

Authors: *M. H. PERKINS, E. C. CROPPER, K. R. WEISS;
Mt. Sinai Sch. of Med., New York, NY

Abstract: Repetition priming is an improvement in response quality to a stimulus that has been experienced. Underlying this phenomenon is an alteration of the state of the behavior-generating network. Many networks are multi-functional, and respond to stimuli with different, even antagonistic behaviors. In networks where two antagonistic behaviors are both subject to priming, how do transitions between behaviors occur? We used Aplysia feeding as a model system. The buccal and cerebral ganglia, which form a control network, generate responses that are state dependent. When rested, the network responds to a stimulus and generates intermediate programs, that are neither ingestive nor egestive. Following repeated stimulation of the interneuron CBI-2, responses are ingestive. In contrast, following repeated stimulation of the esophageal nerve, responses are egestive.
The ingestive vs. egestive character of motor programs is in part dictated by changes in the excitability of the motor neuron B48. We initially hypothesized that the network state would be manifested in B48 as a single variable with ingestive and egestive extremes. Further, we predicted that a transition from an ingestive to an egestive state would involve an erasure of the pre-existing increase in B48 excitability. Instead, we observed that the excitability increase in B48 caused by ingestive priming is transiently suppressed, but not erased, by subsequent egestive priming. In light of this finding, we test a hypothesis, that postulates that the network state depends on a dual-process mechanism. It depends on the degree of increased excitability due to ingestive priming and on the degree of decreased excitability due to egestive priming. Further, we test a simple model for achieving such dual-process control, in which two distinct currents are responsible for the excitability changes in B48. We find that neuropeptides that support ingestive priming (Cerebral Peptide 2, CP2 and Feeding Circuit Activating Peptide, FCAP) modulate a current that does not reverse between -100 and 0 mV, is reduced by removal of sodium, and potentiated by removal of extracellular calcium. A current with similar characteristics was observed, following the iontophoresis of cAMP. This suggests that ingestive priming increases the excitability of B48 via a cyclic nucleotide gated sodium current. A current with different characteristics seems to be involved in the reduction of B48 excitability following egestive priming. It reverses near -85 mV, is sensitive to TEA and to removal of calcium. We conclude that the sum-total network-state arises from integration of a dual-process mechanism at the cellular and sub-cellular level.

Title: Long-term regulation of excitability in the gastric mill network of the crab stomatogastric ganglion

Authors: *A. W. HAMOOD, S. HADDAD, E. MARDER;
Brandeis Univ., Waltham, MA

Abstract: The stomatogastric ganglion (STG) of crustaceans contains the neural circuitry involved in the generation of two motor patterns critical for feeding behavior in the animal. The pyloric (filtering) rhythm, is continuously active both in vivo and in dissected in vitro preparations of the stomatogastric nervous system (STNS). The gastric mill (chewing) rhythm is episodically active and drives a set of teeth in the animal's stomach to perform grinding and chewing movements, typically activated by modulatory inputs only after feeding. Previous work has shown that upon removal of these modulatory inputs by transection of the only input nerve (decentralization), activity in both networks ceases, but the pyloric rhythm gradually returns over a period of several days in vitro. However, recovered activity in the gastric mill network has never previously been reported in decentralized preparations. We have performed long-term extracellular recordings from in vitro preparations of the STNS for a week or more, and find that rhythmic gastric mill activity can return in vitro in the absence of modulatory inputs. Bursting activity in gastric mill neurons was routinely observed and rhythmic bursting activity in gastric mill neurons was observed in more than half of these preparations, starting between 150 and 350 hours following decentralization. Intracellular recordings from the motor neurons of the gastric mill network both immediately after decentralization, and at later time points, including in the presence of recovered gastric mill rhythms show significant increases in neuronal excitability of gastric mill neurons following decentralization, suggesting that the regulation of intrinsic neuronal excitability is a key feature underlying recovery. We have also performed acute modulatory perturbations of the STNS during decentralization, and monitored the changing responsiveness to neuromodulation during the culture period, providing further insight into the changes in network excitability that accompany the observed network response to this dramatic perturbation.

Title: Cloning and sequencing of prepropeptide cDNAs that encode neuropeptides involved in feeding-related behaviors in the pond snail, Helisoma trivolvis

Authors: *N. W. KLECKNER[1], C. O'LEARY[2], J. BERGERON[3], A. HULSE[3], M. ARSNOW[3], D. BIRKHEAD[4], G. BORLAND[2], P. DIXON[4], H. FISHER[4], C. GARVEY[3], J. MEYO[3], V. JARVIS[3], A. SRIDHAR[4], J. D. SATO[5];

Abstract: Molluscan nervous systems have long been used as models for understanding the neural basis of behavior. The sea slug, *Aplysia californica*, has been used, for example, to understand signaling and circuits involved in learning and memory and the neuromodulation of feeding and other behaviors. Motor program switching among a variety of feeding-related behaviors in in *Aplysia* and freshwater mollusks is under the control of cerebral-buccal and buccal interneurons that release neuropeptides such as neuropeptide phenylalanine (NPF), APGWamide, small cardioactive peptide B (SCP_B) and gonadotropin releasing hormone (GnRH) onto central pattern generator (CPG) neurons that pattern feeding behavior. The purpose of these experiments was to identify and sequence cDNAs coding for prepropeptides from freshwater snails to better understand the distribution and roles of the mature peptides in pond snail species that serve as intermediate hosts for parasites. RNA was isolated from *Helisoma trivolvis* central nervous system and reverse transcribed to cDNA. Primers were designed from alignments of the prepropeptide coding sequences of mollusks, other invertebrates and vertebrates and were used in PCR reactions to amplify cDNA fragments from homologous reqions. 3' and 5' RACE were used to amplify both ends of the prepropeptide cDNAs. Full length *Helisoma* GnRH cDNA encodes a 109 amino acid precursor that contains an 11 amino acid mature hormone that is 91% identical to *Aplysia* GnRH. The whole precursor, however, is only 37% identical to the *Aplysia* prepropeptide. *Helisoma* APGWamide cDNA encodes a 213 amino acid precursor that contains

eight cleavable APGWG repeats from which the mature APGWamide may be derived enzymatically. The precursor is 55% identical to *Lymnaea stagnalis* APGWamide precursor which contains ten cleavable APGWG sequences. Four different cDNAs from *Helisoma* appear to code for SCP precursors, representing combinations of two separate insertion/deletions. The shortest form codes for a 112 amino acid precursor that contains two mature nonapeptide sequences that resemble *Lymnaea* SCP peptides (67 and 100% identity to *Lymnaea* SCP_A). The longer versions contain another possible mature nonapeptide with 33% homology to the other *Helisoma* peptides. These cDNAs will be used to make riboprobes to localize the peptide precursors to pond snail tissues and to synthesize peptides for activity in *Helisoma* and *Biomphalaria glabrata*, the intermediate host to the schistosomiasis parasite. These sequences also enhance our understanding of the families of neuromodulators that control motor behaviors in mollusks and other organisms.

Title: Modulator induced changes in motor patterns are temperature compensated

Authors: *S. A. HADDAD, E. MARDER;
Brandeis Univ., Waltham, MA

Abstract: Central pattern generators (CPGs) are responsible for many life essential behaviors. The stomatogastric ganglion (STG) in the rock crab, Cancer borealis, is a well characterized CPG that controls digestion and filtering in the stomach. Here, we study phase relationships, between the subset of STG neurons that comprise the pyloric rhythm, in response to temperature change and modulatory perturbation. It is known that phase relationships in the pyloric network are maintained across an environmentally realistic temperature range. It is also known that the vast range of cellular processes (channel opening and closing, ligand-substrate binding, enzymatic reactions) have different Q10's (the Δ in rate of a process/ 10°C). Therefore, it is not obvious how the network compensates to maintain phase relationships given the plethora of

temperature variable cellular processes. To study this, each dissected stomatogastric nervous system (STNS) is subjected to three temperature ramp (11°C-31°C in 4° increments) protocols. In the first ramp, the STG receives modulatory input from descending neurons (front end-on). We find that the network frequency increases from ~ 1 hz at 11°C to ~3hz at 31°C . For the second ramp, the descending inputs are severed (decentralized). Under this condition, the frequency of the pyloric rhythm is significantly reduced and on occasion, the triphasic rhythm is lost. Network frequency increases from ~0.5 hz to ~1.5 hz from 11°C to 31°C, respectively. In the third temperature ramp, the preparation (still decentralized) is superfused with saline containing a modulatory substance, either 10-6 M proctolin or 10-5 M oxotremorine, a muscarinic cholinergic agonist. Both open the same modulatory inward conductance, IMI , and have differential densities of receptors depending on cell types. The frequency increase in the oxotremorine condition closely mimics the control condition, averaging ~1hz to ~4hz from 11°C to 31°C, respectively. Conversely, the frequency increase in the proctolin condition more closely mimics the decentralized condition, averaging ~0.5hz to ~1.75hz from 11°C to 31°C, respectively. Interestingly, we show that phase relationships are maintained in the network across the experimental range of temperatures and the two modulatory conditions. Although the neuromodulatory substances differentially effect the degree to which network frequency increases with temperature, in both cases, phase relationship are remarkably similar to the control (front end-on) condition.

Title: Sacral muscarinic-acetylcholine receptors mediate the cholinergic modulation of locomotor-related motor output produced by sacrocaudal afferent stimulation in the neonatal rat spinal cord

Authors: L. ANGLISTER, E. FINKEL, A. ETLIN, M. CHERNIAK, Y. MOR, *A. LEV-TOV; Dept. Med. Neurobiol., IMRIC, Hebrew Univ. Sch. of Med., Jerusalem, Israel

Abstract: Synaptic excitation by sacrocaudal-afferent (SCA) input of sacral relay neurons projecting rostrally through the ventral white-matter funiculi (VF-neurons) is a potent activator of the hindlimb central pattern generators (CPGs) in the isolated rodent spinal cord. Wavelet analysis of the motor output produced in the lumbar spinal segments by SCA-stimulation following sacral application of the acetylcholinesterase blocker edrophonium (EDR) revealed ~10% decrease in the frequency (N-frequency) of the rhythm and >40% increase in its coherent cross power (N-power). The effects of EDR were reversed by sacral application of the muscarinic antagonist atropine or the M2-type receptor antagonist, methoctramine. Immunostaining of the sacral cord revealed that the majority of the VF- neurons express M2- and that some of them express M3-muscarinic acetylcholine-receptors. The sacral VF-neurons also exhibited acetylcholinesterase activity, ability to synthesize acetylcholine, and/or innervation by cholinergic synaptic inputs. Calcium imaging of sacral VF-neurons revealed modification of their activity in the presence of sacral-EDR during SCA-stimulation. We suggest that variations in the sacral level of acetylcholine modulate the SCA-induced locomotor rhythm via muscarinic receptor-dependent mechanisms, that the decreased N-frequency in the presence of sacral-EDR is accounted for by the reduced drive provided by sub-population of VF-neurons to the lumbar CPGs, and that the increased N-power reflects an enhanced activity of sub-population of VF-neurons that project directly and indirectly to lumbar motoneurons. The possible mechanism and implications of the involvement of sacral cholinergic-system in modulation of the locomotor-related motor output in the absence of descending supraspinal control will be discussed.

Title: Circuit state-dependent responses to sensory feedback and hormonal modulation

Authors: *J. C. RODRIGUEZ, M. P. NUSBAUM;
Dept. of Neurosci., Perelman Sch. of Med, Univ. of Pennsylvania, Philadelphia, PA

Abstract: We are addressing the hypothesis that distinct circuit states producing the same output pattern respond differently to the same input. We are testing this hypothesis using the crab (*Cancer borealis*) stomatogastric nervous system, where bath-applying CabPK peptide ($\geq 10^{-7}$ M) and stimulating the projection neuron MCN1 elicit the same gastric mill (chewing) motor pattern despite using different rhythm-generating mechanisms (Saideman et al, 2009 J Neurosci; Rodriguez et al, in prep). MCN1 does not contain CabPK and is silent during the CabPK-rhythm. The MCN1-rhythm response to sensory feedback and circulating hormones is known (DeLong & Nusbaum, 2010 J Neurosci). For example, the GPR sensory neuron relays muscle stretch information to the MCN1-gastric mill circuit, slowing the chewing rhythm by prolonging the retractor phase, while the hormone CCAP slows this rhythm by prolonging the protractor phase. We aim to determine the CabPK-chewing rhythm response to these same inputs, including the underlying mechanisms.
Here we show that the CabPK (10^{-6} M)-gastric mill rhythm exhibits the same response to GPR stimulation as the MCN1-rhythm, but is differentially sensitive to CCAP application. Specifically, GPR stimulation selectively prolonged the CabPK-retractor phase (Retraction: control, 9.9 ± 1.0 s; GPR, 24.6 ± 2.7 s, n=7, $p<0.05$; Protraction: n=7, p=0.1). This conserved GPR action, however, was mechanistically distinct. GPR alters the MCN1-rhythm by inhibiting the MCN1 axon terminals (DeLong et al, 2009 J Neurophysiol). In contrast, GPR appears to alter the CabPK-rhythm by inhibiting the rhythm generator neuron LG. For example, GPR stimulation during the LG burst (protractor phase) prematurely ends this burst prior to the return of activity in the retractor neurons that inhibit it (n=3), and focally applying the GPR cotransmitter (5HT) that inhibits LG also prolongs retraction (n=2). Thus, GPR uses distinct mechanisms to produce an invariant gastric mill rhythm response. With respect to CCAP modulation, whereas CCAP ($\leq 10^{-8}$ M) slows the MCN1-rhythm by prolonging protraction, the CabPK-rhythm is insensitive to its presence (Protraction: n=7, p=0.66; Retraction: n=7, p=0.11). Further, higher CCAP levels (10^{-6} M) increase the CabPK-rhythm speed by reducing retraction duration (Retraction: control, 11.4 ± 0.97 s; CabPK, 8.1 ± 0.76 s; n=4, $p<0.05$; Protraction: n=4, p=0.1), opposite to the CCAP action on the MCN1-rhythm. These results demonstrate that different network states that produce the same steady-state output can be differentially sensitive to a shared input, while maintaining responsiveness to other ones, albeit via distinct synaptic mechanisms.

Title: Dopaminergic contribution to locomotion in the neonatal and adult mouse

Authors: *S. A. SHARPLES[1], J. HUMPHREYS[2], S. A. DHOOPAR[2], N. DELALOYE[2], A. KRAJACIC[2], S. NAKANISHI[2], P. J. WHELAN[2];
[1]Neurosci., [2]Univ. of Calgary, Calgary, AB, Canada

Abstract: Central pattern generators (CPGs) are networks of neurons that are capable of generating rhythmic outputs in the absence of phasic input. CPGs located within the spinal cord are responsible for producing the rhythmic patterns that produce locomotion and are modulated by descending monoaminergic centers from the brainstem. In particular, our lab has established the ability of dopamine (DA) to modulate the locomotor CPG in the neonatal mouse (P0-3) by reducing the frequency and increasing the regularity of the locomotor rhythm. What is still unclear are the mechanisms that mediate this effect. We first tested the dose of DA sufficient to elicit a reduction in locomotor frequency and increase in power and found that doses as low as 10μM were able to modulate the rhythm. We hypothesized that the reduction in frequency of the rhythm in the neonate is mediated by D2-like receptors. In contrast to our hypothesis, administration of the D2 receptor antagonist, L741,626 (6-12μM), did not affect the DA-induced (35μM) modulation of locomotor rhythm, however, sulpiride (20μM), a more general D2/D3 antagonist offset DA effects, increasing locomotor frequency and decreasing power. We suggest that lower concentrations of DA compared to those traditionally used (50μM) are sufficient to evoke regular and long-lasting bouts of rhythmicity. DA appears to be reducing frequency by acting mainly on D3 receptors. In addition, we demonstrate the ability of DA to increase the frequency of locomotor activity in the adult decerebrate mouse preparation. This points to the possibility of a change in DA receptor expression in the spinal cord over development, however further experiments will be required to clarify these differential effects.

Title: Opposing effects of serotonin at different sites within the same neuron

Authors: J. BACQUE-CAZENAVE[1], F. A. ISSA[2], D. CATTAERT[3], *D. H. EDWARDS[2]; [1]Biol., Univ. of Bordeaux 1, Bordeaux, France; [2]Neurosci. Inst., Georgia State Univ., Atlanta, GA; [3]Ctr. de Neurosciences Integratives et Cognitives, Univ. of Bordeaux 1 and Bordeaux 2, Bordeaux, France

Abstract: The different modulatory effects of serotonin are often apparent in different neurons, but they can also appear in a single neuron when different parts of the cell are exposed to the modulator. We have observed this in leg depressor (Dep) motor neurons (MNs) of crayfish, where serotonin focally applied to the cell's dendritic arbor had excitatory effects, whereas the cell was inhibited when serotonin was applied to the cell's initial axon segment at the nerve root. Both inhibitory and excitatory serotonergic effects persisted in low calcium saline when polysynaptic reflexes were blocked, suggesting that serotonergic effects are direct. Moreover, numerous close appositions between 5-HT immunoreactive processes and a labeled Dep MN (injected with dextran rhodamine) were found in the region of the MN's initial segment, whereas almost no close apposition sites were found in the Dep MN dendritic arbor. We suggest that the 5-HT controls the level of excitability of postural network MNs by two mechanisms acting at two different sites: inhibitory responses (consistent with an action involving the opening of K+ channels) occur in the initial segment region and may involve classical synaptic transmission, while depolarizing responses (consistent with an action involving closing of K+ channels) occur on MN branches via apparently paracrine effects. Finally, we found that intracellular stimulation of an identified serotonergic interneuron in the first abdominal ganglion produced either excitatory or inhibitory effects on Dep motorneurons in different preparations. These A1 5-HT neurons project into the thoracic ganglion and have axonal arbors in both the central dendritic region of the Dep motor neurons and the initial axon segment in the motor nerve root.

Title: The Huber-Braun model as a candidate for modeling central pattern generators

Authors: *Q. SKILLING[1], E. ROSA, JR.[2], W. STEIN[3];
[1]Illinois State Univ., Moline, IL; [2]Physics, Illinois State Univ., Normal, IL; [3]Sch. of Biol. Sci., Illinos State Univ., Illinois State University, IL

Abstract: Neuronal oscillators such as central pattern generators (CPGs) are ubiquitous throughout the nervous system and often drive vital behaviors such as breathing, swallowing, and chewing. While many modulatory influences have been shown to affect CPG activity, motor patterns must also be robust against perturbations and function over a broad range of frequencies and modulatory conditions.

We are studying pattern generation and the stability of oscillatory activity using computer modeling of the pyloric (filtering of food) and gastric mill (chewing) CPG circuits in the crustacean stomatogastric nervous system. The type of model used for CPG circuits varies greatly, but in general, simplified integrate-and-fire neurons ignore many of the dynamics of the biological neurons, while detailed modeling often requires extensive knowledge about intrinsic neuronal properties and represent only a snapshot of a particular set of neuronal responses. They can often only be studied numerically. Yet, to characterize the dynamics of the system, analytically tractable models are preferable.

The fast pyloric rhythm is mainly driven by subthreshold oscillatory ionic currents and graded synaptic release, and can be challenged with temperature perturbations to achieve a frequency range of 0.5 - 3 Hz before it crashes. A two-dimensional nonspiking Morris-Lecar model is sufficient to explain network stability in this frequency range [Rinberg, Taylor, Marder, PLOS Comput Biol 2013]. The slow gastric mill rhythm (GMR) operates in a different frequency domain (0.2 - 0.05 Hz), but also includes neurons that support fast pyloric-timed influences. It is mainly network driven, requires spiking and intrinsic oscillatory properties, and can be entrained to different frequencies by synaptic input. We are testing the four-dimensional Huber-Braun (HB) model, which was developed to account for temperature dependent behaviors, as a candidate for capturing the rich dynamics of this CPG circuit. The HB model uses biophysically realistic membrane currents that bring about subthreshold oscillations as well as fast spiking and create a rich repertoire of spike and burst dynamics. Here, we are testing the oscillatory properties of the HB model by determining resonance and spike entrainment properties, as well as changes in firing regime.

Our preliminary data shows that the burst and spike activity of the HB model can be entrained in a frequency range that roughly corresponds to that of the GMR, indicating that the model could

operate in a CPG with these frequencies. Currently, we are determining the resonance properties of the model and its capabilities for accurately representing a CPG circuit.

Title: Long term effects of Fentanyl on postnatal breathing patterns

Authors: *L. C. MCKAY, A. KENNEDY;
GLASGOW UNIVERSITY, GLASGOW, United Kingdom

Abstract: The mammalian respiratory system is immature at birth. In mice, this immaturity is characterized by a fragile and highly variable breathing pattern during postnatal days 1-3 (P1-3). Around P4, the respiratory
system undergoes a step in maturity, after which breathing is less variable and has a higher frequency. The neural mechanisms underlying this maturity step are unknown. The preBÖtzinger Complex (preBÖtC) and Retrotrapezoid nucleus/parafacial respiratory group play a critical role in generating respiratory rhythm but little is known of their interaction during development and early postnatal life when the respiratory system is fragile. Fentanyl, a μ-opioid receptor agonist was used to pharmacologically manipulate the opiate sensitive preBÖtC during early postnatal life and to investigate the long term effects on breathing of being exposed to opiates during this critical period of postnatal maturation. Neonatal mice were exposed to fentanyl (0.08mg/kg i.p daily), or saline as a control, from P1-5 (n=16) or P9-13 (n=16).
Mice were continuously monitored post injection and breathing recorded by closed plethysmography at regular intervals from 5 minutes to 2 hours post injection. Fentanyl had a modest effect on breathing at all postnatal days by increasing variability, decreasing frequency (250±20 *vs* 150±30 breaths per minute) and increasing the number of apneas (2±1 vs 5±2 per minute), compared to saline-exposed mice. At 6 weeks of age, all saline and fentanyl exposed mice were exposed to a further dose of fentanyl (0.04 - 1.0mg/kg ip) and monitored as above. Respiratory frequency was significantly decreased (190±10 *vs*120±15 bpm, $p<0.05$) in all mice

previously exposed to saline as neonates (P1-P5 and P9-13); however, in mice previously exposed to fentanyl as neonates (P1-P5 and P9-13), further fentanyl exposure in adulthood had no effect on respiratory frequency (180±8 *vs* 170±10 bpm).
Tidal volume increased slightly in all mice post fentanyl regardless of whether they had previously been exposed to fentanyl or saline. These data suggest that the respiratory system in younger animals is less susceptible to fentanyl compared to adults and pre exposure to fentanyl during early postnatal maturation results in a long term desensitization to further fentanyl insults.

Title: Do sympathetic preganglionic neurons modulate locomotion by intraspinal activity-dependent release of nitric oxide?

Authors: *P. LOSEY, S. HOCHMAN;
Physiol., Emory Univ. Sch. of Med., Atlanta, GA

Abstract: Though known to receive common input from several descending pathways involved in behavioral drives, intraspinal interactions between activity in sympathetic preganglionic neurons (SPNs) and motor neurons are not thought to occur. Interestingly, only SPNs express nitric oxide synthase (e.g. Dun et al 1992), and intraspinal nitric oxide (NO) complexly modulates vertebrate motor output including locomotor activity (e.g. Kyriakatos et al 2009). Here we sought to determine whether SPN neuronal activity derived NO can contribute to the modulation of locomotor like activity (LLA) in the isolated mammalian spinal cord.
We undertook studies in the isolated neonatal rat spinal cord, some with intact sympathetic chain to independently record SPN activity. We stimulated caudal lumbar or sacral dorsal roots to evoke LLA recorded predominantly in L1 and L2 ventral roots (VRs) known to also contain SPN efferent axons. We observed that during afferent stimulation-induced LLA, SPNs are also recruited to spike. When sympathetic bursting activity continued after stimulation epochs, these bursts were synchronous with those seen in VRs bilaterally. This indicates that some of the rhythmic activity observed in L1-2 VRs reflects firing in SPNs.
We wondered whether spiking activity in SPNs could modulate ongoing LLA via a nitrergic

mechanism since Wu and Dun (1995) showed that high frequency activity in SPNs was sufficient to induce facilitation of excitatory transmission via Ca2+ dependent release of NO. Repetitive trains of stimuli were delivered to VRs at intervening periods between bouts of stimulation evoked LLA (3x10 epochs at 50 Hz) or concomitant with DR stimulation induced LLA (4x5 pulses at 30-50 Hz; n=4). In all cases the amplitude of motor output was facilitated on the contralateral side while ipsilateral motor activity was depressed. Both facilitatory and depressant actions appeared long-lasting (> 1 hour). To associate these actions with NO we tested the effects of the NO donor DEANO (50 μM) on LLA. In the presence of DEANO, motor burst amplitude changes were complex and included amplitude increases and decreases with amplitude increases more consistently observed following washout across all VRs (n=4). These preliminary results suggest spiking activity in SPNs may utilize intraspinal nitrergic volume transmission to directly modulate motor function.

Title: Modulation of the lobster cardiac neuromuscular system: Roles and mechanisms of two related neuropeptides

Authors: *P. S. DICKINSON, A. M. CALKINS, J. S. STEVENS;
Bowdoin Coll, BRUNSWICK, ME

Abstract: Neural networks controlling rhythmic motor behaviors can be modulated on a number of different levels, including the pattern generator itself and the response of the muscle to a given pattern of motor output. One family of modulatory neuropeptides in the American lobster, *Homarus americanus*, is the FMRFamide-related peptides, at least 18 of which have been identified. We examined the role of two peptides from this family, GYSDRNFLRFamide (GYS) and SGRNFLRFamide (SGRN), in modulating the neurogenic lobster heartbeat, which is

controlled by the cardiac ganglion (CG) located within the lumen of the heart. When perfused through an isolated whole heart at concentrations ranging from 10^{-11} to 10^{-8} M, both GYS and SGRN elicited large and similar increases in contraction amplitude. Amplitude increased by over 100% at the higher concentrations, with smaller increases at lower peptide concentrations. In contrast to the consistent effects of GYS and SGRN on contraction amplitude across concentrations, the effects of the two peptides on contraction frequency were similar at low concentrations, but differed at higher concentrations. Thus, at low concentrations, both peptides elicited increases in frequency, but at high concentrations (e.g., 10^{-8} M), SGRN continued to significantly increase contraction frequency, while GYS significantly decreased frequency. Moreover, when we recorded CG motor output in semi-intact hearts, GYS significantly increased both contraction duration and motor neuron burst duration at higher peptide concentrations, while SGRN did not elicit significant changes in either of these parameters. To determine the mechanisms through which these two peptides exert their effects, we examined the effects of the peptides on the periphery (neuromuscular junction and cardiac muscle) as well as their effects on the motor neuronal output in the isolated CG. We thus removed the CG and stimulated the motor nerve with constant bursts of stimuli, designed to mimic the CG output. When neural input was held constant, both GYS and SGRN elicited similar increases in contraction amplitude, indicating that the two peptides similarly modulate the muscle and/or the neuromuscular junction. When applied to the isolated CG, both peptides significantly increased burst duration and the number of action potentials per burst. However, GYS did not alter cycle frequency, whereas SGRN significantly decreased burst frequency, suggesting that the differences in responses of the whole heart to the peptides at higher concentrations are due largely to the differential modulatory effects of GYS and SGRN on the CG.

Title: Functional implications of distinct transmitter phenotypes in higher-order interneurons

Authors: J.-S. WU[1], M. SINISCALCHI[1], N. WANG[2], J.-W. GU[2], F. S. VILM[1], E. C. CROPPER[1], K. R. WEISS[1], *J. JING[1,2];
[1]Neurosci., Mt Sinai Med. Ctr., NEW YORK, NY; [2]Sch. of Life Sci., Nanjing University, China

Abstract: The specific complement of neurotransmitters, especially, peptide modulators, that are expressed in a particular interneuron may help determine its functional identify, but the underlying mechanisms remain poorly understood. We examine this issue in three electrically-coupled higher-order interneurons, cerebral-buccal interneuron-2 (CBI-2), CBI-11 and CBI-3, that activate/modulate feeding motor programs with biphasic protraction-retraction sequences in the mollusc *Aplysia californica*. Although electrical coupling between the interneurons suggests that they are functionally related, only CBI-2 and CBI-11 express the peptide FCAP that promotes motor program generation. This is consistent with the fact that CBI-2 and CBI-11, but not CBI-3, can drive motor programs. Previous work showed that CBI-2 also contains peptide CP2 that enhances motor program generation. We show, however, that CBI-11 is not immunoreactive to CP2. Consistent with this, CBI-11 requires a higher firing frequency than CBI-2 to reliably drive motor programs. In addition, the latency to protraction initiation is longer when stimulating CBI-11 than CBI-2. Interestingly, CBI-2 pre-stimulation shortens the latency of programs elicited by CBI-11, which may be accounted for by the actions of CP2 present in CBI-2. On the other hand, we found that CBI-11 also modulates CBI-2-elicited programs, making them more ingestive and extending the protraction duration. These CBI-11 effects can be accounted for, at least partially, by CBI-11's abilities to enhance the activity of the ingestion-promoting interneuron B40 and to inhibit the retraction interneuron B64. Thus, distinct transmitter phenotypes of higher-order interneurons provide one effective means of defining their functional classes.

Title: Distinct regulatory mechanisms of ionic conductances in a central pattern generating network

Authors: *D. SALLOUM, J. GOLOWASCH;
biological sciences, NJIT, Newark, NJ

Abstract: Neurons express variable levels of ionic conductances but the sources of variability are unknown. Short-term regulation of ionic conductances by activity has been shown in the inferior cardiac (IC) neuron (Golowasch et al., 1999) and in cultured neurons (Haedo & Golowasch, 2006) of the pyloric network of the stomatogastric ganglion (STG) in the crab Cancer *borealis.* On the other hand, in pyloric dilator (PD) neurons, several ionic conductances have been shown to be regulated over long-term by neuromodulatory input. Khorkova & Golowasch (2007) showed that removal of neuromodulatory input to the pyloric network induces changes in ionic conductances of PD neurons over several days. This contrasts with the acute activation of a single target current (I_{MI}) by some of these neuromodulators. To maintain these conductances within physiological limits, neurons may possess mechanisms that link the effects of activity and neuromodulation. We hypothesized that there is an interaction between activity-dependence and neuromodulatory control of the ionic conductances in pyloric neurons. We tested the effects of activity in control preparations devoid of neuromodulatory input (decentralized) and in preparations in which neuromodulators were reintroduced exogenously. We predicted that neuromodulators would regulate activity-dependent changes of the K^+ currents in PD neurons. We tested activity-dependence by stimulating PD cells with depolarizing voltage steps at 1Hz in voltage clamp. We observed that PD neurons exhibit time-dependent changes in the high-threshold (I_{HTK}) and transient (I_A) potassium currents, with I_{HTK} conductances decreasing and I_A conductances increasing over time, but that there was no effect of induced activity. Applying a 'cocktail' of four neuromodulators has a significant effect on the K^+ currents in comparison to control conditions, independent of activity: in the case of I_{HTK} the time-dependent decay of the current is significantly larger in magnitude than in control preparations. In the case of I_A neuromodulators significantly inhibit the increase of current conductance seen in control preparations. The leak conductance does not change significantly in response to either of these treatments.
In summary, IC alters its current conductances in an activity dependent manner (Golowasch et al. 1999), while the PD neurons do not. Instead, PD neurons modify their ionic conductances depending on the neuromodulatory input they receive. We conclude that different cell types within the pyloric network in the crab STG have distinct mechanisms of regulating their ionic conductance levels depending on activity and neuromodulatory input.

Title: The effects of neuromodulation on output and synchrony in electrically coupled motor neurons with variable intrinsic conductances in the crab cardiac ganglion

Authors: *B. J. LANE[1], J. L. RANSDELL[2], P. SAMARTH[3], S. S. NAIR[3], D. J. SCHULZ[2];

Abstract: The capability of neurons and networks to generate reliable outputs as well as to maintain appropriate phase is a critical aspect of nervous system organization. In addition, many networks require short term adaptability influenced by neuromodulation. One such network which clearly displays the convergence of these demands is the cardiac ganglion (CG) of the crab *C. borealis*. This small central pattern generator network consists of 4 small pacemaker cells that give excitatory input to 5 bursting large cell motor neurons (LCs) which are responsible for the monophasic contraction of the crab's single-chambered heart. Previous work has shown that individual LCs show substantial variability in their underlying voltage-gated conductance magnitudes, including two potassium currents, I_A and I_{HTK}. These cells are able to maintain consistent output in part by differentially balancing conductance magnitudes, as revealed when pharmacological blockade of I_A or I_{HTK} caused disparate outputs across network LCs. If multiple neurons within the same network achieve synchronized output despite variable underlying conductances, then what are the implications for neuromodulation, known to target subsets of ionic conductances, for neuron output and synchrony in this model system? Here we identify serotonin as a neuromodulator with direct effects on LC motor neurons, and further show that serotonin increases I_A magnitude but has no significant effect on I_{HTK} magnitude. The activation voltages of both I_A and I_{HTK} remain unaffected. We then test the effects of these changes in I_A on changes in LC neuron output both at the level of individual isolated neurons as well as within the intact network. By distinguishing the effects of neuromodulation on individual cells with variable underlying conductances from effects on the entire network output, we can begin to determine whether modulation itself is capable of resulting in conserved output, or whether higher level network properties (such as electrical coupling) constrain variability in output to ensure robust activity in this network which is critical for survival.

Abstract: The crustacean cardiac ganglion (CG) network in Cancer borealis consists of 9 cells, 5 'large cell' motor neurons (LCs) and 4 small endogenous pacemaker cells (SCs). The CG network coordinates the rhythmic bursting of the heart muscle contractions to control the circulation of blood. We developed a biophysical model for the LCs using data from currents measured in our Lab. Our data suggests that although the five LCs burst synchronously, their underlying ionic conductances vary considerably, even within the same animal. We created a nominal model using the biological conductance data and performed statistical rejection sampling to determine parameter sets that preserve LC output characteristics. To be included in the model cell data set, a given LC model had to have passive properties within biological bounds and then have appropriate output responses to multiple current injection protocols that are consistent with experimental traces.Parameter sets obtained in this fashion were mined to predict relationships that might exist between currents in native LCs. We then use multiple LC models with variable underlying conductances to study the role of electrical coupling in synchronizing LC responses in multiple model cardiac ganglion networks.

Title: Cell-type specific neuropeptide receptor transcript levels are correlated with physiological response threshold

Authors: *V. J. GARCIA[1], S. TEMPORAL[2], D. J. SCHULZ[3], D. BUCHER[4];
[1]Univ. of Florida, Whitney Lab. For Marine Biosci., Saint Augustine, FL; [2]Faculté de Médecine, Aix Marseille Univ., Marseille, France; [3]Div. of Biol. Sci., Univ. of Missouri - Columbia, Columbia, MO; [4]Biol. Sci., New Jersey Inst. of Technol. and Rutgers Univ., Newark, NJ

Abstract: The crustacean stomatogastric ganglion (STG) is modulated by a multitude of substances, mostly neuropeptides. Apart from some effects on synapses, most peptides converge onto the same voltage-gated current (IMI). Peptide-specific effects on circuit activity are thought to arise mainly from modulation of different subsets of neurons by different peptides. However, in the absence of identified crustacean neuropeptide receptors, the role quantitative differences in receptor expression across cell types could play in circuit modulation is unclear. Furthermore, as second messenger signaling and downstream target activation could differ quantitatively, it is unknown how receptor expression levels correlate with the magnitude or sensitivity of current responses. Here we describe the complete coding sequence of the putative crustacean cardioactive peptide (CCAP) receptor in the crab Cancer borealis. We show neuron-specific differences in mRNA expression level correlated with differences in threshold of receptor-mediated IMI activation in STG neurons.
The CbCCAPr is a G protein-coupled receptor (GPCR), homologous to various insect cardio-acceleratory peptide receptors, as well as mammalian vasopressin and oxytocin receptors within the rhodopsin-like GPCR superfamily. PCR employing gene-specific primers reveals the presence of CbCCAPr transcripts in a variety of nervous tissues, including the STG. We show that CbCCAPr transcripts are present in only a subset of neuron types in the STG, and, with one exception, only in neuron types that show IMI activation in response to CCAP application. The exception is one neuron that does not show IMI activation but displays a CCAP mediated increase in responses to synaptic input.
Quantitative RT-PCR reveals variability in transcripts across 3 different CbCCAPr-expressing neurons, but only moderate variability within each cell type across individuals. The IC neuron shows moderate expression, while the LP and LG neurons show 4-5 times higher expression. Measurements of IMI responses show inconsistent peak current values. However, expression levels correlate well with concentration dependence. LP and LG show an activation threshold and EC50 about 1 order of magnitude lower than IC. Occlusion experiments with other peptides reveal that in LP and LG, micromolar CCAP is sufficient to fully activate IMI. In contrast, CCAP does not occlude IMI responses to other peptides in IC. These findings suggest that there can be large quantitative differences in neuropeptide responses in different cell types, with potentially important consequences for circuit modulation.

Title: Removal of neuromodulation increases receptor transcript abundance and subsequent response to a peptide neuromodulator in lp neurons of the crab stomatogastric ganglion

Authors: *K. LETT[1], V. J. GARCIA[2], D. BUCHER[2], D. J. SCHULZ[1];
[1]Biol. Sci., Univ. of Missouri-Columbia, Columbia, MO; [2]Whitney Lab. and Neurosci. Dept., Univ. of Florida- St. Augustine, St. Augustine, FL

Abstract: Neuromodulation is essential for regulating and initiating the activity and the resulting appropriate physiological output of central pattern generating (CPG) networks. Elimination of a neuromodulatory source can result in a change in sensitivity to restored modulatory input. Crustacean Cardioactive Peptide (*Cb*CCAP) has been shown to be released solely hormonally and is able to alter the pyloric network output of *C. borealis* stomatogastric ganglion (STG) by increasing the activity of the lateral pyloric neuron (LP). We have shown previously that the pyloric network exhibits differential sensitivity to restored modulation when deafferented. Similar findings were observed in other models where sensitivity to neuromodulatory input is increased after injury. We hypothesize that removing hormonal and descending modulatory input to the LP neuron will alter its excitability and sensitivity to CCAP. We further hypothesize that these changes may be due to modification of *Cb*CCAP receptor expression which in turn affects inward currents that contribute to excitability in LP. We investigated this by quantifying neuromodulator receptor mRNA in individual LP neurons using quantitative RT-PCR and measuring neuronal excitability in the presence of different concentrations of *Cb*CCAP using current clamp. Preparations were subdivided into 3 groups to address the hypothesis; control, decentralized for 24 hours in culture, and decentralized and CCAP incubated for 24 hours. Overall we observed a concomitant increase in *Cb*CCAPr transcript and CCAP-induced excitability in the LP neuron when neuromodulatory input was removed from the pyloric network. Incubation of the ganglion with the peptide for 24 hours prevented this increase in the *Cb*CCAPr transcript and the change in excitability in LP despite the lack of descending input from the commissural ganglia. Our findings suggest that there is a compensatory change in the

excitability of individual neurons of a deafferented motor network which is likely attributed to modification of neuromodulator receptor mRNA expression and intrinsic excitability.

Title: The integrities of spontaneous and hunting locomotor repertoires of zebrafish larvae are dissociably dependent on the conserved dopaminergic diencephalospinal tract

Authors: *A. M. LAMBERT, M. A. MASINO;
Neurosci., Univ. of Minnesota- Twin Cities, Minneapolis, MN

Abstract: Zebrafish larvae employ a hunting repertoire of short, slow, and fine orienting and advancing locomotor maneuvers during prey-tracking of paramecia. Most of this hunting repertoire resembles their mature spontaneous locomotor repertoire at 4-7 days-old, and we have shown that the ontogeny of the latter conspicuously correlates with the ontogeny of prey capture performance. Interestingly, we have found that chemogenetic ablation of the dopaminergic diencephalospinal tract (DDT) or antagonism of D4 receptors, through which the DDT putatively signals, relegates 5-7 day-old larvae to an immature spontaneous locomotor repertoire of long, fast, erratic swimming episodes and compromises prey capture performance. This suggests that the integrity of the spontaneous locomotor repertoire is predictive of prey capture performance and that the DDT plays a role in both phenomena. Here, we investigated the cause of the compromised prey capture performance of DDT-perturbed larvae by assessing paramecia-induced changes in locomotor activity and, moreover, the kinematics of prey encounters and the integrity of the hunting repertoire.
Addition of paramecia to the arena reversibly increased the total distance travelled by both controls and DDT-perturbed larvae, suggesting that both groups were similarly engaged with paramecia. During prey encounters, DDT-perturbed larvae detected and pursued paramecia, similar to controls, by initiating and maintaining ocular convergence while attempting hunting locomotor elements, including hunting-specific j-turns. Controls employed short, slow and orienting locomotor elements that effectively reduced their distance and angular heading to paramecia before attempting prey capture. Surprisingly and, unlike their spontaneous activity,

DDT-perturbed larvae did not exhibit any long, fast, erratic swimming while engaged in prey encounters. In contrast, they attempted the finely controlled locomotor elements observed in controls, but were unsuccessful in reducing their distance or angular heading to paramecia due to executing bradykinesia-like swims and turns that often resulted in negligible displacement and shallow orienting.
Collectively, these results suggest that DDT-perturbed larvae have functional vision and visuomotor initiation, respectively, to detect paramecia and attempt hunting locomotor elements toward them. However, while ocular convergence induces a predatory mode of behavior in DDT-perturbed larvae that surprisingly and powerfully overrides their spontaneous bias for erratic swimming, it exploits their lack of fine motor control which results in compromised prey capture performance.

Title: Substance P depolarizes lamprey spinal cord neurons by inhibiting background K+ channels

Authors: *C. T. PEREZ, R. H. HILL, S. GRILLNER;
Karolinska Inst., Stockholm, Sweden

Abstract: Substance P accelerates the burst frequency of fictive locomotion, which is known to be endogenously released in the spinal cord of the adult lamprey. This increase in burst frequency is achieved by multiple effects on interneurons and motoneurons, of which attenuation of calcium currents, potentiation of NMDA currents and reduction of the reciprocal inhibition have been studied. Membrane depolarization combined with a conductance decrease during substance P application has been reported however, the underlying mechanism has not been resolved. This study focuses on the possible effects of substance P on background K+ channels as the main source for this depolarization. Hyperpolarizing steps induced inward currents during whole-cell voltage clamp that were reduced by substance P. We further test for involvement of a two-pore domain channel being modulated by varying the extracellular pH. Lower pH values reduced the outward currents and increased input resistance. Anandamide a selective blocker of

the two-pore, TASK-1 subtype K+ channel was also tested and it reduced the current during voltage steps and prevented substance P effect on membrane properties. Inhibition of the background K+ channels induces depolarization, which is likely to contribute to the frequency increase observed with substance P during fictive locomotion.

Title: Longitudinal analysis of the cholinergic neuromodulatory system in the spinal lumbar enlargement of SOD1 mutant mice

Authors: L. MILAN, G. COURTAND, L. CARDOIT, F. MASMEJEAN, M. GARRET, *S. S. BERTRAND;
INCIA CNRS UMR5287, Bordeaux, France

Abstract: Spinal cholinergic interneurons connect alpha-motoneurons through large “en passant” synapses associated with subsynaptic cisterns in the postsynaptic membrane, the C-boutons. These synapses have been demonstrated to be associated with the postsynaptic muscarinic type 2 (M2) receptors. Recent studies have reported divergent results about morphological reorganization of the C-terminals in a mouse model of amyotrophic lateral sclerosis (ALS), a neurodegenerative disease characterized by the progressive loss of cortical and spinal motor neurons. To further extent these studies, we performed a longitudinal analysis of the number and morphological parameters of C-boutons at 6 different developmental stages (1 day postnatal: P1, P10, P21, P40, P75, P100) on lumbar motoneurones in SOD1 mice, an animal model of ALS, and age-matched control littermates. Interestingly, our result show that in early developpemental stages (P10-P21), the number of choline acetyltransferase positive (ChAT+) C-boutons was decreased by 50% in SOD1 mice compared to control animals. This discrepancy vanishes at P75 and is reversed at P100 with a higher mean number of C-boutons per motoneurons in SOD1 mice. The area of C-boutons as well as their distribution across the soma and proximal dendrites of motoneurones also exhibit shrinking differences between SOD1 and control mice. This analysis was completed by a western blot quantification of M2 receptors in ventral lumbar spinal cord and an immunohistochemical study of the expression of M2 receptors

into motoneuron membrane. A significant positive correlation was computed between M2 receptor expression and the presence of a C-terminal regardless of the animal age and genotype. The correlation powers were however significantly different between SOD1 and control animals. To investigate the physiological impact of C-boutons number and size reduction, we performed patch-clamp recordings from motoneurons in lumbar spinal cord slices. The sensitivity of SOD1 and control motoneurons to the wide range muscarinic agonist, oxotremorine, was compared in SOD1 and control P10 mice. The efficacy of commissural electrical stimulations in inducing sustained muscarinic responses in motoneurones was also tested.
Finally, a stereological method was used to count the cholinergic interneurones that originate the C-boutons in both SOD1 and age-matched control mice.
Altogether these data show that as early as the second postnatal week, the cholinergic synapses and their associated receptors are permanently reconfigured in SOD1 mutant mice to maintain an appropriate level of cholinergic control onto motoneurons.

Title: Modulation of axonal spike initiation in a sensory neuron by descending modulatory projection neurons

Authors: *C. STAEDELE[1,2], W. STEIN[1];
[1]Sch. of Biol. Sci., Illinois State Univ., Normal, IL; [2]Inst. of Neurobio., Ulm Univ., Ulm, Germany

Abstract: Sensory inputs play a pivotal role for the execution of behavior and decision making by selecting appropriate motor output patterns. Yet, sensory information is state- and history-

dependent and can be modulated, resulting in sensory ambiguity such that identical stimuli elicit distinct sensory outputs. Generally, it is assumed that either sensory spike activity or the sensory influence on postsynaptic targets is modulated. Little is known about the modulation of spike activity in the sensory axon, despite the fact that spike propagation in many axons is affected by neuromodulators. Even less is known about the origin of axonal modulation and its functional relevance.

We are studying the modulation of the anterior gastric receptor (AGR, Smarandache & Stein, J Exp Biol, 2007), a muscle tendon organ in the stomatogastric nervous system of the crab, *Cancer borealis*. AGR's soma is located in the stomatogastric ganglion (STG) and protrudes one axon to the periphery and a second, central axon to its postsynaptic targets, modulatory projection neurons in the commissural ganglia. While each axon possesses a spike-initiation zone, the one in the central axon dominates AGR's spontaneous firing. This tonic spike activity (2-5 Hz) is functionally relevant and even small frequency changes cause prominent changes in the motor response (Daur et al, Europ J Neurosci , 2009).

Here we show for the first time that the axonal spike initiation zone is influenced by the actions of descending modulatory projection neurons. We found that the instantaneous firing frequency of AGR changed rhythmically (oscillations) when a gastric mill rhythm (GMR, the chewing motor pattern generated by neurons in the STG) is present. AGR firing frequency changed by about 35% during spontaneously occurring and sensory-induced motor patterns (N=33). Oscillations were timed by the GMR, with higher firing frequencies during the activity phases of the LG and GM motor neurons.

Using intracellular recordings from descending projection neurons, we found that the presence of the gastric mill rhythm was not sufficient to elicit the oscillations, but that they rather depended on the oscillatory activity of the projection neurons. In particular, the projection neurons MCN5 and CPN2 modulated AGR firing. AGR's central spike initiation zone is located close to the anterior neuropil of the STG, and correspondingly we found that AGR possesses 1 to 3 neurites in this region (average 1.85± 0.89, N=13).

Our results thus indicate that AGR's axonal spike initiation zone is synaptically influenced by the modulatory projection neurons. Currently, we are testing whether this influence is caused by chemical or electrical coupling.

Title: Modulation of the voltage dependence of an electrical coupling by a hyperpolarization-activated inward current

Authors: *L. Y. BRAUN[1,2], A. M. YARGER[2], W. STEIN[2];
[1]Inst. of Neurobio., Ulm Univ., Ulm, Germany; [2]Sch. of Biol. Sci., Illinois State Univ., Normal, IL

Abstract: Electrical synapses play an important role in information propagation and processing in the nervous system by facilitating synchronization between coupled neurons. However, electrical coupling can be too weak to cause significant synchronization and little is known about its function in this case, but current flow across the gap can be modulated either directly, by affecting the gating of the gap junction, or indirectly via voltage-dependent membrane properties. (Curti & Pereda, J Neurosci 24, 2004; Herve & Derangeon, Cell Tissue Res 352, 2013). While the mechanisms of direct modulation are well understood, the interactions between electrical coupling and local voltage-gated ion channels and the effects of the modulation of the electrical coupling on the coupled neurons are often unclear.

We study electrical synapses in the stomatogastric nervous system of the crab, Cancer borealis, a well-characterized motor system that controls the rhythmic movements of the foregut. In this system, the modulatory projection neuron 1 (MCN1) controls the gastric mill (chewing of food) central pattern generator via chemical and electrical synapses. The electrical synapse between MCN1 and the LG motor neuron contributes to the overall excitation of LG, but does not synchronize firing. We found that the electrical postsynaptic potentials (ePSPs) in LG were affected by the hyperpolarization-activated inward current (Ih): Blocking Ih increased ePSP amplitude. Computer simulations indicated that introducing Ih in either LG or MCN1 is sufficient to elicit this increase, but also resulted in a voltage-dependence such that ePSP amplitude increased with LG depolarization and decreased with LG hyperpolarization. Changes in ePSP amplitude followed the slow time course of Ih. A voltage dependence had been shown previously in the biological system (Coleman et al., Nature 378, 1995), but its mechanisms are unclear.

We thus characterized the voltage-dependence of the ePSPs, as well as its time course. The slow time course (>500 ms) plus the presence of a concomitant slow change in LG input resistance indicated that Ih may modulate current flow across the electrical synapse. Blocking Ih confirmed this: ePSP amplitudes increased at all LG membrane potentials, but more so at hyperpolarized

values, and the voltage dependence disappeared.
Our results support the idea that Ih, diminishes the electrical coupling between MCN1 and LG and causes the voltage-dependence of the MCN1 PSPs. Since Ih is modulated by several neuromodulators in this system, the voltage-dependence of this electrical synapse and thus its influence on the motor pattern may change depending on the modulatory context.

Title: Mapping location and activity patterns of modulatory projection neurons in the stomatogastric nervous system of the crab Cancer borealis

Authors: *C. J. GOLDSMITH, W. STEIN;
Sch. of Biol. Sci., Illinois State Univ., Normal, IL

Abstract: Different sensory inputs can configure the same central pattern generator (CPG) motor circuit to produce distinct motor patterns. Little is known about the mechanisms enabling this motor pattern selection, but it is clear that control neurons in higher centers of the nervous system are involved in sensory processing and the subsequent motor pattern selection. We are addressing this issue using the well-characterized pyloric (filtering) and gastric mill (chewing of food) CPGs in the stomatogastric ganglion (STG) of the crab Cancer borealis. Several different sensory and modulatory pathways in this system elicit distinct versions of the gastric mill motor pattern that differ in the phasing of the motor neurons as well as in their firing and burst patterns. The gastric mill CPGs in the STG receives input from modulatory projection neurons (PNs) in the paired commissural ganglia (CoGs) and the oesophageal ganglion. PN activity is initiated and modulated by different sensory modalities, but only four out of about twenty CoG PNs have been sufficiently characterized to (1) identify their location, (2) show their influence on the STG motor circuits and (3) determine their activity patterns.

Each CoG has about 500 neurons and a subset of them, including the PNs, receives ascending feedback from the STG CPGs (Blitz & Nusbaum, J Neurosci 32, 2012). As a prerequisite for characterizing PN activity, we are thus mapping somata location of CoG neurons whose activity is timed with the STG motor patterns using a combination of electrophysiological recordings and voltage-sensitive dye (VSD) imaging. The VSD di-4-ANEPPS was bath-applied to the desheathed CoGs and the pyloric and gastric mill motor patterns were recorded simultaneously after stimulation of a mechanosensory pathway (Beenhakker & Nusbaum, J Neurosci 24, 2004). The cell membranes of most, if not all CoG neurons were stained and could be separated within and across focal planes, revealing distinct landmarks such as the large L-cell. More than 50 neurons in one focal plane could be imaged simultaneously. We observed pyloric-timed oscillations in the fluorescence of several neurons with a signal-to-noise ratio high enough to detect membrane potential oscillations in non-averaged recordings. The strength and phasing of the oscillations depended on the region of interest selected, indicating that individual cells can be distinguished by their fluorescence profile.
We next aim to determine if neurons in different focal planes can be imaged with a similar signal-to-noise ratio. We will then combine optical imaging data with retrograde backfill labeling to create a 3D map of CoG neuron location and activity patterns.

Title: Effects of hypocretin antagonist interaction with isoflurane anesthesia on locomotor behavior in mice

Authors: *A. J. CASTANEDA[1], K. BOWYER[2], R. RYDEN[2], K. D'ANNA-HERNANDEZ[2]; [1]Psychology, [2]California State Univ. San Marcos, San Marcos, CA

Abstract: Hypocretin (HCRT), a hypothalamic neuropeptide, is involved in arousal and wakefulness (Sakurai, 2007). HCRT acts in the lateral preoptic area of the hypothalamus; an area that opposes wakefulness by regulating sleep-promoting behavior via inhibitory GABAergic connections (Szymusak & McGinity, 2008). Isoflurane anesthesia, has been shown to enhance the effects of sleep-promoting systems though GABAergic pathways (Szabdi, 2006). Though much research has been done on the effects of HCRT on wakefulness, the interaction effects of HCRT and anesthesia is relatively underrepresented. Early work suggests that an HCRT/anesthesia interaction with mice will alter the ability to regain posture on foot-paws (Kelz

et al., 2007). In this study we examine recovery from a HCRT-receptor 1 antagonist SB-334867 and the interaction effects with isoflurane anesthesia by measuring gross locomotor movement over a 30 minute time period in an open field apparatus. We hypothesized that mice given SB-334867 (30mg/kg) while under isoflurane anesthesia will exhibit significantly less locomotor movement on an open-field
test than saline injected mice while under anesthesia. Forty male mice (n=10 per group in 4 groups) were exposed to isoflurane anesthesia or no anesthesia for 3 min then given ip injections of a vehicle control or SB-334867 (30mg/kg). Animals were immediately placed in a open field apparatus for 30 minutes and locomotion monitored. The data was analyzed at separately at 10, 20 and 30 min. There was no significant effect of anesthesia, SB-334867 (30mg/kg) treatment nor
their interaction on total distance travelled during the first, second or third
10 minutes of the total 30 min test period ($p<0.05$). However, we found that mice who received only the HCRT-1 antagonist with no anesthesia spent significantly more time immobile during the first ten-minutes of testing when compared to mice which received the HCRT antagonist with anesthesia ($p>0.05$). These results suggest that there are no
long term immobility effects of the interaction between anesthesia and the downregulation of HCRT-1 activity. Anesthesia may actually be blocking the stressful effects of the injections themselves and provide beneficial effects for behavioral studies with HCRT. These results have methodological implications for further work.

Title: Effects of dorsal root stimulation on locomotor network output and V2a interneuron activity in isolated mouse spinal cord

Authors: *S. DIETZ[1], N. A. SHEVTSOVA[2], I. A. RYBAK[2], R. M. HARRIS-WARRICK[1]; [1]Neurobio & Behavior, Cornell Univ., ITHACA, NY; [2]Neurobio. and Anat., Drexel Univ. Col. of Med., Philadelphia, PA

Abstract: Sensory feedback is critical for modulating locomotion in response to changes in the environment or body position. Studying the effects of sensory input on the output locomotor activity and the activity of neurons potentially involved in the spinal central pattern generator (CPG) network will allow us to better understand CPG organization. The isolated mouse spinal cord permits simultaneous recordings of the output of the spinal locomotor network and the activity of identified neurons. Sensory afferents were activated by stimulation applied to the flexor-dominated (dL2) or extensor-dominated (dL5) dorsal roots during fictive locomotion evoked by bath application of NMDA and serotonin. Very low concentrations of NMDA (typically 2-3 μM), which evoked weak fictive locomotion, allowed us to obtain a variety of responses to the dorsal root stimulation. Specifically, dL2 stimulation at lower intensities typically modified the locomotor activity only within the ongoing cycle, causing an advance burst onset in the ipsilateral flexor ventral root (iL2), and burst delay in the ipsilateral extensor (iL5) and the contralateral flexor (cL2) ventral roots. The exact effect of stimulation depended on the phase of stimulus application, with maximal effects at the end of the iL2 burst before the onset of the cL2 burst. Higher-intensity dL5 stimulation evoked a multi-cycle acceleration of the motor pattern, retaining correct right-left and flexor-extensor alternation, that was often followed by a prolonged slowing or inhibition of the rhythm. To further investigate the effects of afferent stimulation we extended our previous CPG model (Zhong et al. 2012) by incorporating sensory inputs. The model was able to closely reproduce the experimentally observed effects of dL2 and dL5 stimulations and allowed us to suggest the possible organization of afferent inputs to the spinal CPG. Our earlier studies of V2a interneurons suggested that they participate in the locomotor CPG in several ways, with subsets driving ipsilateral motoneurons and subsets projecting to commissural interneurons involved in regulation of left-right alternating activity. During relatively weak dL5 stimulation applied within the 2nd and 3rd quadrants of the locomotor cycle, V2a interneurons typically received inhibitory synaptic input. During higher intensity dL5 stimulation, some V2a received prolonged inhibition. However, other V2a interneurons received excitatory drive. We propose that the V2a class encompasses subclasses with different responses to sensory input, which correspond to their different roles in the CPG. Supported by NIH grant R01 NS081713.

Title: Characterization of rostral medullary and pontine reticulospinal projections in the late fetal and neonatal mouse

Authors: M. S. SIVERTSEN[1], M.-C. PERREAULT[2], *J. C. GLOVER[1];
[1]Dept Physiol, Univ. Oslo, 0317 Oslo, Norway; [2]Dept of Physiol., Emory Univ., Atlanta, GA

Abstract: Reticulospinal (RS) projections represent one of the principal substrates for regulation of spinal neural networks. To provide more insight into the organization of these projections in the developing mouse, we have conducted a series of retrograde tracing studies at late fetal and early neonatal stages, focusing on reticulospinal neuron populations located in the rostral medulla and the pons. In this regard our region of interest has been rostral to the rostral limit of the raphespinal neuron population, which in developmental terms lies roughly at the boundary between rhombomeres 4 and 5.

Unilateral labeling from spinal cervical segment C1 shows that RS neurons in this region comprise a continuous population spanning the length of the rostral medulla and the pons. The population is also continuous with the main medial population of medullary RS neurons in the caudal medulla, but attains more lateral positions as it extends rostrally. The RS neurons in this region are predominantly ipsilaterally projecting, but a minority population (about 30%) projects contralaterally. Differential retrograde labeling of the two sides at C1 shows that the contralaterally projecting population lies in the more ventral, lateral, and rostral regions of the total population. The ipsilaterally and contralaterally projecting populations appear to be distinct: there is no evidence of individual RS neurons with bilateral projections. Selective labeling of defined portions of the C1 white matter shows that the majority of ispilaterally projecting RS neurons projects in the ventral funiculus and medial part of the ventrolateral funiculus. These reach the cord via the mlf as well as via trajectories lateral to the mlf. Those that project along trajectories lateral to the mlf tend to be located more rostrally. The contralaterally projecting RS neurons, by contrast, project in the lateral part of the ventrolateral funiculus.

Our findings provide a more comprehensive picture of the anatomical organization of mammalian RS projections and in particular highlight a little appreciated contralaterally projecting population of pontine RS neurons.

Title: Electrophysiological and molecular characterisation of long, descending propriospinal neurons in mice

Authors: *J. FLYNN[1,2], M. GOULDING[3], R. J. CALLISTER[1], B. A. GRAHAM[1];
[1]Sch. of Biomed. Sci. and Pharm., Univ. of Newcastle, Newcastle, Australia; [2]Hunter Med. Res. Inst., Newcastle, Australia; [3]Salk Inst., San Diego, CA

Abstract: Long descending propriospinal neurons (LDPNs) are spinal interneurons that project over long distances within the spinal cord. Importantly, they connect forelimb and hindlimb motor circuits, allowing for interlimb coordination. Recent evidence also shows that following spinal cord injury, intact LDPNs facilitate the formation of de novo neural pathways that bypass a lesion site and contribute to functional recovery (Bareyre et al, 2004, Nat. Neurosci. 7:269). Surprisingly, little is known about the electrophysiological and molecular properties of LDPNs. This information is needed to better understand their role in spinal cord function under both normal and pathological states.

To examine the electrophysiological properties of LDPNs, we used targeted whole-cell patch-clamp electrophysiology. Mice (C57Bl6, 22-27 days) were anaesthetized (1-3% isoflurane) and injected with a fluorescent retrograde tracer (DiI) in the right lumbar spinal cord (L2) to identify cervical LDPNs that project to this region. After 48 hours, mice were overdosed with ketamine (100 mg/kg, i.p.) and transverse spinal cord slices were obtained. Recordings (23°C, KCH3SO4-based internal) were made from fluorescently labeled LDPNs whose somata were located in upper thoracic and cervical spinal cord segments. Recordings were obtained from 12 identified LDPNs and 8 control (non-fluorescent) neurons (RMP -46.6 ± 2.7mV vs. -55.4 ± 1.4mV, Rin 602.2 ± 244.5MΩ vs. 515 ± 95.1MΩ, Mcap 27.3 ± 2.9pF vs. 15.9 ± 1.3pF). Compared to control recordings, LDPNs were more likely to discharge action potentials (APs) spontaneously (75% vs. 38%) and exhibit a tonic AP discharge pattern (80% vs. 38%) in response to depolarizing current steps (1s duration, 20 pA increments). Also, 88% of LDPNs (vs. 66% control) exhibited a depolarizing, Ih-like inward current.

To investigate the molecular phenotype of LDPNs, GlyT2-GFP and GAD67-GFP mice were labeled with Fluoro-Gold using the injection technique described above. 15% of LDPNs were GlyT2 positive (n=3 mice), while 10% were GAD67 positive (n=3 mice). Interestingly, 85% of

these inhibitory LDPNs exhibited ipsilateral or midline projections. A number of genetically defined interneuron populations (including V3, V2a, V2b, V0, and dI3) were also examined for LDPN projections. Of these, only V2b (Gata3+) neurons contributed to LDPN circuitry (8% of total LDPN population; n=1 mouse).
Our data shows LDPNs have electrophysiological properties consistent with neuronal populations known to participate in rhythmic motor behaviours. Additionally, they have inhibitory projections that are predominantly ipsilateral.

Title: Directional control of locomotion in the touch-evoked escape behavior in zebrafish

Authors: *K. ASAKAWA[1,2], G. ABE[1], A. MUTO[1,2], K. KAWAKAMI[1,2];
[1]Dept. of Developmental Genet., Natl. Inst. of Genet., Mishima / Shizuoka, Japan; [2]SOKENDAI, Mishima, Japan

Abstract: An animal moving through the environment determines its direction of progression based on internal and/or external sensory information. Escape behaviors of zebrafish (Danio rerio) have been good models to study directional control of locomotion because the escape direction varies flexibly and accurately depending on the position of aversive stimulus. Here, we analyzed the escape behavior of zebrafish embryos observed around 48 hour post-fertilization, which can be evoked mainly by tactile stimulation. In the touch-evoked escape, the direction is largely determined by the angle of the lateral body turn (C-bend) that occurs prior to swimming. The angle of C-bend is typically 177° and 114° against the head and tail stimulation, respectively. To identify the neural network regulating the C-bend angle, we first performed a gene trap screen to generate Gal4 lines that labeled specific population of cells in the central

nervous system. Then, by crossing with UAS-tetanus toxin light chain (TeTxLC) lines, the Gal4 lines were screened for abnormal C-bend angle phenotype. From this screen, we identified a trap line for the mafb-transcription factor gene, in which Gal4 is widely expressed in the rhombomeres 4, 5 and 6. We found that, when TeTxLC was induced in the mafb-positive domain, the embryos displayed a larger C-bend angle, thereby escaping in an abnormal direction. The increase in the C-bend angle was observed againt the head, as well as tail stimulation. In parallel, we found that the laser ablation of the Manuther cell and its homologues, the reticulospinal neurons that are activated when an escape occurs, had a minor effect on the C-bend angle. To identify the candidate neurons that is involved in the C-bend regulation, we performed the calcium imaging of the mafb-positive domain with GCaMP. We found that the mafb-positive domain contained a population of cells that were selectively activated depending on the stimulus position, as well as ones that were activated regardless of the stimulus position. The above results support the idea that the mafb-positive domain in the hindbrain can discriminate the position of the tactile stimulus and determine accordingly the C-bend angle to define an appropriate direction of locomotion.

Title: Visuomotor integration in the motor cortex during skilled locomotion

Authors: *E. E. STOUT, I. N. BELOOZEROVA;
Barrow Neurol Inst., PHOENIX, AZ

Abstract: The activity of the motor cortex is essential for skilled movements, but its mechanism of response to emergent changes in the environment is poorly understood. In this study, we investigated the impact that unexpected visual and motor stimuli have on the activity of individual neurons in the motor cortex during a skilled, accuracy-dependent locomotion task. Cats were trained to walk over the evenly spaced rungs of a raised horizontal ladder. One rung was connected to a motor, and would be transiently displaced at different points along the cat's

progression. Six disturbant stimuli were applied: a motor disturbance, a visual disturbance, and an integrated visuomotor disturbance, each involving rung displacements either towards or away from the cat.

We found that the motor cortex response to these disturbances is well-defined, but that the responses of individual cortical neurons were strongly related to their anatomical and physiological characteristics. Neurons projecting to the pyramidal tract (PTNs) were more likely to respond to the disturbance than non-PTNs. PTNs with fast conduction velocities (>25 m/s) were more likely to respond than slow PTNs. PTNs receiving somatosensory information from different sources responded to different types of disturbances, at different points within the step cycle. Visual responses were observed almost exclusively in shoulder-receptive PTNs and PTNs with no receptive field.

In every neuron showing a response to the disturbances, the motor response was strongly and positively correlated with the integrated response. The visual response, when present, was always negatively correlated with the integrated response. Simple summation of motor and visual responses could not explain the integrated visuomotor response. There was little evidence of a motor cortex role in planning the adaptation to the disturbance; rather, the responses were almost exclusively concerned with on-line modification of motor commands.

We conclude that the differentiation of responses of motor cortex neurons with differing anatomical and physiological properties suggests that the functional organization of the motor cortex may be more regular and constrained than previously thought. The fact that the integrated response is not a summation of visual and motor responses raises the possibility the visual and motor streams may merge at earlier stages in motor processing. Finally, the lack of evidence for motor planning in the motor cortex suggests that that parallel processing in other motor-related structures may be occurring.

Title: Locomotor rhythmogenesis in the caudal hindbrain of the lamprey

Authors: *J. T. BUCHANAN[1], S. BLEL[2], M. EVANS[2], M. M. MCLOED[2];
[2]Biol. Sci., [1]Marquette Univ., Milwaukee, WI

Abstract: It is well established that the central pattern generator (CPG) for locomotion in vertebrates resides within the spinal cord. In lampreys, a lower vertebrate, the locomotor CPGs are distributed throughout the rostral-caudal extent of the spinal cord, and these neural networks generate rhythmic alternating left-right motor bursts that propagate from head to tail during forward swimming. Recently, we discovered that the motor nerves of the most caudal segment of the hindbrain, the spino-occipital (S-O) nerves, also exhibit rhythmic locomotor activity. The goal of the present study was to determine 1) whether the caudal hindbrain segment is capable of generating alternating rhythmic activity when isolated from both the rostral brainstem and the spinal cord and 2) whether the rhythmic activity of the hindbrain leads the rhythmic activity of the first spinal segment during fictive swimming.
To determine whether the most caudal segment of the hindbrain is capable of generating rhythmic activity independent of the rostral brainstem and the spinal cord, the caudal hindbrain segment hindbrain was physically isolated. The isolation was accomplished with complete transverse cuts made at the rostral border of the S-O motor column and caudally near the midpoint between the caudal S-O nerve and the first ventral root (VR). Motor activity was recorded with extracellular suction electrodes on the SO nerves. In all cases (n = 12), bath application of D-glutamate induced alternating bursting between the left and right S-O nerves in the isolated hindbrain segment. Thus, the most caudal segment of the hindbrain contains sufficient neural components for the generation of locomotor activity.
To determine whether the rhythmic activity of the caudal hindbrain leads or follows the rhythmic activity of the spinal cord, fictive swimming was induced in the isolated brainstem-spinal cord preparation by bath application of D-glutamate. Extracellular suction electrodes were used to record from the S-O nerves of the hindbrain and from the first VR and a more caudal VR of the spinal cord. Cross-correlation analysis of rhythmic bursts was used to assess the phase relationships among the nerves. During clear episodes of forward swimming in the rostral spinal cord, the S-O nerves of the caudal hindbrain burst in advance of the first VR in most preparations. Thus, the hindbrain may serve as the lead locomotor CPG in the chain of spinal locomotor CPGs.
In conclusion, the most caudal segment of the lamprey hindbrain contains a locomotor CPG which may serve as the pacemaker for the chain of spinal locomotor CPGs.

Title: Brainstem control of trunk and hindlimb motoneurons during fictive locomotion in the neonatal mouse

Authors: C. JEAN-XAVIER, *M.-C. PERREAULT;
Emory Univ. Sch. Med., Atlanta, GA

Abstract: Efficient and fluent locomotion in limbed animals requires appropriate coordination of trunk and hindlimb muscles. We have shown that the brainstem reticular formation, via the medullary reticulospinal system, is organized to provide both independent and integrated control of trunk and hindlimb motoneurons (MNs) (Szokol et al 2008, Szokol and Perreault 2009). How the reticulospinal system controls the two sets of MNs during ongoing motor activity is however not well understood. Here we use an ex vivo brainstem-spinal cord preparation of the neonatal mouse (postnatal day (P) 0 - P2) to examine the pattern of activity of trunk and hindlimb MNs during fictive locomotion, both before and after removal of supraspinal inputs.
Fictive locomotor activity was induced by pharmacological activation of the spinal locomotor networks (dopamine 50 µM; serotonin 10 µM; N-Methyl-D-aspartate 5 µM), and monitored using calcium imaging to ascertain that the MNs recorded belonged to the medial motor column (MMC) controlling trunk muscles or the lateral motor column (LMC) controlling hindlimb muscles. In the brainstem-attached preparation, rhythmic locomotor activity in MMC MNs overlapped with rhythmic locomotor activity in ipsilateral LMC MNs but alternated with the rhythmic locomotor activity in contralateral MMC MNs. Typically, MMC MNs displayed a double-burst during each locomotor cycle which was about 20% longer than the burst in LMC MNs (4.3 ± 0.1 s vs 3.4 ± 0.4 s, n=4). Removal of the brainstem decreased the locomotor cycle duration by about 18 % from 6.5 ± 0.5 s to 5.3 ± 0.6 s, and the burst duration in MMC and LMC MNs by about 10 % and 20%, respectively.
Our results are in agreement with the idea that descending control of locomotion is operational already by birth (Gordon and Whelan 2008) and further suggest that modulation of trunk activity is an important part of this control.

Title: Optogenetic activation of V2a interneurons produces locomotion in zebrafish

Authors: *J. AUSBORN, E. EKLÖF LJUNGGREN, S. HAUPT, A. EL MANIRA; Karolinska Inst., Stockholm, Sweden

Abstract: Neural networks in the spinal cord can generate locomotion in the absence of rhythmic input from higher brain structures or sensory feedback. The ability of the spinal networks to produce rhythmic locomotor patterns originates from the capacity of the excitatory interneurons to provide the necessary drive to other spinal network neurons. The identity of these spinal interneurons underlying the excitatory drive within the locomotor circuit has, however, remained unclear. We have previously shown that the V2a interneurons represent an intrinsic source of excitation necessary for the generation of swimming movements in larval zebrafish. In the present study, we utilize optogenetic tools to determine if activating the V2a interneurons is sufficient to produce swimming activity. We used a transgenic zebrafish line that selectively expresses Gal4 to drive the expression of channelrhodopsin-2 (ChR2) in V2a interneurons. To make sure that Gal4 expression is limited to V2a interneurons, we used a specific antibody for Chx10, a transcription factor expressed in these interneurons. We then performed whole-cell patch-clamp recordings from ChR2-expressing V2a interneurons. Blue light stimulation induced a large depolarization associated with a burst of action potentials. In spinalized larval zebrafish, blue light stimulation was sufficient to produce coordinated swimming activity. This optogenetically induced motor pattern displays left-right alternation and a rostro-caudal delay, which are characteristic of swimming in intact zebrafish. Blocking glycinergic transmission transformed the left-right coordinated activity into synchronous bursting on both sides. Our results indicate that the V2a interneurons provide the excitatory drive to initiate and maintain the swimming activity. These interneurons can thus be considered a sufficient intrinsic source of excitation within the spinal locomotor circuits.

Title: Functional connectomics of fast and slow locomotor microcircuits in adult zebrafish

Authors: *K. AMPATZIS, J. SONG, J. AUSBORN, A. EL MANIRA;
Karolinska Institutet, Dept. of Neurosci., Stockholm, Sweden

Abstract: Locomotor movements are produced by an intricate processing within the spinal networks that results in the sequential activation of motoneurons. It is, however, still unclear if these networks are composed of uniformly connected circuits, or if they are subdivided into multiple microcircuits. In adult zebrafish, we previously showed that only secondary motoneurons (sMNs) participate during swimming, while primary MNs (pMNs) are active only during escape. At swimming frequencies up to 12-15 Hz, only slow and intermediate sMNs are recruited, while fast sMNs become recruited at higher frequencies. We also showed that V2a interneurons represent a major source of excitation within the spinal locomotor network, and display a frequency-dependent recruitment pattern similar to that observed in MNs. In this study, we set out to determine if the different V2a interneurons are uniformly connected to all MNs or if they are preferentially connected to MNs recruited within the same frequency window. For this we deploy dual whole-cell patch-clamp recordings from identified slow, intermediate and fast MNs and V2a interneurons. Our results show that V2a interneurons that are recruited during fast swimming make strong monosynaptic connections with fast sMNs and pMNs. These connections comprise both chemical glutamatergic transmission and electrical gap-junctions. In contrast, fast V2a interneurons make very weak or no synaptic connections with slow and intermediate sMNs, which instead receive strong chemical monosynaptic connections from V2a interneurons that are recruited during slow/intermediate swimming frequencies. During swimming, the peak activity of V2a interneurons and sMNs recruited at slow/intermediate swimming is always occurring before that of V2a interneurons and MNs that are recruited at faster frequencies. In addition, the activity of the connected V2a interneurons and MNs is tightly coupled with firing of V2a interneurons, always preceding that of corresponding MNs. These results suggest that the locomotor network is composed of multiple microcircuits consisting of preferentially connected V2a interneurons and MNs that are recruited within the same frequency window during swimming.

Title: Speed dependent shifts in the ratio of excitation to inhibition shape motoneuron recruitment in larval zebrafish

Authors: *S. KISHORE[1], M. W. BAGNALL[2], D. L. MCLEAN[2];
[1]NBP, [2]Neurobio., Northwestern Univ., Evanston, IL

Abstract: Movements of increasing intensity are produced by the progressive recruitment of larger motor units. Motoneuron size and input resistance (Rin) are thought to play a significant role in determining recruitment order, but the relative contribution of these intrinsic cellular properties, versus differences in premotor synaptic input, in governing recruitment during locomotion is harder to assess. Using cell attached and whole cell voltage-clamp recordings from motoneurons in the spinal cord of larval zebrafish, we tested two possible explanations for the observed order of recruitment: (1) That the entire motor pool receives similar levels of excitation and inhibition, making Rin the primary determinant in recruitment order; or (2) that levels of excitation and inhibition vary across the motor pool in a systematic fashion, such that differences in premotor synaptic input primarily determine recruitment order. We find that at slow swim speeds, all motoneurons receive approximately equal amounts of peak excitatory current. Consequently, high Rin motoneurons are recruited, while low Rin motoneurons remain below threshold, consistent with the hypothesis that cellular excitability governs recruitment at slow speeds. In contrast, as swim speed increases, excitatory synaptic current increases far more for low Rin motoneurons than for high Rin motoneurons (i.e., the excitatory synaptic gain is inversely proportional to Rin). As a result, the bigger increases in synaptic input selectively engage low Rin motoneurons at higher swim speeds, consistent with the hypothesis that

differences in premotor synaptic input can also govern recruitment. We next examined whether synaptic inhibition follows a similar pattern as excitation. At slow swim speeds inhibitory synaptic currents are similar across all neurons, consistent with the postsynaptic intrinsic hypothesis. However, in contrast to excitation, inhibition increases with increasing swim speed across all motoneurons, indicating that it may not be as selective as excitation. The net result of these synaptic data is that for high Rin motoneurons, the excitation/inhibition (E/I) ratio actually decreases with increasing swim speed, eventually turning off firing at the highest speeds; but in low Rin motoneurons, the E/I ratio increases with increasing swim speed, allowing those cells to be recruited effectively. Our data suggest that spinal rhythm generating circuitry transitions from an intrinsic strategy based on postsynaptic excitability at slow speeds, to a network-based strategy based on differential premotor synaptic input at higher speeds.

Title: Motoneuron excitability shapes vision-based action selection in the spinal cord

Authors: *W.-C. WANG, D. L. MCLEAN;
Neurobio., Northwestern Univ., Evanston, IL

Abstract: The recruitment of motoneurons in the spinal cord follows Henneman's size principle. When generating increasing force, smaller motoneurons with higher input resistances are recruited first, while larger motoneurons with lower input resistances are added to the active pool later. However, little is known about how descending inputs from the brain utilize this organization to select different movements in response to sensory stimuli. In 4-6 day old larval zebrafish, spinal motoneurons are arranged dorsal-ventrally according to their size, input resistance, and recruitment order during swimming. We find that a sudden increase in light elicits low frequency swimming and more reliably activates smaller, ventral motoneurons with higher input resistances. Based on this observation, we next asked how this light-elicited, differential recruitment pattern of spinal motoneurons is achieved. The nucleus of the medial longitudinal fascicle (nMLF) is a compact cluster of descending neurons in the midbrain, which is activated by visual stimuli and is thus a good candidate for relaying visual information to the spinal cord.

Unlike spinal motoneurons, neurons in the nMLF respond to the light stimulus more homogeneously with similar reliability. By examining the anatomy and physiology of identifiable nMLF neurons, we demonstrate that one of the nMLF neurons (the caudal medial-lateral neuron, MeLc) synapses onto both larger and smaller spinal motoneurons. MeLc-elicited EPSPs in motoneurons with input resistances ranging from 30-600MΩ have similar amplitudes, but different waveforms. The slower decay of the EPSP waveform in higher input resistance motoneurons permits temporal summation of EPSPs, which allows small motoneurons to reach threshold more easily. Thus, the size principle helps explain the preferential activation of motoneurons and the selection of slow swimming movements in response to visual stimuli.

Title: Spinal axial microcircuits provide evolutionary template for limb control

Authors: *M. W. BAGNALL[1], Y. KIMURA[2], S.-I. HIGASHIJIMA[2], D. L. MCLEAN[1]; [1]Neurobio. & Physiol., Northwestern Univ., Evanston, IL; [2]Natl. Inst. for Physiological Sci., Okazaki, Japan

Abstract: Neural circuits controlling vertebrate limbs are thought to have evolved from fish axial circuitry, but the nature of this transformation is unknown. How did the axial circuit reorganize to produce flexor and extensor motor and premotor circuits? Using physiological recordings from motor neuron pairs in vivo, we show that in fact the zebrafish axial circuit is composed of two largely distinct parallel microcircuits, producing independent control of dorsal and ventral musculature. Both excitatory (V2a/Chx10+) and inhibitory (V1/En1+) premotor circuits are segregated into these two streams. We further demonstrate that fish rely on differential control of dorsal and ventral musculature for vital postural movements. We conclude that parallel microcircuits governing dorsal and ventral musculature, which originally developed to facilitate postural behaviors, are likely templates for the evolution of extensor/flexor control in

limbed vertebrates. Reweighting of existing connectivity, rather than extensive reorganization, is thus a strong candidate mechanism for this evolutionary transformation.

Title: Dendritic filopodial dynamics of motoneurons in larval zebrafish during the day and night

Authors: *J. V. DIPIETRO, JR[1], J. R. FETCHO[2];
[1]Neurobio. and Behavior, [2]Cornell Univ., Ithaca, NY

Abstract: The dendrites of neurons are highly dynamic structures. Throughout development, dendrites extend and retract filopodia as they search for new synaptic inputs. Some filopodia are stabilized by synapse formation, while previously stabilized filopodia may retract resulting in removal of synapses and dendritic pruning. Understanding dendritic filopodia dynamics may provide clues about how the nervous system homeostatically regulates the formation and breaking of synaptic contacts throughout the circadian cycle, during sleep and wake, and across development. The genetic and optical techniques available for zebrafish also allow for analysis of these dynamics in individual neurons. We used two-photon microscopy to take high-resolution three-dimensional time series images of single zebrafish primary motoneurons in vivo, giving us the opportunity to analyze all of the processes of individual neurons in an identifiable class. Because the animal remains intact during the imaging, the same cell can be analyzed at multiple times. The entire dendritic arbor of individual cells (one cell per fish, n=9) was imaged over the course of 15 minutes (6 z-stacks, 3 minutes apart), once during the day and once at night. Fish were light shifted at birth and age matched to account for order-of-imaging and age related effects. We find that the level of dendritic dynamics remains similar in day and night, without a precipitous drop or rise in overall dynamics during the day or night in association with changes in motor activity. Our early evidence, however, supports the conclusion that the balance of extensions and retractions may shift during day and night, with the ratio of retractions to extensions being greater at night than during the day. This has potential implications for how

patterns of formation and removal of synaptic connections are shaped in relation to changes in overall levels of motor activity or behavioral state during day and night.

Title: Functional organization of post-migratory facial motor neurons in zebrafish

Authors: *K. L. MCARTHUR, J. R. FETCHO;
Neurobio. & Behavior, Cornell Univ., Ithaca, NY

Abstract: The time and place of a neuron's birth set the stage for its functional development, but many neurons migrate away from their places of origin before and during periods of initial circuit formation. In order to understand the interplay between neuronal migration and development, we are exploring the functional properties of facial branchiomotor neurons (FBMNs) in zebrafish hindbrain, which undergo a dramatic caudal migration from rhombomere 4 to rhombomeres 6 and 7 in wild type embryos. In a previous study, we used whole-cell patch clamp recordings and dendritic dye fills to demonstrate the existence of physiological and morphological heterogeneity in the FBMN post-migratory population. We present here additional data pertaining to the functional organization of the FBMN population. Using a newly generated transgenic line (zCREST1:Dendra) in which FBMNs express a photo-convertible fluorescent protein, we show that post-migratory FBMNs establish a clear age-related organization, wherein dorsal cells are younger than ventral cells (similar to the age order of hindbrain interneurons). Using a second transgenic line (zCREST1:GCaMP5) in which FBMNs express a genetically encoded calcium indicator, we confirm and extend our previous observation of functional heterogeneity across FBMNs, with only a subset of neurons exhibiting smaller spontaneous bursts (0.5-1Hz) in addition to larger tail movement-related bursts. Further, we observe that neither bursting pattern appears until migration has been terminated, suggesting that FBMNs do not receive functional synaptic input until they reach their final destination. The next step in this project will be to compare this wild type functional topography to that of mutant

zebrafish in which FBMN caudal migration is specifically disrupted, to determine if the functional organization of this population is maintained despite the aberrant location of its cell bodies.

Title: *In vivo* kinetics of glycine receptor re-distribution

Authors: *D. M. CHOW, J. R. FETCHO;
Neurobio. and Behavior, Cornell Univ., Ithaca, NY

Abstract: The regulation of neurotransmitter receptor insertion and removal from synaptic sites plays an important role in synaptic plasticity. Despite the longevity of individual synapses, bound synaptic proteins exchange constantly with a cytosolic pool. Furthermore, the dynamic equilibrium maintained between insertion and removal of synaptic components influences receptor concentration and synaptic weighting. Understanding the regulation of receptor turnover may yield insights into how neurons regulate changes in synaptic plasticity and tune the relative weights of their inputs. Receptor turnover, however, is little studied in vivo due to the difficulty of visualizing synaptic proteins in intact preparations. We chose to study the re-distribution dynamics of the glycine receptor, the pre-dominant inhibitory neurotransmitter receptor in the spinal cord, in primary motoneurons of the larval zebrafish. The transparency of the larval zebrafish has allowed us to monitor the distribution of glycine receptors in single neurons of an intact living animal. We stochastically expressed glycine receptor α1 subunit tagged with the photo-convertible fluorescent protein dendra in isolated motoneurons. By precise targeting with converting pulses from a UV laser followed by two photon imaging, we have been able to quantify the rates of receptor turnover at single synaptic puncta. Our analysis indicates that the exponential time constant for turnover in primary motoneurons is on the order of 10 hours. We hope that by determining the kinetics of receptor turnover at defined synaptic contacts in vivo we may be able to link regulation of receptor turnover with synaptic properties under physiological conditions.

Title: Optogenetic rostro-caudal inhibition of movement without inhibition of afference in the spinal cord of mice

Authors: *V. CAGGIANO, M. SUR, E. BIZZI;
MIT, Cambridge, MA

Abstract: The γ-aminobutyric acid (GABA) and glycine are the main inhibitory neurotransmitters in the adult mammalian spinal cord. Several line of research have supported the idea that inhibitory interneurons have a local organization defined by sensory terminals which contribute to control motor neurons for limb alternation/coordination and for regulation of sensory-motor reflexes.
In order to understand the role and the organization of inhibitory neurons in the control of motor and sensory information within the spinal cord with both higher precision in space and in time, we developed a new method to optogenetically manipulate the spinal circuits in anesthetized and in awake freely moving animals using transgenic mice expressing ChR2 (Channelrhodopsine-2) in GABAergic/glycinergic neuronal populations (VGAT-mhChR2).
In anesthetized animals, light was shined at different levels of the spinal cord (from middle thoracic to middle lumbar with about 0.5 - 2 mm steps) by means of a movable optical fiber. Movements produced by electrical stimulation of the motor cortex were strongly reduced when light stimulation was applied (about 90% reduction, $p < 0.05$ sign-rank test, $n = 10$ mice). Maximum suppression was obtained at the middle-lower thoracic sector. These observation were confirmed by testing motor behavior in freely moving animals when light was shined above T12. Brief periods of optical stimulation of the spinal cord produced a loss of muscular tone (median latency of EMG suppression 6.55 ms) in all of the muscles i.e. agonist and antagonist, caudal to the stimulated point.
Some of the animals from the previous experiment were tested to evaluate the sensory consequences of the inhibition of the motor behavior. Once we identified the muscle(s)

suppressed during light stimulation, we anesthetized the animal and we recorded single neuron activity in the somatosensory cortex evoked by electrical stimulation of one of the muscles affected. In addition, stimulation of the hind-paw/foot was performed. Overall, the cortical sensory responses evoked by peripheral electrical stimulation showed the same pattern (time and amplitude) with only electrical and electrical-couple-optical stimulation of the spinal cord.
In conclusion, we developed a new technique for investigating the spinal inhibitory network in both anesthetized and awake freely moving mice. These experiments showed a new global rostrocaudal inhibitory effect without modifying the sensory information transmitted to the cortex at the middle/lower thoracic level in addition to the well-established local inhibition for postural control and locomotion which is present at the lumbar and sacral levels.

Title: Localization of glycinergic neurons selectively activated during paradoxical (REM) sleep in the rat: their potential role in muscle atonia

Authors: *S. VALENCIA GARCIA, O. CLÉMENT, P. A. LIBOUREL, S. ARTHAUD, P. H. LUPPI, P. FORT;
Lyon Neurosci. Res. Ctr., Lyon, France

Abstract: During paradoxical sleep (PS), somatic motoneurons are strongly inhibited causing a loss of tone in the whole skeletal musculature, a distinctive motor event of this sleep state. As revealed by intracellular recordings in the cat, glycine is the main inhibitory neurotransmitter responsible for the sustained hyperpolarization of both masseter and lumbar motoneurons during PS. Our current functional model thus assumes that glutamatergic PS-on neurons of the pontine sublaterodorsal nucleus (SLD) generate PS atonia by means of excitatory efferent projections to glycinergic premotoneurons. However, the exact location within the brainstem and/or spinal cord of these PS-on glycinergic neurons still remains a matter of debate. To bridge this gap, we used three experimental groups of rats prepared for polysomnographic recordings (EEG and EMG): 1) control (PSC); 2) deprived for PS during 72h with the flower pot technique (PSD, n=4); and 3) allowed to recover for 150 minutes of such deprivation during which they experienced ≈40% of PS (PSR, n=4). Ten days before PS deprivation, PSR rats were submitted to a retrograde tracer

Fluorogold (FG) injection into the ventral spinal cord at T13-L1 levels. An additional control group included rats forced to walk for 2h (STEP, n=4) in order to activate neurons involved in locomotion. Brainstem and spinal cord sections were then processed for double labeling combining immunohistochemistry of Fos (used as a marker of neuronal activity) with non-radioactive in situ hybridization of GlyT2 mRNA (the specific neuronal glycine reuptake transporter). Other sections from PSR rats were submitted to Fos/FG double immunostaining. Double-labeled Fos+/GlyT2+ neurons were quite exclusively observed in the ventral medulla oblongata of PSR rats. They were localized in the lateral paragigantocellular, alpha (Giα) and ventral gigantocellular (GiV) and raphe magnus nuclei (RMg). In the GiV, almost 80% of Fos+ neurons expressed GlyT2, whereas there are respectively 70% and 60% Fos+/GlyT2+ neurons in the Giα and RMg. At lumbar level, occasional Fos+/GlyT2+ neurons were seen in PSC, PSD and PSR rats while they were numerous in STEP rats with sustained locomotor activity. Finally, Fos/FG double immunostaining in PSR rats unraveled that a large number of Fos+ projecting to the ventral spinal cord is present only in the GiV.
These results highly suggest that GiV glycinergic neurons selectively activated during PS project directly to the spinal cord and are responsible for the hyperpolarization of somatic spinal motoneurons during this state.

Title: Bursts of spikes driven by T-type calcium channels occur in motor but not visual thalamocortical neurons in brain slices

Authors: H. R. KIM, S. Z. HONG, *C. D. FIORILLO;
Bio and Brain Engin., KAIST, Daejeon, Korea, Republic of

Abstract: Within an intact nervous system, neurons can be classified as either sensory or motor based on anatomy and physiological responses. However, it is not known whether there is any

systematic difference between the neurons of sensory versus motor systems at the cellular or molecular level. Based on theoretical considerations, we formulated the hypothesis that motor but not sensory neurons generate “all-or-none” bursts of action potentials under natural conditions. A major challenge in testing this hypothesis is that different types of neurons display differences in the electrical properties of their membranes that are unrelated to any distinction between sensory and motor. Although it would be desirable to systematically compare a large diversity of sensory and motor neurons in order to overcome this variability, we have taken the modest initial step of comparing sensory versus motor thalamus. We chose thalamus because it has both sensory and motor divisions, and yet thalamocortical neurons are known to share many common features, including the expression of T-type calcium channels that are capable of generating bursts of spikes under certain conditions.
Whole-cell current clamp recordings were made in the dorsal lateral geniculate nucleus (LGNd) (visual) and ventral lateral nucleus (VL) (motor) in brain slices from 3-4 week old rats. Depolarizing currents of 10 ms duration were increased in small increments from potentials of -70 and -80 mV. At -70 mV, when most T-type channels were inactivated, no difference was observed between LGNd and VL in the number of evoked sodium spikes. From -80 mV, we observed a “low threshold spike” (LTS) mediated by T-type calcium channels. When the LTS was evoked by a minimal depolarizing current, it often caused just 0 or 1 spike in LGNd (0.9±0.2, mean±sem, n=31), but 2 or more in VL (2.5±0.3, n=48), indicating that it had an all-or-none burst property in VL but not LGNd. The maximal number of spikes (evoked by large 10 ms current injections) was also greater in VL than LGNd. A second experimental protocol used dynamic clamp to evoke the LTS under more natural conditions by injecting artificial excitatory postsynaptic conductances (EPSCs) at various times after hyperpolarization to -80 mV by injection of a chloride-like conductance. Once again more spikes were found in VL. We often observed 2 or more spikes in response to a single EPSC in VL (7 of 14 neurons), but never in LGNd (0 of 26 neurons). In conclusion, our comparison of two thalamic nuclei supports the hypothesis that motor but not sensory neurons generate bursts of spikes.

Title: Laser ablation of Dbx1 pre-Botzinger interneurons impairs and then precludes respiratory rhythm generation

Authors: *C. A. DEL NEGRO[1], X. WANG[1], M. C. D. PICARDO[1], J. A. HAYES[2];
[1]Dept. of Applied Sci., The Col. of William & Mary, Williamsburg, VA; [2]Neurobiologie et Developpement, Inst. de Neurobiologie Alfred Fessard, Gif-sur-Yvette, France

Abstract: Neurons whose progenitors express Dbx1 may comprise the excitatory core of the preBotzinger complex (preBotC), a rhythmogenic site essential for breathing behavior in mammals. We dub this the Dbx1 core hypothesis, and it predicts that cumulative destruction of Dbx1+ neurons in the preBotC should degrade its rhythmicity and ultimately lead to irrevocable rhythm cessation. We used a cell-specific laser detection and ablation methodology to selectively destroy Dbx1+ neurons in slice preparations that retain the preBotC as well as hypoglossal (XII) motoneurons and premotor neurons, and thus encapsulate a complete respiratory motor circuit and in vitro model of the behavior. Ablating Dbx1+ neurons in sequence progressively diminished the frequency, amplitude, and regularity of XII output. The rhythm stopped irreversibly after 85±45 ablations, which corresponds to ~26% of the minimum estimated population size. Neuropeptide stimulation evoked transient but unsustainable XII output in lesioned slices. These data support the hypothesis that Dbx1+ neurons comprise the preBotC rhythmogenic core, and further show that Dbx1+ neurons may play a premotor role. Dismantling the Dbx1+ core piecewise precludes rhythm-generating functionality in the preBotC without completely destroying the underlying network. Our results clarify the genetic cellular core of a mammalian central pattern-generating circuit and quantify the parameters that govern its functionality.

Title: Ontogeny and plasticity of GABAergic inhibition in respiratory control

Authors: *E. A. MACMURRAY, C. M. CARTAGENA DE JESUS, B. E. TAYLOR;
Biol. and Wildlife, Univ. of Alaska Fairbanks, Fairbanks, AK

Abstract: The tadpole brainstem preparation is a facile model for studying the isolated, yet intact, central network that controls vertebrate breathing. γ-aminobutyric acid (GABA) signaling plays a role in this neural network, as it does in many rhythmically oscillating networks. Previous studies depict an interaction between ethanol and GABA receptors; however, few have investigated this interaction with respect to respiratory control. Sudden Infant Death Syndrome (SIDS), which is characterized by respiratory failure, is associated with deficits in serotonergic and GABAergic systems, and its incidence increases with prenatal and postnatal alcohol exposure. We are interested in developmental changes in GABAergic inhibition and critical developmental periods in which ethanol can modulate GABAergic activity. We hypothesized that respiratory GABAergic inhibition varies with development and that early chronic ethanol exposure attenuates the GABA response during specific developmental periods. Preliminary analyses of cranial nerve output before and after bath application of 0.25 mM GABA suggest that this traditionally inhibitory signaling increases the frequency of lung-breathing in early tadpole development. Ethanol modifies the effect of GABA in pre-metamorphic but not post-metamorphic tadpoles. Additionally, preliminary results suggest that nonchloride-mediated GABA signaling is the primary mode of GABAergic inhibition underlying early tadpole lung breathing. By further understanding the developmental changes in GABAergic inhibition, we hope to delineate critical developmental periods that may be useful targets in the study of respiratory disease.

Title: The RTN and pFRG are functionally separate nuclei in the control of respiration

Authors: *R. T. HUCKSTEPP, K. P. CARDOZA, L. E. HENDERSON, J. L. FELDMAN;
Neurobio., UCLA, Los Angeles, CA

Abstract: A distinct respiratory oscillator driving active expiration appears to be located close to the facial nucleus in the regions of the retrotrapezoid nucleus (RTN) and the parafacial respiratory group (pFRG). Here, we address whether these two nuclei have distinct functional roles in central pattern generation for breathing in adult rat. Neurons in each region were transfected with adeno-associated viruses (AAVs) containing inserts for either the allatostatin or HM4D (DREADD) receptor. The RTN and pFRG were silenced independently, with allatostatin or CNO respectively, under conditions where expiration was active, i.e., during hypoxia, hypercapnia, and disinhibition (with bicuculline and strychnine) of the pFRG. We found that the pFRG and RTN had different roles in the patterning of breathing. Silencing the RTN altered tidal volume and the amplitude of EMGs of inspiratory- and expiratory-related muscles. Disinhibiting the pFRG altered respiratory frequency by increasing expiratory duration. Silencing the pFRG reduced expiratory-related abdominal muscle EMG without affect on inspiratory-related muscle EMGs. We suggest that the RTN affects the overall drive to breathe, with the pFRG a key element of the expiratory oscillator.

Title: Functional loss of peripheral nerve conduction following embryonic pyridoxine administration in chick

Authors: *Y. FEDOROVICH[1], A. A. SHARP[2];
[1]Physiol., [2]Anat., Southern Illinois Univ. Sch. of Med. Carbondale, Carbondale, IL

Abstract: Our long term goal is to understand how sensory information is used during embryogenesis to modulate motor behavior and establish normal sensorimotor circuitry. Towards this end, we have been studying the effect of embryonic administration of pyridoxine

(vitamin B6) on chick embryos. Studies in adult mammals have shown that large doses of pyridoxine cause large fiber sensory neuropathies accompanied by ataxia. While pyridoxine mostly kills muscle proprioceptive neurons, there is still a significant loss of some skin innervating neurons in mammals. Previously, our lab has shown that embryonic administration of pyridoxine in chick on embryonic day (E) 7 and E8 causes an alteration of leg movement on E9 as well as post hatch. Anatomical examination of this lesion on E13 reveals a significant decrease in the number of large diameter axons in the N. Tibialis, a 70-100% decrease in trkC positive dorsal root ganglion (DRG) neurons, no effect on substance-P and CGRP positive DRG neurons, and no effect on the number of motor neurons. These data suggest that pyridoxine toxicity is largely restricted to proprioceptive neurons innervating muscle in chick. The goal of the current study is to examine the functional effects of embryonic pyridoxine lesion. Specifically, we hypothesized there would be a decrease in the amplitude of the rapid component of evoked compound action potentials (CAPs) in N. Ischiadicus (analogous to the mammalian sciatic nerve) corresponding to a loss of large diameter proprioceptive axons. Animals were incubated in a forced-air incubator. The treated and control animals were injected with either 3.75 mg of pyridoxine in 100 µl of physiological saline or 100 µl physiological saline, respectively, through an opening made in the shell on E7 and E8. At E13, embryos were removed and placed into oxygenated physiological saline. The N. Ischiadicus was exposed at the point of its formation by the Ischiadic plexus and stimulated with current pulse via a suction electrode. The resulting CAPs were recorded distally before the nerve bifurcated proximal to the popliteal fossa with another suction electrode. We have observed that pyridoxine causes a decrease in the amplitude of the first peak and trough of the CAP, but only the decrease in trough amplitude is significant. This finding is consistent with our anatomical studies indicating that pyridoxine kills proprioceptive neurons innervating muscle. We are currently examining the effects of pyridoxine on CAPs in skin and muscle innervating nerves to assess the specificity of the lesion and CAPs in younger embryos to delineate the onset of functional loss.

Title: Similarities and differences in the neuronal wiring of the cerebellar nuclei of rodents and primates

Authors: S. HAMODEH, *F. R. SULTAN;
Univ. Tuebingen, D-72076 Tuebingen, Germany

Abstract: The deep cerebellar nuclei (DCN) undergo marked changes during the evolution of mammals and especially in primates. It is little known whether and how these morphological changes relate to changes in the cellular architecture of the DCN and also how these changes may lead to an added vulnerability in humans leading to neurodegenerative diseases such as Friedreich´s ataxia. Addressing this question has been hindered by the limited scope of methods so far to compare the neuropil in phylogenetically diverse species. In this study we quantified the components of the neuropil of the rhesus monkey's deep cerebellar nuclei (DCN) to compare it to the results we have previously obtained in rats. We obtained 3D immunostained samples that were segmented, reconstructed and quantified with a 3D quantitative immunohistochemical method. The method was sufficiently fast enough to cover the different subregions of the DCN. The neuropil was either stained with an antibody against dendrites (microtubule associated proteins, MAP2a, b) or against the Purkinje cell axons (PCP2 antibody). We obtained 512 probes sampling from a total volume of 163.8mm3. We observed systematic differences in fiber length density, average fiber diameters and volume fraction within different parts of the DCN. In the rat the dendritic and axonal (PCP2) fiber diameters were highest in the phylogenetically older medial and anterior interposed nuclei (MN and AIN), whereas the fiber density was higher in the newer posterior interposed and lateral nuclei (PIN and NL). In the rhesus monkey a similar picture emerged with the exception that the dendritic diameters within the PIN were as large as those in the AIN and NM. This could indicate that the PIN neurons are scaled up in the larger rhesus monkey cerebellum. In contrast, this effect was not seen in the NL. This observation could point towards a cellular mechanism that leads to the gyral folding observed within the primate NL. A detailed mapping on the NL surface will allow us to further test this hypothesis.

Title: Form and function in the cerebellar noradrenergic and serotonergic systems

Authors: M. LONGLEY, *C. H. YEO;
Dept. Neuroscience, Physiol. & Pharmacol., Univ. Col. London, London, United Kingdom

Abstract: Noradrenaline (NA) and 5-HT are important for learning and memory across several brain regions. The cerebellum is crucial for certain forms of motor learning including classical conditioning of the eyeblink response and cerebellar β-adrenoceptor function is essential for its consolidation (Paredes et al, Neur Learn Mem 92:267,2009), consistent with an earlier theory that NA may provide the consolidation signal (Gilbert, Nature 254: 688,1975). As the next step in understanding their roles, we here analyze the detailed anatomy of these monoaminergic afferent systems and the distribution of β-adrenoceptors in the cerebellum.
Immunofluorescent labelling of the noradrenaline reuptake transporter (NET) and serotonin reuptake transporter (SERT) revealed strong, orthogonal anisotropies in the NA and 5-HT afferent fibres throughout the cortical molecular layer in rats. In the vermis, NA fibre trajectories were sharply confined to the parasagittal plane with very restricted transverse extensions, suggesting they travel within the parasagittal zones and, possibly, the microzones of the cerebellar cortex. In sharp contrast, 5-HT fibres of the vermis travelled extensively in the transverse plane with very restricted trajectories rostro-caudally. This pattern of intrazonal NA and transzonal 5-HT afferent trajectories was seen in all regions of the cortex, including the hemispheres.
Both NA and 5-HT are released from multiple varicosities along every fibre. Their distributions indicate that individual NA fibres may be capable of modulating activity within a zone or even within a microzone but 5-HT fibres may not. A single 5-HT fibre would influence all microzones and zones along its trajectory, inconsistent with the suggestion that 5-HT might serve as a responsibility signal to select a specific set of microzones sufficient to form the basis of an internal model for a particular movement (Schweighofer et al , Brain Res Rev 44:103,2004).
NA function in cerebellar consolidation was revealed by local application of propanolol, an antagonist of both β1- and β2-adrenoceptors (Paredes et al 2009). Here we report the distribution of both types. Immunofluorescent labelling of β1- and β2-adrenoceptor proteins clearly dissociated their cellular distribution in the cerebellar cortex. β1-adrenoceptor protein was entirely restricted to Purkinje neurons. In contrast, β2-adrenoceptor protein was restricted to the cell bodies and processes of Bergmann glia. Further studies with selective antagonists will reveal whether consolidation of cerebellar learning is β1 or β2-adrenoceptor-dependent and thus whether Purkinje cells or Bergman glia are directly implicated.

Title: The cerebellar nucleocortical tract includes a corollary discharge pathway in mouse

Authors: *B. HOUCK[1], A. L. PERSON[2];
[1]Physiol. and Biophysics, Univ. of Colorado Anschutz Med. Campus, Aurora, CO; [2]Physiol. and Biophysics, Univ. of Colorado Sch. of Med., Aurora, CO

Abstract: Theoretical models suggest that the cerebellum supports precise movements through feedforward motor control. Accurate feedforward computations are hypothesized to require information about outgoing motor commands via corollary discharge (CD) - a copy of an efferent motor command. A key candidate source of CD to the cerebellar cortex is the nucleocortical pathway. Previous studies in cats and primates have suggested that collaterals of nuclear output neurons may terminate in the cerebellar cortex, forming part of this pathway. These collaterals could provide a source of motor input to the cerebellum, but the literature is equivocal on its organization with recent data suggesting that the mouse nucleocortical pathway includes a glycinergic projection. To test whether the nucleocortical pathway in mice includes a corollary discharge pathway, we injected biotinylated dextran amines into the ventrolateral thalamus of wildtype mice, the targets of premotor nuclear output neurons. Following injections, we observed retrogradely labeled somata in the cerebellar nuclei and corresponding collateral terminals ascending into the granule cell layer making up the nucleocortical pathway (n = 8). Collaterals terminated as mossy fiber rosettes that were immunopositive for synaptic vesicle protein 2 (SV2). The most densely innervated cortical areas were the Simple, Crus I and Crus II lobules with a lighter terminal distribution within several other cerebellar lobules. Nucleocortical terminals formed close contacts with Golgi cells as visualized with antibody staining against neurogranin (n=4) and mGluR2/3 (n=2) or with genetic label using GlyT2-GFP transgenic mice (n=4), suggesting that this CD pathway could induce feedforward inhibition to modify convergent sensory pathways. To confirm that the mouse nucleocortical pathway also includes a glycinergic projection, we injected AAV-Syn1-mCherry into the cerebellar nuclei of transgenic GlyT2-GFP mice and traced double labeled neurons from the nucleus to their termination in the granule cell layer (n=6). These fibers did not terminate as mossy fibers but rather ended in simple boutonal swellings. These results (1) suggest a mechanism by which CD can modify sensory input through inhibitory interneurons and (2) confirmed the existence of an inhibitory nucleocortical population with direct input to the cerebellar cortex. These pathways could be critical for the computation of a forward model.

Title: Parasagittal organization of visual mossy fiber projections from the nucleus lentiformis mesencephali to folium VIII of the pigeon cerebellum in relation to Zebrin II stripes

Authors: *J. P. LAM[1], D. J. GRAHAM[2], C. GUTIERREZ-IBANEZ[3], D. R. WYLIE[2]; [1]UBC, Vancouver, BC, Canada; [2]Dept. of Psychology, [3]Univ. Ctr. for Neurosci., Univ. of Alberta, Edmonton, AB, Canada

Abstract: The cerebellar cortex is organized into parasagittal zones. This has been shown with respect to the physiological responses of Purkinje cells, projections of Purkinje cells, afferent inputs from climbing and mossy fibres and the expression of several molecular markers including zebrin II (ZII; a.k.a. aldolase C). In numerous mammalian and avian species ZII is expressed heterogeneously in Purkinje cells, such that there are sagittal stripes of high expression (ZII+) interdigitated with stripes of little or no expression (ZII-). Several studies have attempted to determine how the ZII stripes are related to the other aforementioned aspects of cerebellar organization. For example, previously we have shown that the majority (~90%) of mossy fibres from the nucleus of the basal optic root (nBOR) and nucleus lentiformis mesencephali (LM) that project to the vestibulocerebellum terminate in sagittal bands that are aligned with the ZII+ stripes. The nBOR and LM are retino-recipient nuclei that process optic flow resulting from cell motion. The LM also projects to the folia VI-VIII in the posterior vermis. These folia also receive visual mossy fibre inputs from a tecto-potine involved in the analysis of local visual motion. This integration of optic flow with local-visual motion information is thought to be important from obstacle avoidance during locomotion through cluttered environments. In this study we examined the projection from LM to folium VIII in relation to the ZII stripes. Anterograde fluorescent tracer (BDA) was injected into LM, and serial sections through the posterior cerebellum were immunoprocessed for ZII expression. We found that, as is the case for the vestibulocerebellum, the majority (85-90%) of the mossy fibre rosettes terminated in sagittal bands that were aligned with the ZII+ve stripes.

Title: Heterogeneity of calretinin expression in the avian cerebellar cortex of pigeons and relationship with zebrin II

Authors: *D. WYLIE[1], M. JENSEN[2], C. GUTIERREZ-IBANEZ[2], D. J. GRAHAM[1], A. N. IWANIUK[3];
[1]Dept. of Psychology, [2]Univ. Ctr. for Neurosci., Univ. of Alberta, Edmonton, AB, Canada;
[3]Canadian Ctr. for Behavioural Neurosci., Univ. of Lethbridge, Lethbridge, AB, Canada

Abstract: The cerebellar cortex has a fundamental parasagittal organization that is reflected in the physiological responses of Purkinje cells, projections of Purkinje cells, afferent inputs from climbing and mossy fibres inputs and the expression of several molecular markers. The most thoroughly studied of these molecular markers is zebrin II (ZII; a.k.a. aldolase C). ZII is differentially expressed in Purkinje cells, resulting in a pattern of sagittal stripes of high expression (ZII+) interdigitated with stripes of little or no expression (ZII-). The calcium binding protein calretinin (CR) is known to be expressed heavily in mossy fibres terminating throughout the cerebellar cortex although it is not known if it heterogeneously expressed with a parasagittal distribution. In this study we examined CR expression in the cerebellum of pigeons and compared it to that of ZII.
We found that CR was expressed heavily in the granule layer in mossy fibres and their terminal rosettes. Moreover, CR was expressed heterogeneously in the granule layer such that there were sagittal stripes of heavy CR labeling (CR+) alternating with stripes of weaker labeling (CR-). The CR heterogeneity was most notable in folium IXcd and folia II-IV in the anterior lobe. In the anterior lobe, the central CR+ stripe spanning the midline was aligned with the central ZII+ stripe, whereas the other CR+ stripes were aligned with the ZII-ve stripes. In IXcd, the CR+ stripes were aligned with the ZII+ stripes. We suggest that the CR+ mossy fibres to IXcd originate in two retinal recipient nuclei involved in the processing of optic flow.

Title: Olfactory stimulation by airborne scents induces c-Fos expression in the vermis cerebellum of sexually experienced male rats

Authors: P. GARCIA-BAÑUELOS, Z. HERNANDEZ-BRIONES, G. HERRERA-MEZA, G. ARANDA-ABREU, P. CARRILLO, M. HERNANDEZ, G. CORIA-AVILA, J. MANZO, *L. I. GARCIA;
Ctr. de Investigaciones Cerebrales, Univ. Veracruzana, Xalapa, Mexico

Abstract: The cerebellum functions have been ascribed related movements, reflexes, memory, sex, language, planning and forecasting, and perceptual ability. Recent studies have demonstrated that distance stimulation of male rats through sexual signals significantly increases the expression of c-Fos in the granular layer in each cerebellar lobe. Although this activity could correspond to sensory stimulation (visual, auditory or olfactory) or the motor execution.There is little information on the role of the cerebellum in sensory integration, particularly of smell The objective of the present study is to analyse and compare the expression of c-Fos protein in the cerebellar vermis male rats who have performed sexual behavior after being stimulated olfactory. Male rats (250-300 g) that have run one, three and five times the sexual behavior were placed alone for 5 min into the acrylic chamber (30 X 30 X 60 cm), and then 100 g of wood chip bedding was placed in a hide compartment underneath the floor, that had holes to prevent direct contact with it but allow olfactory stimulation. Test lasted 60 min with clean wood chip, wood chip impregnated with almond essence or wood chip from a bedding of receptive females. Finally, males were anaesthetized with an i.p. injection of sodium pentobarbital (60 mg/kg), a transcardial perfusion was made and immunohistochemistry done in the cerebellar tissue. Immunoreaction analysis of c-Fos protein in the granular layer of the cerebellar vermis shows an

increase. Olfactory stimulation showed an increase in the activity of the cerebellar vermis in the group stimulated with receptive female odor compared with almond and this in turn with the control. That pattern in all three groups increased with the acquisition of experience in sexual behavior. Our study confirmed that the cerebellum is activated differently to different stimuli and also that this activity is modified by acquired experience in sexual behavior.

Title: Fine scale correspondence between the cerebellar microzones and the aldolase C compartments in mice

Authors: *S. TSUTSUMI[1], M. YAMAZAKI[2], K. SAKIMURA[2], K. KITAMURA[1], M. KANO[1];
[1]Univ. of Tokyo, Tokyo, Japan; [2]Niigata Univ., Niigata, Japan

Abstract: The cerebellar cortex has an elaborate zonal structure extending rostro-caudally. Purkinje cells (PCs) located in this parasagittal stripe show synchronous complex spike (CS) activities. This functional structure is considered to arise from anatomical organization of olivocerebellar projection (Sugihara et al., 2001) and electrical coupling among neurons in the inferior olive (Lang et al, 1999). The longitudinal compartment of aldolase C (zebrin II) expression in the cerebellar cortex has been shown to correspond to anatomical climbing fiber (CF) innervation from the inferior olive. Aldolase C compartments have been shown to correlate with functional complex spike synchrony at the resolution of several hundred micrometers (Sugihara et al., 2007). To elucidate the relationship between the CS synchrony and the aldolase C compartments at finer spatial resolution, we performed two-photon calcium imaging in

anesthetized mice that express fluorescent protein in their aldolase C-expressing PCs. We found a highly precise correlation between the CS synchrony and the aldolase C compartments. Spontaneous CS activities within aldolase C positive-PCs and those within aldolase C negative-PCs were both highly synchronized. The border of these high synchrony areas precisely corresponded to that of the aldolase C compartments at single cell resolution. We further investigated the relationship between the aldolase C compartments and functional microzones identified by responses to sensory stimuli. Fine microzonal structure could be activated in response to perioral air puff stimulation. The border of this sensory-evoked microzone precisely corresponded to that of aldolase C compartments. During awake state, sensory-evoked microzones could be extended and overlapped. These results suggest that aldolase C compartments represent physiological zones, which can cooperate during sensorimotor activities.

Title: Mapping cerebellar circuit function in zebrafish (Danio rerio) using electrophysiology and calcium imaging

Authors: J.-Y. HSIEH, F. A. ISSA, J. WAN, J. C. JEN, *D. M. PAPAZIAN;
Geffen Sch. Med. UCLA, LOS ANGELES, CA

Abstract: The zebrafish, a lower vertebrate, provides numerous advantages for investigating the development of neuronal circuits and their role in controlling behavior, including rapid development outside the body of the mother, optical clarity early in life, and the ability to image neuronal activity in living animals using genetically-encoded calcium indicators (GECIs). However, GECIs have relatively low temporal resolution, limiting their usefulness for detailed analysis of circuit function. In addition, it is often difficult to identify the electrical events that

trigger calcium transients. In contrast, electrophysiological methods provide detailed information about neuronal activity but have not yet been widely used to investigate circuit function in the zebrafish brain. To characterize the development and maturation of electrical activity in the zebrafish cerebellum, we performed in situ patch clamp electrophysiology and in vivo calcium imaging in cerebellar Purkinje cells during the first 12 days post-fertilization (dpf). Patch clamp experiments were performed using an albino transgenic line that expresses a membrane-bound Venus fluorescent protein specifically in Purkinje cells under the control of the *aldoase Ca* (*aldoca*) promoter. Alternatively, a membrane bound GECI, lck-GCaMP5, was transiently expressed in Purkinje cells using the *aldoca* promoter. Spontaneous tonic firing and complex spikes were recorded using an extracellular patch electrode between 5-12 dpf. The frequency of tonic firing was ~10 Hz at room temperature (21-24^{o}C), whereas the frequency of complex spiking was between 0.2-0.5 Hz. Spontaneous calcium transients characterized by rapid rise and a decay phase that lasted several seconds were detected during the same time period. The development of a functional cerebellar circuit was monitored by direct electrical stimulation applied using a theta glass electrode. At 5 dpf, stimulation of the inferior olive evoked complex spikes, indicating that functional synapses had been made between climbing fibers and Purkinje cells. Previously, anatomical evidence has shown that cerebellar granule cells receive mossy fiber inputs from pretectal neurons in the anterior diencephalon. We investigated whether this pathway was functional. Stimulation of the pretectum increased the frequency of tonic firing in Purkinje cells and generated large calcium transients that sometimes spread to neighboring cells. Our results indicate that Purkinje cells, which are born beginning at 3 dpf in zebrafish, rapidly become electrically excitable and exhibit robust tonic firing and complex spiking as part of a functional cerebellar circuit by 5 dpf.

Title: Projections from the spinal cord to the cerebellar cortex in the mouse

Authors: *G. SENGUL[1], Y. FU[2,3], Y. YU[4], G. PAXINOS[2,3];
[1]Ege Univ. Sch. Med., Izmir, Turkey; [2]Neurosci. Res. Australia, Sydney, Australia; [3]The Univ. of New South Wales, Sydney, Australia; [4]Dept. of Pediatric Surgery, The First Affiliated Hosp. of Harbin Med. Univ., Harbin, China

Abstract: We have investigated the topography of projections from the spinal cord to the cerebellum using neuronal tracers Fluoro-Gold (FG) and cholera toxin B (CTB). Although there are a number of studies on spinocerebellar projections, the majority concern the connections of cerebellar nuclei and, hitherto, there is no detailed study on the distribution of spinal cord neurons projecting to the cerebellar cortex, either vermis or hemispheres. Pressure injections of FG or CTB were made into the lobules 1-10 of the cerebellar vermis (1Cb to 10Cb) and on the right side of the cerebellar lobules (simple lobule, flocculus, paraflocculus, paramedian lobule, copula of the pyramis, and Crus1 and 2 of the ansiform lobule) on 13 C57BL/6J mice. Projections to 1Cb, 2Cb and 3Cb of the vermis were found from the central cervical nucleus (CeCv), deep dorsal horn (DDH), dorsal nucleus (D), lumbar and sacral precerebellar nuclei (LPrCb and SPrCb, respectively), and laminae 7-8 and 10 neurons. We did not find any neurons projecting to 4-7Cb. The 8Cb and 10Cb received projections from the CeCv, DDH, lamina 7, LPrCb and SPrCb neurons, while the crus1 and crus2 of the ansiform lobule received afferents from the DDH and laminae 7-8 neurons. The paraflocculus and flocculus received projections from neurons of the intermediolateral nucleus (IML), lamina 10 (presumably paraependymal part of the intercalated nucleus) and the lumbar dorsal commissural nucleus. Projections to the copula of the pyramis were from the DDH (mainly lamina 5), laminae 7, 10, D and LPrCb. The distribution of spinocerebellar neurons were mostly bilateral; however, in some cases, CeCv neurons were more numerous contralateral to the site of the cerebellar injection, and DDH neurons were more numerous ipsilaterally.

Title: Lower level of inhibitory synaptic transmission in the vestibulo cerebellum

Authors: C. RYU, J. KIM, *S. KIM;
Physiol., Seoul Natl. Univ. Coll Med., Seoul, Korea, Republic of

Abstract: In accordance with functional classification, the cerebellum is categorized as three subdivisions, the cerebro-cerebellum, the spino-cerebellum, and the vestibulo-cerebellum (VC). It has been known that the VC, or flocculonodular lobe which is comprised of flocculus, paraflocculus, lobule IX and X of vermis receives substantial vestibular input directly from vestibular nuclei, and its extensive output projects to vestibular nuclei. Among several types of neurons in the cerebellar cortex, Purkinje cells (PCs) on which external inputs via parallel fibers and climbing fibers converge are the exclusive output neurons and, accordingly, regarded as the principal neurons of the cerebellar circuits. Therefore, understanding properties of PCs that are related to input-output is necessary for comprehending the operating principles of the cerebellar circuitries. With distinguishable characteristics of input and output functions in the vestibule-cerebellum, previous studies have shown that PCs in the VC have distinct electro-physiological properties. For example, PCs have higher resistance to excitatory synaptic plasticity and lower intrinsic excitability in the VC than those in any other cerebellar regions. Besides excitatory inputs via parallel fibers and climbing fibers, PCs receive inhibitory inputs from molecular layer interneurons which form feed-forward inhibition influencing the fidelity of PCs output. However, there has been no research regarding inhibitory synaptic transmission of the VC. In this study, we investigated the nature of inhibitory synaptic transmission in the VC and their functional implication, using whole cell patch clamp techniques. Since cerebellar vermis, which is subdivided into ten lobules, has both the VC (lobule IX and X) and the spino-cerebellum (the other lobules), we compared PCs between lobules III~VI and lobule X of vermis. We found that inhibitory inputs into PCs of the VC have much lower amplitude, but not lower frequency than those in other cerebellar regions. In an aspect of the relationship between amplitude and rise time, it is plausible that this difference is due to basket cell-PC synapse rather than stellate cell-PC synapse. In addition to the variation of basal inhibitory level, PCs of lobule X showed limited inhibitory synaptic plasticity such as rebound potentiation or DSI. Paradoxically, although inhibitory inputs are much lower in the VC, their effect on the output of PCs (Spontaneous Firing of PCs) is more profound in the VC. Thus, we suggest that the lower level of inhibitory synaptic transmission in the VC enables the output of PCs to be regulated by subtly altering the inhibition pattern.

Title: A granule cell - golgi cell feedback circuit in the cochlear nucleus

Authors: *D. B. YAEGER[1], L. O. TRUSSELL[2];
[1]Physiol. and Pharmacol., Oregon Hlth. and Sci. Univ., Portland, OR; [2]Oregon Hearing Res. Ctr. / Vollum Inst., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: The dorsal cochlear nucleus (DCN) is a cerebellum-like circuit positioned at the earliest stage of auditory processing in the brainstem. Auditory granule cells receive excitatory nonauditory input from mossy fibers. Parallel fibers are the axons of granule cells and project to DCN principal cells. Granule cells are subject to prominent inhibition, but the source of the inhibition is unknown. Using paired recordings in mouse brain slices (P16-24), we identified GABAergic, mGluR2-positive Golgi cells as at least one local source of inhibition to granule cells. Moreover, granule cells frequently made monosynaptic excitatory, facilitating synapses onto Golgi cells. Indeed, approximately 25% of connected granule-to-Golgi cell pairs were also connected in the Golgi-to-granule cell direction. Thus, feedback inhibition is a prominent feature of this circuit. However, most unitary granule-to-Golgi cell synapses were too weak to excite Golgi cells, indicating that multiple granule cells are required to drive Golgi cells. To monitor feedback inhibition, we therefore used extracellular stimulation of groups of parallel fibers in the DCN molecular layer to synaptically activate Golgi cells while recording from either Golgi or granule cells. Golgi cells were most effectively excited when stimulating parallel fibers at high frequencies, as expected due to the strong facilitation of parallel fiber synapses. Similarly, feedback inhibition onto granule cells also showed facilitation and was best recruited when stimulating parallel fibers at high frequencies. Facilitation of inhibition was surprising because Golgi-to-granule cell synapses exhibited prominent synaptic depression when Golgi cells were directly stimulated. The build-up of Golgi cell firing probability during parallel fiber stimulation may therefore mitigate depression of feedback inhibition. Our results suggest that feedback inhibition modifies information transfer between granule cells and their postsynaptic targets by selecting for particular patterns of mossy fiber activity.

Title: Cerebellar control of electronic coupling in the inferior olive I: Anatomy of the nucleo-olivary projection

Authors: *M. Y. UUSISAARI[1], Y. LEFLER[2], Y. YAROM[2];
[1]Optical Neuroimaging Unit, [2]Hebrew Univ. of Jerusalem, Israel, Jerusalem, Israel

Abstract: The olivo-cerebellar loop consists of cerebellar cortex, the cerebellar nuclei and the inferior olive (IO). The GABAergic projection from the cerebellar nuclei to the inferior olive (the nucleo-olivary (NO) pathway) has long been considered a critical part of the olivo-cerebellar circuitry and knowledge of its properties is critical for formulation of conceptual and computational models of the cerebellar function.

Specifically, it has been proposed that the cerebellar GABAergic input to the IO acts mainly via a shunting mechanism, reducing the coupling coefficient between the IO neurons. However, this proposed functionality has not been experimentally demonstrated.

In the present two works we employ targeted expression of optogenetic tools to I) examine the anatomical organization of this pathway and II) specifically activate the GABAergic nucleo-olivary axons in a spatially constrained manner.

In the first (anatomical) part of the study, we utilize single- and double labeling of the neuronal circuit elements (NO and IO neurons) by viral transfection as well as by intracellular filling of individual IO neurons via patch electrode. This allows us to create 3D reconstructions of the nucleo-olivary circuit structure. Examining the olivary volume thus labeled demonstrates that the extremely dense GABAergic innervation of the IO is mostly targeting dendritic locations. Furthermore, we explore the regional variation of the cerebello-olivary projection, prompting for further examinations of the components of this structure.

Title: Cerebellar control of electronic coupling in the inferior olive II: Optogenetic activation of the nucleo-olivary pathway modulates coupling coefficient and sub-threshold oscillations

Authors: *Y. LEFLER, M. Y. UUSISAARI, Y. YAROM;
Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The olivo-cerebellar loop consists of cerebellar cortex, the cerebellar nuclei and the inferior olive. The GABAergic projection from the cerebellar nuclei to the inferior olive has long been considered a critical part of the olivo-cerebellar circuitry and knowledge of its properties is critical for formulation of conceptual and computational models of the cerebellar function. Specifically, it has been proposed that the cerebellar GABAergic input to the inferior olive acts mainly via a shunting mechanism, reducing the coupling coefficients between inferior olive neurons. However, regardless of the importance of this pathway in the cerebellar network, due to technical limitations this proposed functionality has not been experimented.
In the present work we virally expressed ChR2 in GABAergic cells of the cerebellar nuclei and specifically activate the GABAergic nucleo-olivary axons in a spatially constrained manner in the inferior olive in-vitro. Using patch clamp recordings of inferior olive cells we show for the first time that GABA release from nucleo-olivary terminals has 3 significant effects: 1. reducing the coupling coefficient between pairs of olivary neurons. 2. Changing the asymmetry of the coupling 3. Completely eliminates the spontaneous subthreshold voltage oscillations of olivary neurons. These effects have substantial consequences on our understanding of the functional organization in the olivo-cerebellar system.

Abstract: The cerebellar nuclei (CN) play an important role in the temporal and spatial control of motor function. Despite the fact that the CN integrate information from the entire cerebellar cortex via axonal projections from the inhibitory Purkinje neurons (PNs), the anatomical organization of the PN to CN connectivity has been difficult to address due to technical limitation. In order to determine the manner in which information is being processed between the PNs and their target nuclei, we designed a viral transfection technique in which we achieved a differential expression of fluorescent reporters in CN neurons and PNs of adult mice. The resulting non-overlapping fluorescent expression pattern allowed confocal imaging and unambiguous reconstruction of both CN neurons and PN axons. This enabled the comparison of the varied PN innervation pattern among a population of different CN neurons. Examining the ratio of PN terminals innervating the CN soma versus dendrites demonstrated that at the population level most of the reconstructed CN cells had stronger PN innervation on the soma than on the dendrites; however, in a subpopulation of CN neurons the PN innervation was denser on the dendrites. The observed differences of connectivity pattern of PNs to CN point towards different readouts indicative of different PN activity input to the CN neurons, and call for further exploration of the CN neuronal diversity.

Title: Interconnections between the lateral cerebellum and the prefrontal cortex

Authors: *A. C. BOSTAN[1], R. P. DUM[1], P. L. STRICK[1,2];
[1]Neurobio., Univ. of Pittsburgh, PITTSBURGH, PA; [2]VA Med. Ctr., Pittsburgh, PA

Abstract: Kelly and Strick (‘03) proposed that cerebro-cerebellar connections are organized as closed-loop circuits. They demonstrated this structural arrangement for a motor circuit with the arm area of the primary motor cortex, and for a non-motor circuit with area 46 of the prefrontal cortex. In particular, area 46 sends projections to Crus II in the lateral cerebellar cortex and is a target of output from Crus II. Several other areas in the prefrontal cortex send inputs to the cerebellar cortex via the pons (Glickstein et al. ‘85) and are known targets of outputs from the lateral cerebellum (Middleton & Strick ’01). Here, we further explored how the connections between the lateral cerebellum and regions of the prefrontal cortex are organized at the level of the cerebellar cortex. We used retrograde transneuronal transport of rabies virus (RV) to investigate whether prefrontal areas that provide dense inputs to Crus II are also targets of output from Crus II. We injected RV into Crus II of cebus monkeys (n=3) and set the survival time at 42 hours to allow retrograde transport of RV to first-order neurons that project to the cerebellar cortex and then, retrograde transneuronal transport of RV from these neurons to second-order neurons in the neocortex. We observed RV labeling in several non-motor neocortical areas, with substantial numbers of labeled neurons in the rostral dorsal premotor cortex (pre-PMd) and lateral area 9 (9l) of the prefrontal cortex. We then injected RV into pre-PMd (n=2) and 9l (n=1) to determine whether these regions receive projections from Crus II. We set the survival time to 60 hours to allow retrograde transport of RV to first-order neurons in the thalamus that project to the cerebral cortex, retrograde transneuronal transport of RV from these neurons to second-order neurons in the cerebellar nuclei, and retrograde transneuronal transport of RV from the cerebellar nuclei to third-order neurons (Purkinje cells) in the cerebellar cortex. After injections of RV into either the pre-PMd or 9l, we observed large numbers of Purkinje cells labeled in Crus II. These results further support the hypothesis that prefrontal regions with dense inputs to Crus II are also targets of Crus II output. Interestingly, we observed potential regions of overlap between the areas in Crus II that send projections to pre-PMd, 9l, and area 46. This finding raises the question of whether the closed-loop circuits linking Crus II with the prefrontal cortex are distinct or

partially overlapping. Future experiments using dual labeling techniques will be necessary to answer this question and clarify the topography of connections between the lateral cerebellum and the prefrontal cortex.

Title: Projections from the cerebellar nuclei to the cerebellar cortex: A possible feedback to golgi cells in the cerebello-olivary loop

Authors: *L. ANKRI, Y. YAROM, M. Y. UUSISAARI;
Hebrew Univ. of Jerusalem, Jerusalem, Israel

Abstract: The cerebello-olivary feedback loop consists of an inhibitory connection originating from Purkinje neurons (PN) in the cerebellar cortex to the cerebellar nuclei (CN), followed by a projection to the inferior olive by inhibitory CN neurons. This pathway is considered a critical part of the cerebellar circuitry that is thought to control PN spiking via modulating inferior olivary activity. Additionally, there is anatomical evidence for an opposite synaptic pathway (the nucleo-cortical), directly connecting the CN to the cerebellar cortex (Tolbert et al., 1976). However, this pathway and the implied possibility of direct feedback from CN to the cerebellar cortex have been mostly ignored in physiological studies.
Notably, the anatomical evidence for nucleo-cortical pathway has not identified the postsynaptic targets in the cerebellar cortex. In this work we set to clarify this with electrophysiological recordings from adult mouse cerebellum slices. Electrical stimulation of the white matter between the CN and cerebellar cortex evoked inhibitory synaptic responses in Golgi cells, suggesting that they are among the targets of nucleo-cortical neurons. In addition to the electrophysiological experiments, we used specific viral transfections to anatomically examine the connection. We suggest that the main elements for this proposed connection are the glycinergic projection neurons of the lateral CN ("Gly-I"; Uusisaari & Knöpfel, 2010). Interestingly, unlike all other CN neurons, the Gly-I neurons are not spontaneously active but

show very short and fast bursts of spikes in response to synaptic input, possibly implying a role in controlling timing in the granule cell layer.

Title: The cytoarchitecture and neurochemical profile of the rat deep cerebellar nuclei with a focus upon nucleus interpositus

Authors: *J. P. CARD[1], D. W. VOLK[2], E. J. SENGUPTA[2], N. Z. KHAN[3], G. J. WOJACZYNSKI[3];
[2]Psychiatry, [3]Neurosci., [1]Univ. of Pittsburgh, Pittsburgh, PA

Abstract: The deep cerebellar nuclei (DCN) are complex computation units that integrate afferents from the cerebellar cortex and collaterals of axons entering the cerebellar hemispheres. Whereas the synaptic and functional organization of the cerebellar cortex is well described, DCN organizational principles are only generally understood, and it is not know if they differ among the deep nuclei. Data from a variety of experimental approaches suggest that functional localization within the cerebellar cortex is also represented in the DCN. For example, the dorsolateral portion of the anterior interpositus nucleus is known to mediate classical conditioning of the eyeblink reflex. Here we test the hypothesis that the DCN contain subfields distinguished by cytoarchitecture and the differential distribution of phenotypically defined neurons. In the first stage of the analysis the brain of an adult male Sprague-Dawley rat was paraffin embedded and sectioned serially at 12 μm/section. Sections at a frequency of 60 μm were stained with the Klüver-Barrera technique and subjected to detailed cytoarchitectural analysis. Distinct subfields in each of the DCN were distinguished by neuronal morphology,

cellular packing density, and the extent of neuropil. Morphologically distinct classes of neurons included 1) large, intensely basophilic, multipolar neurons ranging in size from 35 to 70 μm in widest diameter; 2) intensely basophilic neurons ranging from 25 to 35 μm in diameter; 3) small intensely basophilic neurons with a diameter less than 25 μm; and 4) small pale staining neurons less than 25 μm in diameter. In situ hybridization characterization of neuronal phenotype using a radiolabeled riboprobe generated against the glycine transporter 2 (GlyT2) supported the conclusion that cytoarchitecturally distinct classes of neurons were also distinguished by neurotransmitter phenotype. For example, GlyT2 mRNA+ neurons in nucleus interpositus were of intermediate size and distributed through all cytoarchitecturally distinct subfields, whereas GlyT2 mRNA+ neurons in the fastigial nucleus constituted two populations of neurons: large cells differentially concentrated in the ventral portion of the nucleus and neurons of intermediate size distributed throughout the nucleus. Ongoing studies using riboprobes generated against GAD65, GAD67 and vGlut1 mRNAs will provide further insight into the hypothesis that subfields of the DCN defined by cytoarchitecture can be further subdivided on the basis of transmitter phenotype. Collectively the data are consistent with a modular organization of the DCN and provide a strong foundation for defining the synaptology of each subfield.

Title: Model of interactions between spinal border cells and cerebellar granule cells

Authors: *A. SPANNE, P. GEBOREK, F. BENGTSSON, H. JÖRNTELL;
Lund Univ., Lund, Sweden

Abstract: Spinocerebellar systems are likely to be crucial for cerebellar hallmark functions such as coordination. However, in terms of cerebellar functional analyses, these are perhaps among

the least explored systems. The aim of the present study is to achieve activation of a single component of the spinocerebellar systems and to explore to what extent it can influence the spike output of granule cells. For this purpose, we took advantage of a unique arrangement discovered in neuroanatomical studies, in which the spinal border cell component of the ventral spinocerebellar system was found to be the only the only spinocerebellar tract which ascends in the contralateral lateral funiculus and have terminations in sublobulus C1 of the paramedian lobule in the posterior cerebellum. Using electrical stimulation of this tract, we found that a subset of the granule cells displayed high intensity responses whereas the majority of the granule cells displayed no response at all. A model of the spinocerebellar interactions was constructed, in which the integration of motor command signal and sensory feedback by SBC neurons during motor control was simulated using behavioral data. The model illustrates how this information becomes represented at the level of the granule cells. The implications of these findings for the view of the cerebellar cortex as a linear integration circuitry for multi-dimensional sensorimotor signals (Spanne and Jörntell (2013) PLoS Comp Biol) are discussed.

Abstract: Development and synaptic plasticity in complex neurons requires local protein synthesis. To clarify the mechanisms controlling protein synthesis in the Purkinje cell and in particular in its dendrites, we combined several technologies to specifically extract ribosomes from this neuron. As the main component of the protein synthesis machinery, the ribosome is transiently bound to the messenger RNAs being translated into proteins. By encoding a ribosome-binding probe (“TRAP”) into a virus vector targeted to PCs, we succeeded to capture several thousand ribosome-bound PC RNAs (translatome). Differential fractionation allowed us

to discriminate cytoplasmic polysome from ER-associated ribosomes. High-sensitivity NanoCAGE and deep-sequencing were then used to identify all the isolated RNAs, either as protein-coding sequences or as regulatory RNAs. Using microdissections to separate the PC dendrites from its cell body, we could identify a group of several hundred RNAs that appear to be transported into dendrites for remote translation. Interestingly, in addition to transcripts of protein known to be involved in synaptic plasticity, we also found that these ribosome-bound RNAs include a large fraction of transcripts with no known function, representing either novel genes or regulatory RNA sequences.

Title: A novel transgenic model for protecting motoric function from the repeated use of benzodiazepine

Authors: *M. E. JUNG, D. B. METZGER;
Univ. N Texas Hlth. Sci. Ctr., FORT WORTH, TX

Abstract: Purpose: Benzodiazepine (BZD) is the most prescribed CNS depressant in America to treat hyper-excitatory disorders such as anxiety and insomnia. However, a prolonged use of BZD often creates adverse effects including psychomotor deficit. In this study, we investigated a novel protective mechanism by which chronic BZD-induced motoric deficit can be minimized in mice. We tested the hypothesis that the down-regulation of p38 (stress-activated protein) in cerebellar Purkinje neurons contributes to protection for motoric function from chronic BZD use.
Methods: transgenic mice that were designed to lack p38 in cerebellar Purkinje neurons were generated by crossing Pcp2 (Purkinje cell protein 2)-Cre mice with p38loxP/loxP mice. When they reached 21 days old, genotyping was conducted using PCR. BZD injection (lorazepam, 0.5 mg/kg, IP) began when mice were two months old. Wild-type (C57BL/6 mice) or the transgenic mice lacking Purkinje p38 received BZD in the afternoon, and next morning they were tested on Rotarod in which a quicker fall from rotating rod indicates poorer motoric performance. This

procedure was repeated for 14 days. Cerebellum was then collected to detect p38 in Purkinje neurons and to measure mitochondrial respiration using immunohistochemistry and real-time XF respirometry, respectively.
Results: Compared to vehicle-treated mice, BZD-treated mice showed poorer motoric performance, a higher number of Purkinje neurons containing p38, and lower mitochondrial respiration. These effects of BZD were much smaller in p38-knockdown mice.
Conclusions: These results suggest that the excessive accumulation of p38 in cerebellar Purkinje neurons contributes to motoric deficit and mitochondrial respiratory inhibition associated with chronic BZD. Our findings may provide a new mechanistic insight into chronic BZD-induced motoric deficit.

Title: The mechanisms of late-onset synaptic responses in a realistic model of Unipolar Brush Cells

Authors: S. SUBRAMANIYAM[1,2], F. LOCATELLI[1], P. PERIN[1], S. MASETTO[1], S. SOLINAS[3], *E. D'ANGELO[1,3];
[1]Dept of Neurosci., Univ. of Pavia, 27100 Pavia, Italy; [2]Consorzio Interuniversitario per le Scienze Fisiche della Materia (CNISM), Via Bassi 6, 27100 Pavia, Italy; [3]Brain Connectivity Center, Inst. Neurologico IRCCS C. Mondino, Via Mondino 2, 27100 Pavia, Italy

Abstract: Unipolar brush cells (UBCs) are excitatory glutamatergic interneurons of the cerebellar granular layer receiving both primary and secondary vestibular inputs through mossy fibers (excitatory input) and Golgi cell axon (inhibitory input). When injected with a depolarizing current, the UBC generates a spike burst sustained by a low-threshold spike, which,

at higher current intensity, is followed by a tonic firing showing frequency adaption. The intrinsic excitability of UBCs is characterized by an H current and by Low Voltage activated and High Voltage activated calcium currents. Fast inactivating T-type Calcium channels generate the low-threshold spikes while L-type Calcium channel sustain tonic firing. The H current (activating in the hyperpolarizing direction) produces a slow hyperpolarization characterized by a ”sag” and a rebound depolarization at the end of a depolarizing step. Here we present a biologically realistic multi-compartmental mathematical model of the UBC realized with the NEURON simulator. According to experimental data, the model includes 9 different ionic channels generating voltage-dependent A-type M-type BK-type and DR-type K currents, Na (transient, persistent and resurgent) currents, T-type and L-type Ca currents, the H-current and the TRP-current. These channels are sorted and distributed among compartments (soma, dendrite, and axon). The UBC model faithfully reproduces the excitable properties of real UBCs. In particular, the model includes mechanisms capable of reproducing the recently characterised "late onset response" (Locatelli et al., 2013). These mechanisms are based on the modulation of TRP- and Ih-channels by the activation of G-protein-dependent intracellular pathways yielding to the increase of cAMP concentration. This model, in addition to confirm the primary role of the aforementioned currents in UBC's electroresponsiveness, will prove a valuable tool for investigating the UBC's function in the cerebellar network.

Title: Glutamate-activated currents in unipolar brush cells

Authors: *C. GLOGOWSKI[1], L. TRUSSELL[2];
[1]Vollum Inst. - Neurosci. Grad. Program, [2]Oregon Hearing Res. Ctr. / Vollum Inst., Oregon Hlth. & Sci. Univ., Portland, OR

Abstract: Unipolar brush cells (UBCs) of the dorsal cochlear nucleus (DCN) and vestibular cerebellar cortex receive glutamatergic mossy fiber input on a complex brush-like dendrite. Studies of cerebellar UBCs identified different subtypes of UBC based on immunohistochemical markers and physiological profiles. We have examined auditory and cerebellar UBCs with respect to the physiology of the mossy input and glutamate sensitivity. Patch-clamp recordings were made in brain slices from P16-30 mice. Extracellular stimulation evoked biphasic NBQX-sensitive EPSCs with a profile similar to that reported in cerebellum: a small, fast inward current followed by a very slow delayed inward current. However, in some cells a train of stimuli would result in a delayed outward current consistent with a glutamate-activated K^+ current. We determined the glutamate receptors expressed in UBCs by applying 1 mM glutamate as well as selective agonists and antagonists. A variety of response profiles were elicited, suggestive of different levels of expression of glutamate receptors and two different UBC subtypes. UBC subtype 1 had a biphasic inward current, which is primarily AMPAR mediated, with a small mGluR1α component. The biphasic AMPAR component is similar to the synaptically evoked current and strongly excited UBCs. In this cell type, mGluR2 mediated outward currents were extremely weak, and were thus overwhelmed by AMPAR-mediated currents. In contrast, UBC subtype 2 responded to glutamate with a prominent outward current, occasionally preceded by a small inward transient mediated by AMPAR. The mGluR2 mediated outward K^+ current caused a prolonged hyperpolarization of membrane potential and pause in action potential firing. The pause was followed by rebound high-frequency firing mediated by a hyperpolarization-activated current and voltage-activated Ca^{2+} channels. This subtype was mGluR1α negative. In summary, subtype 1 UBC had an excitatory response to glutamate, due to high expression of AMPARs and mGluR1α, and low expression of mGluR2. Subtype 2 UBC had an inhibitory response to glutamate due to a low expression of AMPARs and high expression of mGluR2 and GIRK channels. These UBC subtypes may function as ON and OFF cells in regard to their response to excitatory input, and may thus provide distinct processing of multisensory input to their targets.

Title: The TRPC3 moonwalker gain-of function mutation is accompanied by selective and complete ablation of type II unipolar brush cells

Authors: *J.-A. KIM[1], G. SEKERKOVÁ[2], E. B. E. BECKER[3], J. HARTMANN[4], L. BIRNBAUMER[5], E. MUGNAINI[2], M. MARTINA[1];

Abstract: Unipolar brush cells (UBCs) are glutamatergic interneurons in the cerebellar granule cell layer, which are enriched in the vestibulocerebellum. UBCs receive monosynaptic input from external mossy fibers, mainly the primary and secondary vestibular afferents and transfer signals to a myriad of granule cells through their axonal terminals (intrinsic mossy fiber). Thus, they are suggested to act as an amplifier of the vestibular signal. Recently data show that UBC can be divided into two histochemically and functionally different subtypes; type I and type II. In situ hybridization suggests that the UBCs may express TRPC3 (Schilling and Oberdick, 2009). In this study we investigated whether TRPC3 are indeed present in UBC. To this end we used immunohistochemistry and patch clamp recording from cerebella of wild-type and TRPC3-/- mice. Using UBC type specific markers mGluR1α (type I) and calretinin (type II) we show that TRPC3 channel are expressed selectively in type II UBCs. Moreover we show that activation of group I mGluR in type II UBCs gates TRPC3 channels. In moonwalker (MWK/+) mice, an ataxia model, which have a heterozygous dominant gain-of-function TRPC3 mutation, type II UBCs were totally ablated from 18 day-old when their ataxic behavior is obvious. Depletion of type II UBCs may contribute to the ataxic phenotypes of MWK/+ mice. We suggest that fine regulation of calcium influx through TRPC3 plays an important role in neuronal cell survival, especially, in type II UBCs, where no major calcium binding proteins have been identified so far.

Title: Early electrophysiological impairment of cerebellar Purkinje cells in the moonwalker mouse

Authors: *M. J. NIGRO, G. SEKERKOVA, E. MUGNAINI, M. MARTINA;
Dept. of Physiol., Northwestern Univ., Chicago, IL

Abstract: The moonwalker mouse is a recently described rodent model of ataxia. This mouse carries a gain-of-function mutation of the gene encoding for the TRPC3 channel; this mutation leads to increased mGLUR1 receptor-dependent activation of the channel and possibly to a constitutively open channel (Becker et al., 2009). The moonwalker mouse shows severe motor deficits such as gait abnormalities, retropulsion and impaired balance as early as 3 postnatal weeks of age. Additionally, moonwalker mice show altered dendritic development of Purkinje cells and a progressive loss of these neurons. Such morphological changes however only become apparent around 4 months of age and more pronounced from 6 months of age. Little is known about the mechanisms that account for the early development of the ataxia, which precedes the morphological changes by several months. The mismatch between the onset of the motor deficits and the loss of Purkinje cells suggests that different mechanisms might be involved in the generation of the phenotype. In the present work we study the intrinsic properties of Purkinje cells in moonwalker mice. Our results show that, already at three weeks of age, Purkinje cells of moonwalker mice, although normal in gross morphological features, show severe electrophysiological alterations. In particular, cell-attached recordings in acute slices from moonwalker mice showed that only ~10% of these Purkinje cells were spontaneously active, while all cells from control animals were spontaneously firing. Moreover, whole cell recordings showed a reduced excitability in response to depolarizing current steps, and a largely reduced voltage sag in response to hyperpolarizing current steps, suggesting a downregulation of HCN channels in these animals. These results show that intrinsic properties of Purkinje cells of moonwalker mice are severely affected at a very early developmental stage and suggest that these functional changes may contribute to the ataxic phenotype.

Title: Classification of fastigial/medial cerebellar nucleus neurons by quantitative single-cell gene expression profiling

Authors: *H. FUJITA, T. KODAMA, S. GUERRERO, S. DU LAC;
The Salk Inst. for Biol. Studies, La Jolla, CA

Abstract: Increasing evidence indicates that medial part of the cerebellum plays an important role not only in body posture and eye movements, but also in controlling physiological homeostasis, autonomic regulation, cognitive clarity, and emotional learning. However, the medial cerebellar (fastigial) nucleus (MCN), the sole output from the medial cerebellum, comprises multiple functional cell types that are spatially intermingled, making circuit studies challenging. To functionally classify MCN neurons and identify molecular handles for manipulating each cell type, we quantitatively profiled expression of genes related to neurotransmitters, ion channels, and marker gene candidates for individual MCN neurons, as reported previously in the medial vestibular nucleus (Kodama et al., 2012). The expression of transmitter-related genes and ion channel genes, including those controlling post-inhibitory rebound firing, are qualitatively and quantitatively differentiated across sampled MCN neurons, classifying them into at least three excitatory and three inhibitory cell types. Expression of marker gene candidates, such as *Spp1*, differed across cell types. Using such cell-type specific marker genes, we are identifying the projection targets of each cell type via retrograde tracing from known MCN targets, including parafascicular thalamic nucleus, periaqueductal grey, and lateral hypothalamus. Defining molecular and connectivity distinctions among medial cerebellar neurons will enable cell-type specific manipulation of motor, homeostatic, autonomic, and cognitive functions of the cerebellum.

Title: Lobule-Specific differences of hyperpolarization-activated current and rebound depolarization in cerebellar Purkinje cell

Authors: *J. SHIN, C. KIM, J. KIM, S. KIM;
Physiol., Seoul Natl. Univ. Col. of Med., Jongno-gu,Seoul, Korea, Republic of

Abstract: Purkinje cells (PCs), which are known as core neurons in cerebellar motor learning, integrate and encode multimodal afferent inputs of both excitatory and inhibitory information. As each lobule in the cerebellar vermis receives different sensory inputs, the information would be encoded in a lobule specific way. We have already reported that the membrane excitability of PCs are significantly different between spinocerebellum (lobule III-V) and vestibulocerebellum (lobule X) . Although sensory inputs into PCs are mainly excitatory, PCs also receive massive inhibitory synaptic inputs from the local inhibitory interneurons. However, the influences of inhibitory inputs on PCs have not investigated systematically. In this study we compared the change of membrane properties in PCs in response to hyperpolarizing current injection between lobule III-V and lobule X. We performed electrophysiological recordings using patch clamp technique from fresh brain slices of cerebellar vermis. Recordings under voltage-clamp mode showed that hyperpolarization-activated current (Ih current) was significantly larger in lobule X than lobule III-V. Relative sag amplitude, which means the proportion of sag amplitude to maximum hyperpolarizing amplitude during negative current injection, was also significantly higher in lobule X than lobule III-V . We measured first spike latency of rebound depolarization (RD)-associated bursts, which was significantly shorter in lobule X than lobule III-V . The rebound slope from the end of hyperpolarizing current injection to the threshold of the first spike of RD-associated burst was -0.197, -0.230, -0.254 at -60mV, -65mV, and -70mV in lobule III-V, and -0.336, -0.331, -0.332 at -60mV, -65mV, and -70mV in lobule X, which was not significantly different . RD amplitude under 1 uM TTX was significantly different between lobule III-V and X. These results indicate that electrical properties of PCs in response to hyperpolarizing current injection are significantly different between lobule III-V and X, which implies that signal encoding of inhibitory inputs in PCs may be implemented lobule-specifically.

Title: Postural control during transient floor translation while standing with the leg and trunk fixed

Authors: *N. KIYOTA[1], K. FUJIWARA[2], M. MAEKAWA[2], M. IREI[1];
[1]Osaka Hlth. Sci. Univ., Osaka, Japan; [2]Dept. of Human Movement and Health, Grad. Sch. of Med. Sci., Kanazawa Univ., Kanazawa, Japan

Abstract: When subjects are exposed to a postural disturbance, it is important to anticipate the disturbance timing and to prepare for the postural control. Thus, we have investigated event-related potentials (ERPs) that contain the contingent negative variation (CNV) and postural muscle activation pattern during the floor translation task (Fujiwara et al. 2011; 2012). CNV peak time showed a high correlation with the start time of continuously increasing electromyogram (EMG) in the postural muscles just before S2. However, individual differences were recognized in the postural muscles, due to the postural control strategy (Fujiwara et al. 2011). If postural movement is restricted mainly to the ankle, having common postural strategy among individuals, then a higher correlation would be found between CNV peak time and activation timing of a specific postural muscle. In this study, a cast brace that fixes the joints in the leg and trunk, but not in the ankle was made for each subject, and the relationship between CNV and postural muscle activity during postural disturbance was investigated. Twelve healthy young adults repeatedly underwent forward postural disturbance by a backward floor translation (S2) 2 s after an auditory warning signal (S1). Speed and amplitude of floor translation were set, based on the fluctuation of the center of foot pressure in the anteroposterior direction (CoPap) during extreme forward leaning. Under the fixation and non-fixation conditions, a set of 10 translations was repeated, at least 4 sets, until CoPap mean position during floor translation in the final set did not differ from that in the former-set. CNV, CoPap and EMG of the postural muscles in the last two sets were analyzed. In both conditions, CNV peaked just before S2. Around the CNV peak, activity of the triceps surae and CoPap started to increase and move forward, respectively. After S2, CoPap rapidly displaced forward and then moved backward. With the fixation, the CNV peak amplitude increased and the forward displacement of CoPap after S2 significantly decreased. Onset time of the triceps surae after S2 became earlier with fixation. This may be due to an increase in background activity of this muscle just before S2. In addition, activation onset time of the triceps surae just before S2 showed a high correlation with CNV peak time. These changes in postural control may be related to focusing of attention on the ankle joint movement. These findings suggest that it would be useful to execute the backward transient floor translation with the trunk and leg fixed as a muscle training method to improve dynamic balance focused on the triceps surae.

Title: Multi-muscle control of postural muscles: Common neural inputs

Authors: *A. SANTOS[1], C. LEONARD[1], A. DEGANI[2], V. CARDOSO[3], A. MAGALHAES[3]; [1]Sch. of Physical Therapy and Rehabil. Sci., The Univ. of Montana, Missoula, MT; [2]CNSAP, Londrina, Brazil; [3]Federal Univ. of Piaui, Parnaiba, Brazil

Abstract: The notion of muscle synergies has been viewed as a solution to the notorious problem of motor redundancy since it decreases the number of degree-of-freedom to be controlled by the postural system. Recently, it has been proposed that correlated neural input may be the mechanism used by the CNS to coordinate the formation of a synergistic group. In this particular study we investigated this hypothesis by analyzing the strength and distribution of correlated neural inputs to postural muscles previously recognized as synergistic for the execution of whole body tasks. Nine subjects performed the task of standing while holding a 5Kg barbell in front of their bodies at chest level. Subjects were asked to keep the quiet stand position as stable as possible for 10 seconds while the activity of four postural muscles were recorded by surface electrodes: Soleus (SOL), Gastrocnemius Medialis (GM), Biceps Femoris (BF), and Lumbar Erector Spinae (ERE). EMG-EMG pooled coherence estimates were computed taking into account five muscle pairs (SOL/BF, SOL/ERE, GM/BF, GM/ERE, and BF/ERE). The experimental conditions induced a significant increase in the muscle activation levels for all four muscles recorded. EMG-EMG coherence analysis revealed significant coherence estimates within three distinct frequency bands; <1Hz, 5-17Hz, and 23-45Hz. Significant coherence estimates significantly larger for lower frequency bands. These findings suggest the existence of common neural inputs distributed among multiple postural muscles forming a functional group. In addition, the occurrence of significant coherent muscle activation on multiple frequency bands suggests the existence of multiple sources involved on the generation of such common inputs.

Title: Statistical analysis of quiet stance sway in 2-D

Authors: *A. BAKSHI[1], P. DIZIO[1,2], J. R. LACKNER[1,2];
[1]Ashton Graybiel Spatial Orientation Laboratory, Brandeis Univ., Waltham, MA; [2]Volen Natl. Ctr. for Complex Systems, Brandeis Univ., Waltham, MA

Abstract: Spontaneous postural oscillatory behavior during quiet stance shows a stochastic, confined random-walk like trajectory. Its two-point temporal correlations, characterized by the stabilogram diffusion function (SDF), show a power law in the short time spans (τ) indicating positively correlated activity, and saturation at longer τ suggesting anti-correlation. Chow and Collins' (1995) 1-D stochastic continuum pinned polymer model (PPM) shows that such sway can be effectively mimicked by the dynamics of points along a flexible polymer with uniform density, under tension, driven by a stochastic forcing, while embedded in an elastic sheet with viscous drag that pins it to a local stable position. Our overall goal was to extend the 1-D PPM to a 2-D scenario, and use it and the SDF to assess adaptive learning.
Five healthy, adult subjects (age 20-65) passively stood in normal stance, eyes closed, on a force platform at the center of a rotating room. We compared the sway before (baseline), during, and after exposure to 10 rpm rotation. The parameters characterizing the SDF revealed adaptive changes in sway. At $\tau < 1$ s, the initial rise of the SDF showed power law dependence, $\tau^{1+0.5}$ to $\tau^{1+0.9}$, for AP and ML sway and all rotation periods. The absolute difference of the exponents was never more than 0.4. Onset and offset of rotation significantly increased both the intercept and the exponent compared to baseline. At $\tau > 1$ s, the SDF saturated to plateaus for all conditions except immediately after rotation onset where the SDF showed large variations. The SDF plateaus both during and after rotation were significantly different from baseline. A positive plateau residual of the post-rotation SDF versus baseline in the AP direction always correlated with a negative residual in ML, and vice versa, for all 5 subjects. The probability of this reciprocal ML/AP plateau pattern occurring by chance is 0.031. We extended Chow and Collins' 1-D PPM to an equivalent 2-D PPM because in a rotational environment the orthogonal Coriolis forces generated by sway movements lead to a 2-D sway coupling. Our 2-D PPM model correctly predicted the power scaling for the SDF and residuals for $\tau < 1$ for all the conditions. In future work, we will explore the relationship between the model parameters and adaptive learning and expand the 2-D PPM to predict the saturation levels at $\tau > 1$ s and explain the reciprocal relationship of the post-rotation AP and ML residuals.

Title: Muscle activation patterns in very slow walking are different from those of a natural gait

Authors: *R. MURAKAMI[1,2], T. KURAYAMA[1,2], Y. GOTO[1,2], Y. TANI[1,2], Y. TADOKORO[1], C. KONDO[1], K. SASAYA[1], D. MATSUZAWA[2], E. SHIMIZU[2], J. NISHII[3], K. KONDO[1], Y. OTAKA[1,4];

Abstract: [Objectives] Whereas there are infinite combinations of step length and step rate when one walks at a given speed, adult humans usually walk at an invariant ratio of step length divided by step rate (walk ratio) over a wide range of speeds, with little inter-subject variability. It has also been found that the muscle activation patterns in gait are invariant with respect to gait speeds. Researchers have shown that only 4 or 5 basic components of muscle activation patterns account for the majority of muscle activities during gait. We have confirmed, however, that at very slow speeds, the walk ratios were larger than those at preferred and faster speeds and that there was more inter-subject variability. Those results imply that very slow gait might be regulated by a different mechanism. The aim of this study was to explore whether the components of the muscle activation patterns in very slow gait are the same as those in normal gait. [Methods] Thirteen healthy subjects were enrolled in this study. Participants were asked to walk on a treadmill at speeds of 10, 20, 40, 60, 80 and 100 m/min. We recorded muscle activities from 16 unilateral leg and trunk muscles using surface electrodes. The EMG signals of each muscle were then normalized in time with the gait cycle and averaged over 20 step cycles. In accordance with the procedure of Ivanenko et al (2004), we applied a principal component analysis (PCA) to the normalized EMG data sets of each gait speed. The step rates were obtained from a motion capture system and step lengths were calculated from those step rates with the given treadmill speeds. [Results] As reported previously, the results of the PCA indicated that four principle factors accounted for about 90% of the total EMG signals across 16 different muscles at the gait speeds of 60 m/min and 80 m/min. On the other hand, at slower or faster speeds, some component waveforms by the PCA were different from those of 60 m/min and 80 m/min. At the very low speeds, we could no longer derive the basic components. Statistically

significant differences in walk ratios between the very slow speed and the others were also observed (p<0.05). [Conclusion] The basic components of the muscle activation patterns in gait are not invariant at very slow speeds. Walking at very slow speeds may not be regulated by the same mechanism as the cyclically patterned movements of natural gait at normal speeds.

Title: A comparison of movement characteristics between kneeling gait and regular gait after hemiplegic stroke

Authors: *Y. GOTO[1,2], T. KURAYAMA[1,2], R. MURAKAMI[1,2], Y. TADOKORO[1], Y. TANI[1,2], K. SASAYA[1], C. KONDO[1], K. AIMOTO[3], D. MATSUZAWA[2], E. SHIMIZU[2], K. KONDO[2], Y. OTAKA[1,4];
[1]Tokyo Bay Rehabil. Hosp., Chiba, Japan; [2]Chiba Univ. Grad. Sch. of Med., Chiba, Japan; [3]Natl. Ctr. for Geriatrics and Gerontology, Aichi, Japan; [4]Dept. of Rehabil. Med., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: [Background] Trainings in the kneeling position have been anecdotally used in physical therapy to improve postural control of patients with stroke. However, clinical evidence is lacking and the characteristics of movements in the kneeling position have not been well explored. The purpose of this study was to clarify the movement characteristics of gait in a kneeling position (kneeling gait) compared to those of regular gait in post-stroke patients. [Methods] Sixteen post-stroke patients (aged 65.0 ± 11.5 years) who could perform kneeling gait with or without assistance were enrolled in this study. The study was approved by the local ethics committee and all participants gave written informed consent. Participants were required to perform kneeling gait and regular gait at a self-selected comfortable speed. Surface electromyograms (EMGs) of the 6 gait-related proximal muscles from both sides were recorded. Center of mass (COM) displacements were measured using an optical marker at the spinous process of the third lumbar vertebra. The root mean square (RMS) of the EMG signals of 20 gait cycles in each muscle was obtained. Using the Wilcoxon signed-rank test, the RMS value in each

muscle and COM displacements were compared between kneeling gait and regular gait. The RMS ratio of the non-paretic side to the paretic side in each muscle was also compared between the two tasks. [Results] The COM displacement in the lateral direction was significantly larger in the kneeling gait compared to regular gait. On the other hand, the COM displacement in the vertical direction was significantly smaller in the kneeling gait compared to regular gait. There was no statistically significant difference in RMS values for any muscle between kneeling and regular gait. The RMS ratios of the non-paretic side to the paretic side showed a tendency for elevation in the kneeling gait compared to the regular gait. This tendency was statistically significant in the rectus abdominis and the gluteus medius. [Conclusion] Overall, no statistically significant differences in the muscle activations were found between the kneeling gait and regular gait at self-selected comfortable speeds in post-stroke patients. The results, however, indicate that there are some differences in utilization of the gait-related muscles between the kneeling gait and regular gait; namely, there is a tendency to rely on the non-paretic muscles more than the paretic muscles. These findings give us some information about the utility of the kneeling gait to enhance the gait-related muscle activations, though further investigation is necessary to apply the results to the whole post-stroke population.

Title: How dysfunctional is gait asymmetry? Association between metabolic cost and asymmetries in post-stroke walking

Authors: *J. M. FINLEY, A. J. BASTIAN;
Neurosci., Johns Hopkins Univ., Baltimore, MD

Abstract: Stroke survivors often have a slow asymmetric walking pattern. They also walk with an increased energetic cost relative to healthy, age-matched controls. It is often assumed that

spatiotemporal asymmetries are in some sense sub-optimal and therefore contribute to the increased energetic cost of walking in these individuals. As a result, one approach to locomotor rehabilitation is to alleviate asymmetries in foot-placement and timing. Although there is evidence that asymmetric walking patterns are energetically costly for healthy individuals, it remains to be seen if this holds true for stroke survivors. Here, we asked whether kinematic parameters describing post-stroke gait asymmetry explain the metabolic cost of walking beyond what is explained simply by the slowed speed. We used expired gas analysis to compute the metabolic power required to walk at four different speeds for 13 stroke survivors. Each participant walked at their self-selected speed, 80% and 100% of their self-selected speed, and their fastest comfortable speed. We also computed metabolic power for 10 age- and gender-matched control subjects who walked at the same speeds as their matched stroke survivor. Kinematic data from six, bilateral anatomical landmarks were recorded using a motion capture system and these data were used to compute the magnitude of the following kinematic variables characterizing interlimb asymmetry: step length difference, double support difference, difference in single limb support, and difference in swing times. A multiple regression was performed to determine the association between the dependent variable, metabolic power, and the independent variables of walking speed, group (stroke vs. control), and each of the kinematic parameters. The results of the regression revealed that speed, group, and step length difference were the only parameters that were associated with metabolic power. Speed alone predicted 73% and 82% of the variability in metabolic power in stroke survivors and controls respectively, and across all speeds, stroke survivors had a higher rate of energy use than controls. Step length difference was positively correlated with metabolic power and explained an additional 5% of the variability in power for stroke survivors. These findings highlight the influence of step length asymmetry on the metabolic cost of walking post-stroke, and provide a functional rationale for reducing asymmetry using interventions such as split-belt treadmill training.

Title: A marching-walking hybrid induces adaptation of step symmetry on a treadmill

Authors: *A. LONG[1], J. FINLEY[2], A. BASTIAN[2];
[1]Biomed. Engin., Johns Hopkins Univ., Baltimore, MD; [2]Neurosci., Kennedy Krieger Inst., Baltimore, MD

Abstract: Physical rehabilitation with a split-belt treadmill has the potential to correct for asymmetric stepping in stroke survivors. In split-belt adaptation, subjects walk on a treadmill with two belts, one of which is moving faster than the other. Healthy controls and cerebral stroke survivors can adapt their walking pattern during split-belt walking and de-adapt during post-adaptation exposure to regular treadmill walking. It is during post-adaptation that we see improvement in the symmetry of stepping in stroke survivors, though this effect is relatively short lived. Yet repetitive long-term training with the split-belt treadmill can improve post-stroke step length symmetry for months after training, suggesting that this might be a viable rehabilitation treatment (Reisman et al. 2013).
Split-belt treadmills are not easily accessible for physical therapy, whereas single belt treadmills are common. Here we asked if a level of adaptation similar to split-belt walking can be achieved by healthy subjects who walk with one foot on a moving belt while the other marches in place on a stationary belt (i.e. marching-walking hybrid). Subjects were required to march on the stationary belt to maintain a similar reciprocal gait cycle to that of normal walking. Subjects in the marching group adapted to a 1 m/s speed difference for 15 minutes and then de-adapted by walking with both belts at 0.5 m/s. A split-belt control group adapted to belt speeds of 0.5 and 1.5 m/s and then de-adapted with both belts moving at 0.5 m/s. This control group was exposed to the same difference in belt speeds as the marching group. Kinematics were recorded for leg and trunk movement using an Optotrak system. Step symmetry was calculated as the difference in step lengths measured from ankle to ankle.
Results showed that the major difference between the groups was the time course of adaptation and de-adaptation_the marching group was markedly slower compared with the walking group. Both groups experienced similar magnitude perturbations during early adaptation, achieved similar levels of step symmetry by the end of adaptation and showed similar magnitude aftereffects early in post-adaptation. These results indicate that a marching-walking hybrid can induce motor adaptation that is similar to that achieved on a split-belt treadmill. The fact that it takes longer to adapt and de-adapt may be advantageous for training stroke survivors, because it prolongs symmetric walking during post-adaptation in a single session. Furthermore, our findings suggest that physical rehabilitation with this march-walk paradigm potentially could be conducted on single belt treadmills. Supported by NIH HD048741.

Title: Lateral stability for single and multiple step recovery responses to lateral perturbations of standing balance in older adults

Authors: *M. FUJIMOTO, W.-N. BAIR, M. PRETTYMAN, B. BEAMER, M. ROGERS; Physical Therapy & Rehabil. Sci., Univ. of Maryland Baltimore, Baltimore, MD

Abstract: In prospective studies of older adults, an inability to recover from a lateral loss of balance with a single step is predictive of future falls. When balance is disturbed, the central nervous system appears to estimate current and future state of motion of the whole-body center of mass (COM) in relation to the base of support (BOS), which may determine the number and type of steps used to prevent falling. We hypothesized that the state conditions for dynamic stability at the instant of first step-off (SO) would differentiate multiple from single step recovery responses to lateral perturbations of standing balance.

Fifty-four healthy older adults received 60 randomly applied lateral waist-pull perturbations, while kinematic and ground reaction force data were recorded. Responses to the right lateral pull at 30cm/s were analyzed, where the largest number of subjects (n = 17) responded with crossover stepping using the left leg with both single and multiple steps. The COM and center of pressure (COP) positions in the medio-lateral direction were calculated with respect to the right foot BOS width. A single-link-plus-foot inverted pendulum model was used to define lateral stability boundary at SO. The stability boundary also was adjusted using the COP position at SO, considering it as a functional limit of the BOS. Stability margins were calculated as the shortest distance from the experimental data to the stability boundary defined based on both the actual and functional limits of the BOS. A paired t-test was performed to examine differences between single and multiple step responses with a significance level of 0.05.

At SO, a step was initiated later, relative to the pull onset, for multiple step responses than single steps ($p=.051$), resulting in a more laterally located COM ($p=.003$), that was closer to the lateral stability boundaries. Consequently, stability margins were significantly smaller for multiple steps than single steps ($p=.019$). Furthermore, the stability margin for multiple steps was not significantly different from zero when the functional limit was used for the stability boundary estimation, which implies that there was no margin for lateral stability at SO. This suggests that the stability margin based on the functional limit rather than the actual limit of the BOS better differentiated multiple from single step responses. These findings indicate that different protective stepping responses could be predicted by the COM motion state as early as first step-off. While stability margins could differentiate multiple from single step responses, the use of the functional limit provides a more sensitive estimation of the lateral stability boundary.

Title: Developmental changes in activation patterns of postural muscles during bilateral arm flexion

Authors: *T. KIYOTA[1], K. FUJIWARA[2], K. KUNITA[3], K. ANAN[3], C. YAGUCHI[4];
[1]Fac. of Humanities, Sapporo Intl. Univ., Sapporo, Japan; [2]Dept. of Human Movement and Health, Grad. Sch. of Med. Sci., Kanazawa Univ., Kanazawa, Japan; [3]Dept. of Sports Instruction, Fac. of Sports and Human, Sapporo Intl. Univ., Sapporo, Japan; [4]Dept. of Physical Therapy, Fac. of Human Sci., Hokkaido Bunkyo Univ., Eniwa, Japan

Abstract: We investigated developmental changes in activation patterns of postural muscles during bilateral arm flexion. A total of 176 subjects participated in this study (number of subjects (n): 4 years: n = 27; 5 years: n = 35; 6 years: n = 42; 7-8 years: n = 23; 9-10 years: n = 17; 11-12 years: n = 32). Subjects stood on the force platform with closed stance. In response to a visual stimulus (LED signal) presented at 1-3 s after a warning signal, the subjects initiated bilateral arm flexion as quickly as possible and then stopped their arms voluntarily at a horizontal position. After 5 practice trials, 10 test trials were performed with a 30 s-rest between the trials. EMG activity of the following muscles were recorded from surface electrodes: the anterior deltoid (AD), rectus abdominis, erector spinae (ES), rectus femoris, biceps femoris (BF), tibialis anterior (TA), and soleus. The reaction time of the activation onset of AD (D0) in response to the LED signal was measured. Time difference between D0 and the activation onset in the postural muscles were calculated as the start time of postural muscles. Activation rate calculated as the percentage of trials with the burst activation among 10 trials. AD reaction time in 4 years was the longest in all age groups, and the reaction time was significantly shortened with age. A significant effect of age was observed for the start time of ES, BF and TA. The start time of ES and BF was shortened with age, while TA was lengthened. The start time of ES was significantly earlier than D0 after 6 years. The start time of BF was significantly later than D0 in every age group. The start time of TA showed no significant difference with D0 in 4 years, while after 5

years, it was significantly later than D0. The activation rate of ES and BF was more than 90% in every age group and that of TA was about 50%. In adults, the activation onset of ES and BF precedes that of the focal muscles (AD) during bilateral arm flexion (Fujiwara et al., 2003). However, in the children, the preceding activation was observed in ES only and there was no preceding activation of BF even in the latter half of the childhood. Additionally, in adults, the activation rate of TA was less than 20% (Fujiwara et al., 2003). On the other hand, even in 11-12 years, children present results showed the relatively high activation rate of TA (about 50%). These results suggest that developmental changes in the postural muscle activation during bilateral arm flexion in the childhood is earlier in the trunk than in the thigh and lower legs, and even in the latter half of the childhood, the postural control accompanied by the muscle activation in the thigh and lower legs has not attained the adult-like postural control yet.

Title: Alterations in dynamic postural stability with exhaustive repetitive sit-to-stand exercise

Authors: *M. BRYANTON[1], M. BILODEAU[2];
[1]Bruyère Res. Inst., [2]Sch. of Rehabillitation Sci., Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Dynamic multi-articular activities of daily living, such as rising from a chair (sit-to-stand; STS), involve the displacement of limb segments and in turn one's centre of mass (COM). The STS movement not only requires the development of adequate resistive torques, but also precise control of one's vertical projection of COM over a rapidly reducing support surface at the moment of seat off. The purpose of this study was to investigate alterations in dynamic postural control due to fatigue accumulated from exhaustive repetitive STS movements. Voluntary dynamic range testing was performed in 10 healthy young adults, which involved measuring the extent to which each individual could voluntarily shift their centre of pressure (COP) towards the toes and heels without losing balance, under both eyes open (EO) and eye closed (EC) conditions. Maximal and minimal COP coordinates were collected before (PRE), immediately after (POST) and 10 min (RECOV) after a STS fatigue protocol. The fatigue protocol involved repetitive STS to a standardized pace until volitional exhaustion occurred. COP coordinates as

well as ankle, knee and hip joint angle positions were collected at moment of seat off throughout the fatigue protocol. Dynamic range testing indicated that although the EC condition significantly reduced dynamic range, and increased variance ($p=0.001$, and $p=0.002$ respectively) in comparison to the EO conditions, a significant fatigue effect was only seen with an increase in variance measures between PRE and POST ($p=0.004$). Because the STS movement requires higher efforts from the knee extensor in comparison the ankle plantar-flexor and hip extensor musculature, this finding suggests that dynamic voluntary range measurements are most likely dependant on ankle plantar-flexor force control capabilities, while accumulation of fatigue in the larger primary agonist muscle such as the quadriceps may have a role in reduced stability as indicated by increased variance when attempting to maintain the COP within the BOS. In turn, STS fatigue trial data indicated a significant anterior shift of the COP ($p=0.027$), which can be interpreted as a stabilization strategy occurring at seat off due to reduce knee extensor contractile performance with progression of fatigue. Based on previous investigations, it was expected that this would be associated with a compensatory reduction in knee flexion and an increased hip flexion, however, no significant changes in joint angles at moment of seat off were observed ($p>0.05$).

Title: Activation differences during internal and external rotational knee moments during standing target matching tasks in healthy and ACL injured patients

Authors: A. S. LANIER, K. MANAL, *T. S. BUCHANAN;
Delaware Rehabil. Inst., Univ. of Delaware, Newark, DE

Abstract: While many people have surgery to treat knee ligament ruptures (ACL deficiencies), others are able to cope with these injuries and do well without surgery because they adopt different neural control strategies. These individuals have been identified as *copers* and respond differently to tasks involving dynamic stabilization of the knee (Rudolph et al., 1998). The neural

control of knee joint stability involves controlling internal and external rotation (IER) of the tibia relative to the femur and improper control of IE stability has been associated with the development of osteoarthritis (Henrikksen et al., 2012). We are studying how ACL injured subjects compensate for internal and external rotations during a standing target matching task. In this study we compare IER knee moments of three groups: healthy uninjured controls, those with ACL deficiency 1 year after injury who have not had surgery (ACL-d 1yr), and those who have undergone reconstruction (ACL-r).
The 3 subject groups included 8 healthy subjects (4M, 4F), 5 ACL-d 1 yr. subjects (5F), and 8 ACL-r subjects (5M, 3F). During each test, subjects stood barefoot with each foot on a separate force plate. They were given visual feedback of the AP and ML shear forces that one foot exerted on the force plate, visualized by a cursor. Subjects were instructed to move the cursor representing these forces into a target that represented force in the AP-ML plane. Targets appeared at 20° increments around a circle with zero force at the center. Forces in the contralateral limb, the limb not controlling the cursor, were used in the data analysis, as this was the limb of interest. The cursor was required to be at each target for 500ms, and a total of 72 targets were examined. The IE knee moment was determined in the contralateral limb (the one *not* controlling the cursor) using inverse dynamics.
We observed that the shear forces from healthy and ACL-r knees were statistically indistinguishable. However, subjects who did not receive ACL reconstructions (ACL-d 1yr subjects) activated their muscles to have significantly greater IER knee moments compared to both healthy and ACL reconstructed knees, especially during forces involving anterior shear. This implies that subjects with ligament deficiencies use different strategies to stabilize their joints.

Title: Whole-body controlled video games improve dynamic stability in children with degenerative cerebellar disease

Authors: *W. ILG[1], C. SCHATTON[1], B. MUELLER[1], N. LUDOLPH[1], L. SCHOELS[2], M. A. GIESE[1], M. SYNOFZIK[2];
[1]Cognitive Neurology, Section Computat. Sensomotorics, Ctr. For Integrative Neurosci., Tuebingen, Germany; [2]Dept. of Neurodegeneration, Hertie Inst. for Clin. Brain Res., Tuebingen, Germany

Abstract: Background: The cerebellum is crucial for motor control (e.g. of gait and posture) and motor learning. Therefore, motor rehabilitation in patients with degenerative cerebellar disease is challenging, and the capability of motor improvements for these patients is not fully understood. We have recently shown, that a 8 weeks motor training program based on playing whole-body controlled video games can lead to a reduction of ataxia symptoms and an improvement in gait in children with degenerative cerebellar disease (Ilg 2012). In this study, we examined quantitatively, whether this motor training leads to - specific improvements in motor control of complex whole-body movements, which are relevant in everyday life and which cannot be explained simply by improvements in general fitness
Methods: To assess the specific effects of motor training, we analyzed the movement behavior during playing the Xbox Kinect™ game "Light Race" of 10 children with degenerative cerebellar disease versus 10 age-matched controls. Here, subjects have to control an avatar performing one minute sequences of rapid stepping movements towards different goals. Cerebellar children were tested in this game before and after an 8 weeks training program including different video games focusing on dynamic balance, trunk-limb coordination and goal-directed movements. The rapid stepping sequences during game playing were analyzed with respect to dynamic stability (Hof 2005), multi-joint coordination, anticipatory postural adjustments and movement variability.
Results: After 8 weeks training, children improved their general game play with respect to games scores, increased averaged velocity and dynamic stability. In addition, specific measures revealed (a) improved anticipatory postural adjustments before stepping ($p=0.04$), (b) decreased movement decomposition ($p=0.01$), (c) decreased movement variability during stepping ($p=0.04$) as well as increased dynamic stability at the end of the stepping movements ($p=0.01$).
Conclusion: Despite progressive cerebellar degeneration children are able to improve specific aspects of motor performance in complex whole-body movements which are relevant in everyday life (e.g. rapid stepping movements to compensate for gait perturbations). Therefore, directed training of whole-body controlled video games present a highly motivational, cost-efficient and home-based rehabilitation strategy to train dynamic balance, multi-joint coordination and interaction with dynamic environments in a large variety of young-onset neurological conditions.

Title: Assessment of Forces in the palm of the hand in amputee football players during crutch walking, running and shooting

Authors: *S. UZUN[1], N. RAMAZANOGLU[1], Y. TATAR[1], F. CAMLIGUNEY[1], C. KARAGOZOGLU[1], A. POURMOGHADDAM[2];
[1]Physical Educ. and Sport, Marmara Univ., Istanbul, Turkey; [2]Mem. Bone and Joint Res. Foundation- Dept. of Orthopaedic Surgery-Medical Sch., Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX

Abstract: Introduction: In amputee football players have one leg amputee/limb deficiency and use bilateral crutches. Instead of daily prosthesis, amputee football athletes depend on the Loftstrand crutches on the field during walking, running and shooting. The forces on the body are significantly increased at forearms and hands during ambulation with crutches. Since they utilize their arms for bearing body weights, players have to cope with the high loads encountered during high-speed crutch running or shooting. Thus, in these individuals strength of the upper extremity is a key factor to minimize shoulder, elbow and wrist injuries.
Aim: The purpose of the study was to measure forces at the palm of the hand in the stance phase during walking, running and shooting for seven professional amputee soccer players.
Method: The study included seven licensed amputee football players (amputation duration: 42.1±29.3 months; height 172.5±7.97 cm; weight: 63.0±12.6 kg; BMI 21.05±3.07) with unilateral left leg amputation/limb deficiency. The subjects were asked to walk and jog at a comfortable pace on a 20-meter track with Lofstrand crutches. Using an acceleration distance of 3 m, athletes performed penalty shots with crutches.
A F-Grip system (Tekscan Inc, boston, USA) equipped with high-resolution sensors built into a glove was used to assess the impact forces. Dynamic forces at the palm of the hand were recorded during walking, running and penalty shooting.

Results: The measured forces at the palm of the hand were significantly higher immediately before the penalty kick with crutches ($p<0.05$) compared to the running condition. There were no significant differences between the side of amputation and the healthy side regarding palm forces ($p>0.05$).
Conclusions: In the game, Lofstrand crutches transmit forces to the hand and can cause upper extremity injuries that might be correlated with body weight and increasing speed during the stance phase. In order to prevent injuries in amputee football players, the determination of high loads encountered during each movement pattern is important and training regimens should be designed and optimized for increasing strength of the upper extremity.
In addition a proper crutch gripping strategies should be taught to players that may enable them to squeeze the crutches forcefully only during the stance phase of the crutches to further prevent related injuries.

Title: Differential effect of chronic undernutrition on the postnatal development of gait in male and female wistar rats: A kinematic study

Authors: V. MARTÍNEZ-ÁLVAREZ[1], J. GUADARRAMA[2], B. SEGURA-ALEGRÍA[3], *M. ALVARADO[1], I. JIMÉNEZ-ESTRADA[2];
[1]Neuroetology Inst., Xalapa, Veracruz, Mexico; [2]Physiology, Biophysics and Neurosci., CINVESTAV-IPN, México, D.F, Mexico; [3]Biol. Dept., UNAM-FES Iztacala, México, Mexico

Abstract:
This study was aimed to analyze the possible effect of chronic undernutrition on the postnatal development of the gait in female and male rats. Adult Wistar were maintained under different feeding conditions: A) Control group: the rats and their offspring had free access to water and food. B) Undernourished group: three weeks before mating and during gestation, lactation and post-weaning periods the puppy rats were fed with half the food ingested by control animals (each group n=8 per litter). The kinematic analysis of gait activity was performed once a week,

for 9 weeks from the 4th or 5th day of life of the offspring (the day of birth was considered as P0). Once quantified the weight, height and body mass, the following hindlimb joints were inked with a permanent nontoxic: whilst, hip, knee, ankle, and toe, then the unrestricted animal gait was videotaped over an acrylic passeway. The Cartesian coordinates of each joint were determined frame by frame by using the ImageJ program (NIH). Using a video-assisted computerized system developed in our lab it was measured the length, duration and speed of each animal stride (data obtained from stride length and speed was normalized according to the body mass of animals). Chronic food deprivation induces a significant reduction in the morphometric parameters of male (P> 0.01) but less in female rats. At post-weaning stages of development, the gait of undernourished male rats is characterized by strides of lower duration (25-30%) but higher normalized length (146.7 to 199.0%) and notorious higher stride speed (158.0 to 657.1%) than the strides of control male rats (P> 0.01). Meanwhile, the gait of undernourished female rats was practically similar to that of control female rats, at all the postnatal ages analyzed.
According to our results, it is suggested the existence of gender differences in the alterations evoked by chronic undernutrition on the postnatal development of gait in the rat.

Title: The neural control of joint state in the rat

Authors: *M. C. TRESCH[1], B. RELLINGER[2], T. SANDERCOCK[3];
[1]Biomed Engin. & Physical Med. & Rehab, Northwestern Univ., CHICAGO, IL; [2]Biomed. Engin., [3]Physiol., Northwestern Univ., Chicago, IL

Abstract: Understanding why the central nervous system (CNS) uses a particular set of muscle activations during behavior is usually considered in the context of how muscles affect task level variables: how does activation of a muscle contribute to the limb kinematics or joint torques

necessary to achieve desired task goals? However, muscles also affect variables related to joint state, such as contact forces between bones or ligament strains. We examine here whether such joint state variables might also be considered by the CNS when determining muscle activation patterns.

We cut the nerve to vastus lateralis (VL) in the rat and examined the adaptations in EMGs and kinematics over a period of 2 months. EMGs were implanted in up to 15 hindlimb muscles and recorded during treadmill locomotion. In separate experiments, we have shown that because of the deep patellar groove in the rat VL and vastus medialis (VM) produce very similar joint torques across the skeleton when stimulated in vivo. Rectus femoris (RF) has a similar action at the knee as these muscles, but also produces a hip flexion torque. If the CNS regulated only joint torques, one would expect compensation to loss of VL to involve increased activation of VM, avoiding the hip torque produced by RF. However, we have also shown that VM and VL produce distinct mediolateral forces on the patella. Note that these different patella forces have no direct effect on task performance. If the CNS regulated joint state variables related to patellar forces, one would expect compensation to involve increased RF activation since RF does not produce a mediolateral force on the patella.

In 3 of 4 animals, we found that loss of VL initially (1-3 days) caused a substantial reduction in knee extension, along with substantial alterations in ankle and hip angle trajectories. Activation of RF and VM was increased while early stance phase activation of hamstring muscles was reduced. Following 2 months of adaptation, hip and ankle kinematics were similar to those before the cut and knee extension was mostly restored. Activation of RF remained increased but activation of VM returned to levels similar to those observed before the cut, as did activation of hamstring muscles. The preferential increase in RF at later time points suggests that the CNS does regulate joint state variables, minimizing unbalanced forces on the patella. However, activity in VM was not eliminated, suggesting either an incomplete adaption or that regulation of joint torques also played a role in determining adaptation patterns. These results suggest that joint state variables, in addition to task relevant variables, are used by the CNS to determine muscle activation patterns during behavior.

Title: Altered cortical excitability during trunk postural control

Authors: *S. GOTTARDI, S.-Y. CHIOU, P. H. STRUTTON;
Imperial Col. London, London, United Kingdom

Abstract: The muscles of the trunk become active during limb movements, to stabilise the torso; this is known as postural adjustment. These muscles are also activated during voluntary movements of the trunk such as flexion and extension. The extent to which the primary motor cortex is involved in controlling these muscles in each of these different tasks is unclear. Thus, the purpose of the present study was to investigate the corticospinal excitability of the back muscles during tasks with differing postural components.
Twenty healthy adults were recruited (10 female; mean age: 21.7). Bilateral electromyographic (EMG) activity was recorded from erector spinae (ES) at vertebral level L4, rectus abdominis and anterior deltoid. Subjects performed 3 tasks separately; dynamic shoulder flexion (DSF), static shoulder flexion (SSF) and static trunk extension (STE). Transcranial magnetic stimulation was applied over the hot-spot for the contralateral ES muscles at 120% active motor threshold during the tasks. Ten motor evoked potentials (MEPs) were obtained during each task. The background EMG in the ES muscle of interest was measured during the DSF and this was matched by the subject for the static tasks using visual feedback. The procedure was repeated on the other hemisphere. Corticospinal excitability was assessed by measuring the amplitudes of the ES MEPs, these were compared for differences across tasks.
There were significant differences in the MEP amplitudes between the 3 tasks for both hemispheres ($P<0.001$). With right hemisphere stimulation, the MEP amplitudes in the left ES were significantly larger in the DSF (mean±SD mv:0.64±0.41) compared to the other tasks (0.36±0.35, SSF and 0.41±0.44, STE; $P<0.001$). Similarly, with left hemisphere stimulation, the MEP amplitudes in the right ES were significantly larger in the DSF (0.59±0.40) compared to the other tasks (0.36±0.27, SSF and 0.38±0.31 STE; $P<0.001$). The MEP amplitudes were not significantly different between the 2 static tasks for either hemisphere.
The results of the present study indicate that during the dynamic task there is a greater degree of motor cortical involvement controlling the trunk muscles than during the static tasks. This supports the growing body of evidence of cortical involvement in postural control. However, it is not clear why the static task with a postural component (SSF) did not show an increase in cortical excitability over that seen in the voluntary trunk contraction. Overall, these results may be pertinent to patients with low back pain, where altered postural control and cortical excitability have been reported.

Title: Head control is affected by trunk and neck bracing during gait

Authors: *S. MORRISON[1], K. KELLERAN[2], D. RUSSELL[3];
[1]Physical Therapy, [2]Human Movement Sci., [3]Physical Therapy and Athletic Training, Old Dominion Univ., Norfolk, VA

Abstract: When walking, an ongoing control problem faced by the human neuromuscular system is to ensure the impact of gait-related oscillations on head motion is minimized. One possible means by which the system minimizes head motion during gait is through the damping properties of the trunk. The aim of this study was to investigate the effect constraining motion of the trunk and neck (through external bracing) has on 3D head acceleration during walking. Twelve healthy adult individuals were required to perform 3 straight-line walking trials along a 70m level walkway at their preferred walking speed. Changes in movement dynamics were assessed under four conditions; 1) Control (no bracing), 2) Neck brace only, 3) Trunk brace only, and 4) Both neck and trunk braced. Three lightweight tri-axial accelerometers, attached over the occipital pole (head), C7 spinous process (neck), and L3 spinous process (trunk) were used to measure trunk and head acceleration during the walking activity. Data analysis involved assessing changes in amplitude (mean RMS), regularity (Approximate Entropy, ApEn) and smoothness (harmonic ratio) of the respective acceleration signals as a function of the bracing condition. As predicted, the combined effect of bracing both the neck and trunk had the greatest impact on head acceleration patterns and general gait dynamics. Under these more restricted conditions, the pattern of regularity (ApEn) and smoothness (harmonic ratio) of the head acceleration signal in the vertical, ML and AP directions was notably different from that observed under the unbraced (control) conditions. Together these results illustrate that restricting the motion of trunk-neck segments has a significant impact on head motion, and that these changes have a top-down effect for the overall gait dynamics.

Title: Investigating lower extremity functioning via frontal plane movement variability asymmetries during landing

Authors: *A. D. NORDIN, J. S. DUFEK;
Kinesiology and Nutr. Sci., Univ. of Nevada, Las Vegas, Las Vegas, NV

Abstract: The purpose of this research was to examine bilateral differences in frontal plane lower extremity range of motion (ROM) variability during drop landings. Movement variability was used to assess neuromotor functioning, the ability of the motor system to vary internal loads, and subsequent injury susceptibility. Group and single-subject analyses were carried out to explore motor responses to varied task demands, explored through changes in landing height. Kinematic movement variability was assessed via frontal plane lower extremity joint ROM at the hip, knee and ankle joints. Fourteen participants (7 male, 7 female; mean age 22.64±3.41 years; height 1.71±0.10m; mass 67.56±10.31kg) free from previous lower extremity injury were examined. Participants completed 5 bilateral drop landing trials at 5 successive drop heights, computed as a percentage of maximum vertical jump height (MVJH; 20%, 60%, 100%, 140%, 180%). Kinematic data were acquired using a 12-camera Vicon system (200Hz), and 35 marker spatial model. Variability was expressed using coefficient of variation. Comparisons were made via a group 2x3x5 (limb x joint x height) repeated measures ANOVA, as well as 2x5 (limb x height) repeated measures ANOVAs for each participant. Group analysis revealed a significant interaction between limb and height ($F(2,26)=18.36$, $p<.001$, $\eta^2=.586$), where the left (32.8±17.1%) and right limbs (23.7±13.2%) differed at the 20%MVJH landing height ($t(41)=2.95$, $p=0.005$). Additionally, a significant main effect for lower extremity joint demonstrated that the knee (26.1±15.8%, $p=.009$) and ankle joints (20.0±12.6%, $p<.001$) showed significantly lower frontal plane ROM variability relative to the hip (35.4±17.2%). Single-subject analyses highlighted a significant limb by height interaction in a single participant ($F(4,8)=3.98$, $p=.046$, $\eta^2=.666$). Similarly, a significant main effect for limb was shown in a single participant ($F(1,2)=20.91$, $p=.045$, $\eta^2=.913$), while significant main effects for height were shown among 2 participants ($F(4,8)=9.20$, $p=.004$, $\eta^2=.821$, $F(4,8)=6.34$, $p=.013$, $\eta^2=.760$, respectively). From this examination, it is suggested that although the grouped model provides insight into the average movement variability response to alterations in task demands, single-subject analyses allow insight into motor functioning at the level of the individual, potentially demonstrating susceptibility to injury as a result of inter-limb control differences. This avenue of research has practical implications, but also sheds light into fundamental control processes associated with gross motor tasks, which shows considerable variation among individuals.

Title: Control of landing during forward-induced stepping for balance recovery in healthy young adults

Authors: *M. INACIO, R. CREATH, M. ROGERS;
Physical Therapy and Rehabil. Sci., Univ. of Maryland Sch. of Med., Baltimore, MD

Abstract: Protective stepping is a commonly used strategy to stabilize posture and prevent falls when balance is disturbed. Previous results suggest that elderly subjects who respond to balance perturbations with multiple steps are more likely to fall. This study investigated the dynamic features of the first-step landing for single and multiple balance recovery steps after forward waist-pull perturbations for young healthy adults in order to determine the importance of first-step landing in successfully preventing multiple recovery steps.
Twelve healthy young adults received forward waist-pulls via a computer-controlled robotic puller at a magnitude chosen to induce a stepping response. Recovery responses were classified as successful (single step) or unsuccessful (multiple steps) at foot contact (FC), peak vertical ground reaction force (FzPeak), and the interval between these events (BTWN). Kinematic and kinetic data were used to determine body segment and center of mass (COM) motion characteristics, as well as ankle, knee, and hip joint moments and powers. Between-group comparisons were performed using independent samples t-tests (significance: $p \leq 0.05$).
Six subjects were successful and six unsuccessful in preventing multiple recovery steps. Both groups demonstrated similar body segment kinematics and first step length. The unsuccessful group tended to use a wider step. Peak net joint moments were higher for the unsuccessful group at BTWN and FzPeak for the stepping-limb ankle, knee and hip joints. Except for BTWN, the unsuccessful group produced more positive net power for ankle, knee and hip joints while the successful group appeared to prevent multiple steps by absorbing energy at the hip joint. For successful stepping trials subjects had a more posteriorly-extended trunk orientation at FzPeak. Although vertical COM motion and momentum were not significantly different between the groups, antero-posterior COM velocity and momentum tended to be higher in the unsuccessful group. For the unsuccessful stepping trials subjects had a more anteriorly-positioned COM and smaller stability margins, which tended to progressively increase from FC to FzPeak.
The results of this study suggest that: 1) the ability to successfully prevent multiple recovery steps and arrest forward body motion following forward balance perturbations is dependent on first-step landing dynamics; 2) even among healthy younger adults there are individuals who rely on multiple steps to recover their balance. Future efforts will apply these results to elderly high

fall-risk individuals to determine if task-specific training can improve first-step landing dynamics and reduce falls.

Title: Kinematic strategies underlying step responses to postural perturbations

Authors: R. A. MCGOVERN[1], J. CORTES-RAMIREZ[2], P. GREENE[2], G. M. MCKHANN II[1], *P. MAZZONI[2];
[1]Dept Neurosurg, [2]Dept Neurol, Columbia Univ., NEW YORK, NY

Abstract: Taking a step is a major strategy used by humans to recover balance when posture is perturbed. While this response involves a complex set of well-characterized biomechanical, muscular, and kinematic components, a quantitative description at the level of controlled motor variables is lacking. We hypothesized that the stepping response is functionally a kinematic task, and specifically: 1) the disturbance that is ultimately relevant is the initial movement of the body's center of mass (COM), and not the magnitude of disturbing force; 2) the response that mediates recovery is appropriate placement of the stepping foot relative to the moving COM, regardless of forces exerted by the feet; 3) scaling relationships should exist among specific kinematic variables that characterize disturbance and response. Therefore we sought to provide a kinematic account of postural stepping by applying a postural perturbation and studying the initial body motion and the subsequent movements of the stepping feet.
We tested 7 young healthy subjects on a modified version of the clinical pull test and recorded their movements with a motion capture system. Subjects were pulled from behind multiple times, each time with an intensity randomly selected across a wide range. We then tested for correlations among kinematic variables for the COM's initial motion and for the step response. All subjects recovered balance in one step. The stepping foot's placement was tightly linked to the COM's position and velocity at the time of foot landing, consistent with a predominantly kinematic strategy for posture recovery. Of the variables that determine foot placement, step size

was strongly correlated with perturbation intensity, and this correlation was greatest with peak initial COM acceleration. Correlations with COM acceleration were weaker for reaction time (foot lift-off time), and absent for step duration. The postural step response may thus be described as taking a step whose amplitude is scaled to the kinematics of the postural disturbance in order to stop the body's motion. This scaling relationship offers a functional description of the normal postural step response, and may be a candidate descriptor of response adequacy in patients with specific types of postural instability.

Title: Postural coordination pattern as a function of scaling the surface of support dynamics

Authors: *J. KO, J. H. CHALLIS, K. M. NEWELL;
The Pennsylvania State Univ., University Park, PA

Abstract: This study investigated the organizational properties of postural control system as a function of the continuously scaled support surface dynamics. We examined how the number and nature of the dynamical degrees of freedom in the movement coordination patterns changed as a function of the frequency of the support surface and a practice. 12 young adults stood on a moving platform that was sinusoidally translated in the anterior-posterior (AP) direction. Dynamics of the support surface was driven by its frequency that was continuously scaled up from 0.2 Hz to 1.3Hz within a trial at a fixed 16cm amplitude. Task was to maintain postural balance on the moving platform having practice for 3 days. 4 joint angular motions (ankle, knee, hip, and neck) were recorded by 3D motion analysis system and used to run principal component analysis (PCA) to estimate the number of dynamical degrees of freedom of the postural coordination patterns. Continuous relative phase was quantified to investigate coordination patterns between two joint angular motions. PCA revealed that, in early practice, the modal number of dynamical degrees of freedom of the coordination pattern was 3 in the lower frequency conditions (< 0.7 Hz) and 2 or 3 in the higher frequency conditions. With practice, however, the coordination patterns were organized by 2 dynamical degrees of freedom in the higher frequency conditions (> 0.8 Hz). The relative phase analysis revealed that the ankle-hip

coordination was highly variable in the lower platform frequency (0.2 ~ 0.5Hz), whereas it showed the anti-phase pattern () with low variability as a function of the platform frequency and practice. However, the ankle-knee and knee and hip coordination did not show any particular patterns having higher variability across the platform frequencies and practice. Continuously scaled support surface dynamics induced different organizational properties of coordination patterns and it was influenced by practice. Particularly, in the higher frequency conditions, postural control system was constrained by the stable ankle-hip coordination to preserve postural stability. This study has revealed how the postural control system manages a number of joint space degrees of freedom for redundant postural tasks and provided evidence on a particular optimal solution to preserve postural stability.

Title: Inter-joint dynamic interaction during human quiet standing examined by induced acceleration analysis

Authors: *S. SASAGAWA[1], M. SHINYA[1,2], K. NAKAZAWA[1];
[1]Grad. Sch. of Arts and Sciences, The Univ. of Tokyo, Tokyo, Japan; [2]Japan Society for the Promotion of Sci., Tokyo, Japan

Abstract: Recent studies have demonstrated that controlling human quiet standing is one of the multi-joint movements (Hsu et al. 2007; Pinter et al. 2008; Sasagawa et al. 2009), in which the central nervous system (CNS) is required to deal with dynamic interaction among the joints to achieve desired motor performance. The purpose of this study was to investigate how the CNS deals with such inter-joint interaction during quiet standing by examining causal relationship between kinetics (torques) and kinematics (angular accelerations) within the multi-degree-of-freedom body. In this study, the standing body was approximated as a double-link inverted

pendulum (with ankle and hip joints) rotating in the sagittal plane. We conducted a novel analysis called “induced-acceleration analysis” (Zajac et al. 2002) to quantify the mutual contributions of net torques (sum of the joint torque, angular-velocity dependent torque, and gravitational torque) of the ankle and hip joints to induce the angular accelerations in each joint. As a result, we found that the net ankle and hip torques induced angular accelerations of comparable magnitudes in each joint. In addition, the angular accelerations induced by the net ankle and hip torques were consistently counter-directed to one another in each joint. With such quantitative and temporal relationships, the angular accelerations induced by the two net torques counter-compensated, and thus, the amplitudes of resultant, measured angular accelerations of the individual joints were substantially reduced. These results suggest that the CNS may take advantage of inter-joint interaction to reduce combined effects of the individual net torques on each joint motion during quiet standing.

Title: Perturbation motor corrections correlate with features of reaching and proprioception impairments post-stroke

Authors: *T. BOURKE[1], S. D. BAGG[2], S. P. DUKELOW[5], K. E. NORMAN[3], S. H. SCOTT[4]; [1]Ctr. for Neurosci. Studies, Queens Univ., Kingston, ON, Canada; [2]Physical Med. and Rehabil., [3]Sch. of Rehabil. Therapy, [4]Dept. Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada; [5]Univ. of Calgary, Calgary, AB, Canada

Abstract:
Limb afferent feedback is used for perception of our limb geometry and for motor control. Stroke can damage sensory and motor regions of the brain leading to impairments of upper limb function. Our previous work found that deficits in position sense were independent of deficits in reaching performance. This independence is surprising given that limb afferent feedback plays an important role in voluntary motor action. The objective of the present study was to explore in more detail the relationship between sensory and motor impairments in subjects with stroke using three distinct behavioural tasks.
Subjects with subacute stroke (n=18) and non-disabled controls (n=79) were assessed in a

KINARM exoskeleton robot that permits motion in the horizontal plane. A postural perturbation task measured how quickly
subjects can respond to a perturbation and accurately return to their start
target (no vision of hand following perturbation). A limb matching task
assessed the perception of limb position by measuring the mismatch between one arm moved by the robot and the subject's mirror matched limb configuration with their other arm (no vision throughout task). A visual-guided reaching task assessed the use of vision and proprioception to reach quickly and accurately to a target. Both arms were assessed in each task and a number of parameters captured the spatial and/or temporal aspects of task behavior.
In agreement with our previous results, reaching and position matching deficits were found to be largely independent in this sample. Most impairments in reaching parameters were significantly correlated with impairments in perturbation corrections. In contrast, the majority of impairments in limb matching parameters were significantly independent of impairments in perturbation corrective parameters. One exception was that perturbation response endpoint error was significantly correlated with limb matching variability ($r=0.43$, $p<8.8x10^{-4}$).
Overall these results suggest impairments in integrating feedback into motor corrections being related to motor impairments and independent of proprioceptive impairments.

Title: Using clinical and robotic assessment tools to examine the feasibility of pairing tDCS with standard physical therapy in patients with stroke and TBI

Authors: J. A. MIDDLETON, D. LIUZZO, R. NEWMAN-NORLUND, S. L. FRITZ, *T. M. HERTER;
Dept. of Exercise Sci., Univ. of South Carolina, Columbia, SC

Abstract: Introduction: Following neurologic insult, such as a stroke or traumatic brain injury (TBI), an imbalance in excitation and inhibition between the affected and unaffected cortical hemispheres may contribute to functional impairments. Bihemispheric transcranial direct current stimulation (tDCS) may diminish this imbalance by exciting cortical neurons on the affected side of the brain and inhibiting cortical neurons on the unaffected side. Purpose: A case series design was used to examine the feasibility of pairing bihemispheric tDCS with standard upper extremity physical therapy in a heterogeneous sample of individuals with chronic stroke and TBI. Methods: Five individuals with chronic stroke, one individual with TBI, and one individual with stroke resulting from a TBI participated in 24 sessions of standard UE physical therapy (40 minutes, 3 times per week). Bihemispheric tDCS at 1.5mA was delivered over motor cortex during the first 15 minutes of therapy. Outcomes were assessed using clinical (UE Fugl-Meyer, Purdue Peg Board, Box and Block, Stroke Impact Scale) and robotic (position sense, unimanual and bimanual motor control, and executive function) assessments at 8 time points (2 pre-intervention, 2 interim, and 1 post-intervention, and 3 follow-up). Results: Two participants with chronic stroke did not complete the study due to unrelated illness. Of the remaining participants with stroke, one exhibited significant improvements in robotic measures of unimanual and bimanual motor control whereas two did not show significant recovery. The participant with TBI demonstrated improved bimanual coordination and the participant with stroke resulting from TBI demonstrated improvements on clinical and robotic measures of unimanual motor control. All three participants who exhibited significant recovery maintained their improvements at follow-up. Conclusions: Our results show that bihemispheric tDCS may be a feasible, effective adjunct to standard physical therapy for providing sustainable improvement in upper extremity function following stoke and TBI. This intervention may not be effective for individuals with moderate to severe spasticity. Robotic assessment may improve our ability to monitor longitudinal recovery in individuals who respond to treatment.

Title: Comparison of post-stroke position sense and kinaesthesia using robotics

Authors: *J. A. SEMRAU[1], T. M. HERTER[2], S. H. SCOTT[3], S. P. DUKELOW[1];
[1]Clin. Neurosciences, Univ. of Calgary, Calgary, AB, Canada; [2]Univ. of South Carolina, Columbia, SC; [3]Queen's Univ., Kingston, ON, Canada

Abstract: Proprioception allows us to use both static position sense and sense of dynamic limb motion (kinaesthesia) to properly plan and execute movement. Prior work in our lab has shown that in subjects with stroke, damage to both of these aspects of proprioception is common, occurring in ~50% of stroke survivors. While proprioception has classically been sub-divided into position sense and kinaesthesia, it is likely that their integration is key to perceiving sense of limb location and movement. Here, we aim to further characterize the relationship between these two submodalities of proprioception to better understand their contributions to the control of movement and how they are impacted by stroke.

One-hundred neurologically intact control subjects and 110 subjects with unilateral stroke performed two separate robotic tasks. In both tasks, subjects sat in the KINARM robotic exoskeleton with their arms supported against gravity, vision occluded. Task 1: Position Matching - The robot moved one arm to one of nine locations in a virtual workspace. Subjects were instructed to use their opposite arm to mirror-match the position that the robot moved their passive arm to, after the robot stopped moving. Task 2: Kinaesthetic Matching - The robot moved one arm to one of three locations in the virtual workspace at a preset speed, direction and magnitude of movement. Subjects were instructed to mirror-match with their opposite arm the speed, direction, and magnitude of movement as soon as they felt the robot begin to move their arm. For all subjects with stroke, the robot moved their affected arm.

We evaluated spatial parameters of static position sense and static kinaesthesia, as well as dynamic (spatial and temporal) components of kinaesthesia. Preliminary results suggest a strong relationship between deficits in position sense and kinaesthesia, with 45% of stroke subjects impaired on both the kinaesthesia task and position matching. This result is further supported by significant correlations of position matching task measures of variability with kinaesthestic parameters of directionality and response latency ($p < 0.001$). Additionally, we observed significant correlations in position matching variability with kinaesthetic measures of endpoint variability ($p < 0.001$). These results suggest that both static and dynamic components of proprioception play a pivotal role in proper sensory function. Additionally, these components are likely highly integrated due to the high incidence of coincidental impairment of both position sense and kinaesthesia. By using robotics to identify sensory deficits we hope to better inform post-stroke rehabilitation and treatment strategies.

Title: The neural correlates of position sense after stroke

Authors: *S. FINDLATER[1], J. A. DESAI[1], J. A. SEMRAU[1], T. M. HERTER[2], S. H. SCOTT[3], S. P. DUKELOW[1];
[1]Clin. Neurosciences, Univ. of Calgary, Calgary, AB, Canada; [2]Univ. of South Carolina, Columbia, SC; [3]Queen's Univ., Kingston, ON, Canada

Abstract: ***Background:*** Proprioception describes our sense of self-position and movement without the use of vision. It is impaired in approximately one-half of stroke patients. Proprioceptive deficits have been correlated with poor motor recovery after stroke and have been linked to impaired function resulting in longer inpatient stays and increased care requirements upon discharge. Diagnosis and quantification of the severity of proprioceptive deficits poses a challenge in the clinical setting, given that the most widely used bedside assessments have been found to have poor sensitivity, reliability, and lack normative data. We have developed and validated an objective robotic assessment of position sense, a sub-component of proprioception, in subjects with stroke.
Recently, voxel-based lesion-symptom mapping (VLSM) has been used to examine the correlation between brain lesion location and behavioural deficits on a voxel-by-voxel basis. This study used VLSM to examine the relationship between lesion location and impaired position sense after stroke.
Methods: 70 subjects completed the robotic assessment within 3 weeks of their stroke. Position

sense was measured using a matching task where the KINARM robotic exoskeleton moved the affected arm to one of nine locations. Subjects were instructed to mirror match the position with their unaffected arm without the use of vision. The results of the position match task were compared with lesion location on magnetic resonance images, acquired within 10 days of stroke, using VLSM.
Results: As hypothesized, damage to the internal capsule, somatosensory cortex, and somatosensory association cortex (areas 5 and 7) were associated with poor position sense. Further, lesions within the insula, external capsule, and middle frontal gyrus were also observed in association with impaired position sense.
Conclusion: Our results are consistent with traditional views of proprioceptive anatomy while suggesting the involvement of additional structures. Identification of brain regions involved in processing position sense may prove useful to clinicians and researchers who are interested in understanding the role that sensory information plays in stroke recovery.

Title: Identification of brain areas associated with impaired kinaesthesia following stroke using robotics and voxel-based lesion symptom mapping

Authors: *J. M. KENZIE[1], J. A. SEMRAU[1], S. E. FINDLATER[1], J. A. DESAI[1], T. M. HERTER[2], S. H. SCOTT[3], S. P. DUKELOW[1];

[1]The Univ. of Calgary, Calgary, AB, Canada; [2]Univ. of South Carolina, Columbia, SC; [3]Queen's Univ., Kingston, ON, Canada

Abstract: To interact with our environment, we require proprioception - the sense of limb position and movement (kinaesthesia). Clinically, it is difficult to measure kinaesthesia in an objective and sensitive way. Previous work in our lab has developed robotic methodology to measure kinaesthesia and we have found that ~50% of stroke survivors have impairments. Here, we utilize both robotics and imaging-based analysis (voxel-based lesion symptom mapping (VLSM)) in stroke survivors to identify brain areas associated with processing kinaesthetic information.

Seventy-eight subjects with stroke performed a kinaesthetic matching task using the KINARM robotic exoskeleton. MRI/CT imaging and robotic scores were obtained for stroke subjects within 10 days and 21 days post-stroke, respectively. For the kinaesthesia task, the robot moved the subjects' stroke-affected arm at a preset speed, direction and magnitude of movement. Subjects then mirror-matched the movement with their unaffected arm as soon as they felt the robot begin to move. VLSM was used to statistically compare the location of the brain lesions with behavioural scores from the robot task.

We observed significant associations between impaired kinaesthesia and lesions of internal and external capsule, insular cortex, and Broadmann's areas 5 and 7. Several of these structures have previously been found to be important for transmission and processing of kinaesthetic information. Our findings suggest that a widely distributed network is responsible for processing and integrating spatial and temporal elements for sense of limb movement. By identifying brain structures associated with poor kinaesthesia following stroke, we may better predict which individuals with acute stroke will have kinaesthetic deficits.

Title: Influence of elbow angular spasticity zones on one-trial motor learning in chronic stroke

Authors: *S. K. SUBRAMANIAN[1,2], A. G. FELDMAN[3,2], M. F. LEVIN[1,2];
[1]Sch. of Physical and Occup. Therapy, McGill Univ., Montreal, QC, Canada; [2]Feil Oberfeld JRH/CRIR Res. Centre, Jewish Rehabil. Hosp. site of the Ctr. for Interdisciplinary Res. In Rehabil. of Greater Montreal, Laval, QC, Canada; [3]Dept. of Physiology, Univ. de Montréal, Montreal, QC, Canada

Abstract: Motor learning studies in subjects with stroke have mainly focused on the less-impaired arm to separate confounding influences of motor deficits from motor learning capabilities. One previous study assessed motor learning (error correction) in the hemiparetic arm using a one trial learning paradigm ─ rapid adaptation of arm motion to a new load. It was shown that error correction strategies were related to both cognitive and arm motor impairment. Subjects with mild paresis, like healthy subjects corrected movement errors elicited by the new load after one trial, while those with moderate to severe paresis used different strategies or were unable to completely correct movement errors. We hypothesized that resistance of muscles due to spasticity may be responsible for altered correction strategies. Zones in shoulder-elbow angular space in which muscles have spasticity revealed by passive muscle stretches and abnormal agonist/antagonist activation during voluntary movements have been identified by determining the threshold joint angles at which stretch reflex (SR) responses occurred despite the instruction to relax muscles. We assessed the influence of spasticity zones on motor learning in stroke. Stroke subjects (Fugl-Meyer scores: 32-61/66) made rapid 35-50° horizontal elbow extension movements from an initial 3° to a final 6° target in 16 blocks. Each block consisted of 6-10 trials each. In Session 1, movements were made in mid-range and in Session 2, movements were restricted to a joint range that did not surpass the flexor SRT (outside of the spasticity zone). For each block, movements were alternatively not loaded or loaded by a position dependent load (30% MVC). Subjects were instructed to extend the elbow to the final target in a single fast and accurate movement and correct movement errors as soon as possible. Visual feedback of elbow position and movement speed was provided. Angular positions before correction were used to identify error correction strategies. Changes in load condition from load to no load and vice-versa resulted in overshoot and undershoot errors respectively. In Session 1, subjects corrected errors in 1-4 trials. When movements occurred outside of the spasticity zone, the number of trials needed to correct errors fell to 1-3 with the majority needing only 1-2 trials. Results of this study may help distinguish arm motor learning ability from errors due to the underlying motor deficits in the paretic arm. The presence of spasticity zones should be taken into account during interpretations of motor learning results.

Title: Altered obstacle avoidance behaviour in individuals with good arm recovery after stroke

Authors: *M. C. BANINA[1,2], B. J. MCFADYEN[3,4], M. F. LEVIN[1,2];
[1]Sch. of Physical and Occup. Therapy, McGill Univ., Montreal, QC, Canada; [2]Feil-Oberfeld Res. Centre, Jewish Rehabil. Hosp., Ctr. for Interdisciplinary Res. in Rehabil. of Greater Montreal, Montreal, QC, Canada; [3]Dept. de réadaptation, Faculté de médecine, Univ. Laval, Québec, QC, Canada; [4]Ctr. Interdisciplinaire de Recherche en Réadaptation et Intégration Sociale, Québec, QC, Canada

Abstract: After stroke, individuals with good sensorimotor recovery of their affected arm report decreased use of the arm in activities of daily living. Decreased use of the affected arm may be associated with undetected motor deficits only identifiable when individuals attempt higher-order tasks that require complex coordination. One higher-order motor task, the ability to avoid obstacles while reaching, commonly occurs in everyday environments but is not routinely assessed by clinical scales. We hypothesized that well-recovered people after stroke would be less successful in avoiding an obstacle in the reaching path compared to age-equivalent healthy controls. Obstacle avoidance ability during reaching in a virtual environment (VE) was compared between well-recovered stroke subjects and healthy controls. A VE was developed simulating a grocery store aisle and a commercial refrigerator with sliding doors stocked with bottles on 2 shelves. Subjects reached as fast as possible with their affected/dominant arm for a bottle on one shelf (non-obstructed reaching - template). In random trials (RAND, 30% of 60 trials), the door ipsilateral to the reaching arm closed and partially obstructed the bottle at reach initiation. Subjects were instructed to touch and retrieve the bottle without the hand or arm hitting the door. Arm and trunk movements were recorded with 24 active markers by an Optotrak system. Outcome variables were overall success rates, movement performance and movement quality variables for template (T), successful avoidance (Succ), and failed avoidance (Fail) trials, and Succ/Fail divergence points of the endpoint trajectory from template profile (DP=% of reach distance). In T trials, stroke subjects used less wrist flexion, wrist abduction and shoulder rotation compared to controls. In RAND, 36% of controls and 12% of stroke subjects were successful >65% of the time ($z=2.248$; $p<0.05$). For both groups, successful door avoidance was characterized by DP occurring closer to the starting position (Control: DPSucc=11.2±7.0%, DPFail=34.1±37.3%, $p<0.05$; Stroke: DPSucc=20.5±16.1%, DPFail=60.4±33.7%, $p<0.05$). However, the margin of error in the stroke group was about half that of the controls. In addition,

stroke subjects had to significantly increase endpoint trajectory length compared to controls to successfully avoid the door. Stroke subjects had residual movement deficits that were revealed through a challenging motor task. The potential of using challenging UL tasks to identify higher order motor control deficits should be considered when assessing post-stroke motor recovery.

Title: Responsiveness of a new clinical measure of spasticity

Authors: A. A. MULLICK[1,2], A. K. BLANCHETTE[2,3], R. GUBEREK[2], C. BEAUDOIN[2], *P. S. ARCHAMBAULT[1,2], M. F. LEVIN[1,2];

Abstract: While spasticity affects over 12 million people worldwide, there is still no universally accepted tool for its quantification. Spasticity is defined as a velocity-dependent increase in tonic stretch reflexes with exaggerated tendon jerks, resulting from hyper-excitability of the stretch reflex as one component of the upper motor neuron syndrome. However, existing spasticity measures do not adequately quantify these reflex properties. Levin and Feldman (1994) proposed a new approach to spasticity measurement based on the evaluation of the threshold position of body segments at which motoneurons begin to be recruited. This spatial threshold is the tonic stretch reflex threshold (TSRT) and is regulated by descending and segmental influences in a task-specific way, a concept underlying the equilibrium-point theory. Limitations in the regulation of TSRTs lead to motor deficits. In particular, spasticity occurs when the TSRT lies within the biomechanical range of the joint and cannot be regulated outside this range to relax muscles. Active muscle resistance emerges when muscles are stretched beyond the SRT. The

validity and reliability of the TSRT has been measured in the elbow and ankle in patients with post-stroke spasticity. To further develop the TSRT measure for clinical use, we estimated the responsiveness of the measure to changes in spasticity after a clinical intervention (TENS─ transcutaneous electrical stimulation). TENS is thought to decrease spasticity by increasing presynaptic inhibition of motoneurons over repeated applications. Patients with chronic post-stroke spasticity (≤75yr) were matched on elbow flexor spasticity level (Composite Spasticity Index-CSI) and randomly allocated to one of two groups; TENS/sham-TENS in a Pre-Post controlled design. TENS (high frequency-80Hz; low intensity-2x sensory threshold, 60 min) or sham-TENS (no stimulus delivery, but lights activated) was applied to spastic muscle antagonists (triceps). Subjects were instructed to use a portable TENS machine at home on a daily basis for 2 weeks. After 1 and 2 weeks of TENS/sham-TENS, changes in spasticity were measured by TSRT and clinical scales (Fugl-Meyer score, FM; Chedoke McMaster; CSI; Reaching Performance Scale). Between-group differences were analyzed by repeated measures ANOVA. The relationship between changes in TSRT and clinical scores was determined. Our results contribute evidence towards establishing the psychometric properties of TSRT as an objective clinical spasticity measure.

Title: Validity and reliability of the tonic stretch reflex threshold as a measure of ankle plantarflexor spasticity after stroke

Authors: *A. K. BLANCHETTE[1,2], K. MOÏN-DARBARI[2,3], A. A. MULLICK[2,4], C. BEAUDOIN[2], M. F. LEVIN[2,3,4];

Hospital, Ctr. for Interdisciplinary Res. in Rehabil. (CRIR), Montreal, QC, Canada; [3]Neurosci., [4]Sch. of Physical and Occup. Therapy, McGill Univ., Montreal, QC, Canada

Abstract: One of the common impairments observed after neurological lesions is spasticity. Spasticity is defined as "a motor disorder characterized by a velocity-dependent increase in tonic stretch reflexes with exaggerated tendon jerks, resulting from hyperexcitability of the stretch reflex" (Lance 1980). Using an appropriate clinical measure for spasticity is important to evaluate the effectiveness of therapeutic interventions. The validity and reliability of commonly used clinical scales (e.g. Ashworth Scales [AS]) are questionable. Determination of the spatial tonic stretch reflex threshold (TSRT) is a promising objective alternative for spasticity measurement. The TSRT corresponds to the joint angle at which the stretch reflex response begins. In healthy subjects, it is broadly regulated by descending and spinal pathways, as specified in the equilibrium-point theory of motor control. Limitations in the range of regulation of TSRT in post-stroke subjects result in motor disorders, such as abnormal muscle activation patterns and spasticity. The objectives of the study were to: 1) quantify inter-rater reliability of the TSRT measure in ankle plantarflexors (PF) and 2) determine the correlation between spasticity measured with TSRT and clinical scales (AS, Composite Spasticity Index [CSI]). Thirty individuals (9 females; mean age: 57.1±9.8 yrs) with post-stroke ankle spasticity participated. PF spasticity was evaluated by two raters. Each rater manually stretched ankle PFs at different velocities (n=20, randomized). PF EMG activity and ankle angular position were recorded with surface electrodes and an electrogoniometer, respectively. For each stretch, the velocity-dependent dynamic stretch reflex threshold (DSRT), representing the joint angle at which muscle recruitment begins, was computed. TSRT was estimated by extrapolating a regression line through all DSRTs to zero velocity. Inter-rater reliability was good for ankle PF spasticity (two-way random ICC=0.80, $p<0.001$). There was no correlation between TSRT values and AS scores while a high correlation was found with the CSI score ($r=-0.506$; $p<0.005$). Determination of TSRT values is a valid and reliable method that can be a good alternative for the evaluation of spasticity since it is a physiological measure that accounts for the velocity-dependence of the stretch reflex response.

Title: Priming physiotherapy with Theta Burst Stimulation enhances upper limb function in chronic stroke patients

Authors: *S. J. ACKERLEY[1,2], W. D. BYBLOW[3,2], P. A. BARBER[1,2], C. M. STINEAR[1,2]; [1]Dept. of Med., [2]Ctr. for Brain Res., [3]Dept. of Sport and Exercise Sci., Univ. of Auckland, Auckland, New Zealand

Abstract: Upper limb impairment is common after stroke and recovery of function is important for regaining independence in daily activities. This study tested the effects of priming upper limb therapy with intermittent Theta Burst Stimulation (iTBS), which is a form of non-invasive brain stimulation. We enrolled 18 patients with first-ever chronic monohemispheric stroke, in this randomized, controlled, single-centre, double-blinded trial. Priming consisted of real or sham iTBS delivered to the ipsilesional M1 immediately before 45 minutes of individualized upper limb physiotherapy. Primed therapy sessions were delivered on 10 consecutive working days. Upper limb impairment and function were assessed twice at baseline, after 5 (MID) and 10 (POST) primed therapy sessions, and at 4 and 12 weeks after the intervention. Upper limb impairment was assessed with the Fugl-Meyer scale (FM), and function was assessed with the Action Research Arm Test (ARAT). The primary endpoint was change in ARAT score 4 weeks after the intervention. Motor evoked potential amplitudes obtained in either first dorsal interosseous (FDI) and precision grip function were also assessed. Improvement in ARAT score was greater in the primed than control group patients at all time points after baseline ($F_{1,16} = 11.64$, $P = 0.004$), including the primary endpoint ($t_{16} = 2.29$, $P = 0.036$). Secondary analyses found that the primed group had a larger increase in ARAT score than the control group after 10 therapy sessions ($t_{16} = 3.78$, $P = 0.002$) but not after 5 therapy sessions ($t_{16} = 1.53$, $P = 0.15$). ARAT scores returned to baseline 3 months after the intervention. FM scores improved after 10 therapy sessions for both groups ($F_{3,48} = 3.41$, $P = 0.025$), and remained higher than baseline 3 months after the intervention ($t_{17} = 2.34$, $P = 0.032$). Ten sessions of upper limb therapy primed with iTBS boosts upper limb function in patients at the chronic stage of stroke recovery. The benefits last for at least 1 month, but primed therapy may need to be repeated periodically in order to produce a sustained benefit.

Title: Does tractography improve prediction of individual patient's motor recovery after stroke?

Authors: *J. P. COXON[1], C. M. STINEAR[2], M. A. PETOE[2], P. A. BARBER[2], S. S. ANWAR[3], W. D. BYBLOW[1];
[1]Ctr. for Brain Res. & Dept. of Sport & Exercise Sci., [2]Ctr. for Brain Res. & Dept. of Med., Univ. of Auckland, Auckland, New Zealand; [3]Rehab Plus, ADHB, Auckland, New Zealand

Abstract: Predicting whether an individual will regain function of the upper limb after stroke is difficult. The PREP algorithm (for Predicting Recovery Potential, Figure) can be used within the initial days after stroke to predict functional outcomes for the individual patient at 3 months. PREP involves the sequential use of a bedside clinical assessment, transcranial magnetic stimulation of the lesioned hemisphere motor cortex, and diffusion-weighted (DW-) MRI to obtain fractional anisotropy (FA) of the posterior limbs of the internal capsules. The positive predictive power of this approach is good. Our aim was to determine if tractography of corticospinal (CST) and cortico-rubral pathways (CRP) in either hemisphere could be quantified in a way that would further improve PREP's positive predictive power. We examined 57 patients after first ever monohemispheric ischemic stroke. Clinical assessments were made within 72 hours, motor evoked potentials (MEPs) from TMS obtained at 5 days, and DW-MRI obtained within 10 days. All assessments were repeated at 12 weeks. In a small subset of cases, outcomes at 12 weeks exceeded or fell short of predictions. These cases tended to be where MEPs in the affected wrist extensor were present but FA asymmetry was high, or where MEPs did not modulate with stimulation intensity, had prolonged latencies, or both. In most cases tractography of the CST and CRP was unable to resolve uncertainty related to the presence or absence of MEPs. These results indicate that functional measures of CST integrity obtained from affected side MEPs are more salient than FA asymmetry obtained using DW-MRI. The results do not warrant the addition of tractography for predicting recovery potential in individual patients. The PREP algorithm rarely overestimates an individual's prognosis. Interestingly, DW-MRI revealed markers of structural plasticity within the contralesional CST for the group but this was not associated with improved paretic upper limb function, and may instead reflect increased use of

the nonparetic side after stroke.

Title: A semi-automated tool to study limb kinematics of reaching in a mouse model of stroke

Authors: *S. MICERA[1,2], S. LAI[2], A. PANARESE[2], C. SPALLETTI[3], C. ALIA[3], A. GHIONZOLI[2], M. MAINARDI[3], M. CALEO[3];
[1]Ecole Polytechnique Federale De Lausanne, Lausanne, Switzerland; [2]Scuola Superiore Sant'Anna, Pisa, Italy; [3]CNR Neurosci. Inst., Pisa, Italy

Abstract: Mice represent an ideal model to investigate the mechanisms of physiological and functional changes occurring after stroke. Currently, assessment of post-stroke motor impairments and recovery in mice is done by administering a series of behavioural tests, which results are usually evaluated by visual assessment of successful/unsuccessful movements, or by qualitatively studying limb kinematics by means of time consuming frame-by-frame video

analyses.
In this work, we propose a semi-automated algorithm for tracking mouse paw movement during a skilled reaching task, without attaching markers to the skin. The performance of this method was tested both before and after the induction of a focal ischemic stroke. Animals were trained to reach for food pellets with their preferred paw, previously painted with a non-toxic dye. During experimental sessions (lasting 5 min), mice were able to perform an average number of 30 reaching movements. A high frame rate (120 fps) camera was used to record the task. Later, a semi-automated algorithm written in Matlab was used off-line to automatically identify paw position and to track whole reaching trajectories. Inputs by the experimenter were limited to 1) an initial calibration during which the user was required to specify paw position in a few (e.g., 3 or 4) randomly selected frames, and 2) a quick review of successful/unsuccessful trials based on salient task points automatically identified by the algorithm. Various significant parameters were then extracted from the trajectories to assess motor performance similarly to what is currently done with patients after stroke (Panarese et al., Neurorehabil Neural Repair 2012).
Phototrombosis was then utilized to induce a focal ischemic stroke in the Caudal Forelimb Area, which affected forelimb motor performance. Mice were tested again once a week for 30 days. Significant differences were found between pre- and post-stroke values in a selected number of parameters.
This study presented and highlighted the utility of a semi-automated algorithm to study limb kinematics of mice reaching movements unhindered by markers in a quick and unbiased way. Furthermore, key parameters sensitive to post-stroke modifications in forelimb movements were identified. Our results suggest promise for using this method in stroke rehabilitation protocols for mice (e.g., Spalletti and Lai et al., Neurorehab Neural Repair, in press), in particular to assess whether functional gains occur via motor recovery (i.e., restoration of kinematic parameters to pre-injury values) or compensatory strategies.

Title: Quantifying post-stroke movement impairment using motion capture to automate the Wolf Motor Function Test

Authors: *E. V. OLESH[1], S. YAKOVENKO[2], V. GRITSENKO[2];
[2]Ctr. for Neurosci., [1]West Virginia Univ., Morgantown, WV

Abstract: According to the National Stroke Association there are currently 7 million people living in the U.S. who have survived a stroke, half of whom suffer from long term movement impairment. With the increasing cost of rehabilitation and the lack of objective outcome measures of therapy effectiveness, there is a critical need for a low-cost and automated assessment that can provide accurate measurement of motor impairment. We have tested the feasibility of objectively scoring the upper extremity performance using low-cost motion capture. Stroke survivors performed 15 arm movements that are part of the Wolf Motor Function Test (WMFT). Each of these movements were scored by a group of physical therapy (PT) students on a 6-point scale (0 equalling no movement and 5 equalling perfect movement). The total score of 75 indicated no impairment. Subjects performed the WMFT with both arms and were recorded simultaneously by a video camera and a marker less motion capture system (Microsoft Kinect). Motion capture data consisted of 3D coordinates of 10 tracked points on the upper-extremities and the trunk. Joint angles of the shoulder, elbow and wrist were calculated with custom algorithms in Matlab (MathWorks). The analysis objective was 1) to compare the motion capture-based scores to those of PT students and 2) to determine the effectiveness of the WMFT in measuring the full range of motion. To objectively score the Functional Ability domain of WMFT, joint angle changes for shoulder flexion/extension, shoulder abduction/adduction, elbow flexion/extension and wrist flexion/extension were compared between the affected and unaffected limbs using Root Mean Squared Error (RMSE). The cumulative RMSE values for all movements determined a total score (0 indicates no impairment). The comparison of clinical scores to the motion capture-based scores showed a strong negative correlation. We used the span of joint angle from the unaffected arm to determine the difference between the range of motion captured by the WMFT and the physiological range of motion. Results from this multidimensional comparison demonstrate that the WMFT covers a significant portion of the full range of motion of the arm, and that portion diminishes with motor deficits. This study demonstrates the feasibility of using a low cost motion capture system to automate the WMFT and to objectively quantify post-stroke motor impairment.

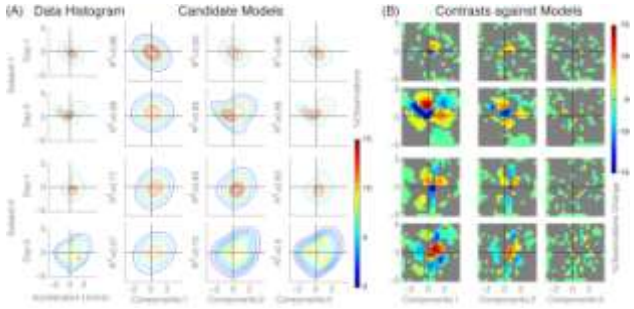
Title: Distribution analysis reveals individual patterns of motor deficits

Authors: J. L. PATTON[1], *F. C. HUANG[2];
[1]Univ. of Illinois at Chicago, Univ. of Illinois at Chicago, Chicago, IL; [2]Sensory Motor Performance Prog, Rehabil Inst. of Chicago, CHICAGO, IL

Abstract: Recent studies have shown benefits of patient-initiated exploratory practice, yet the tools for interpreting adaptation in such movement require further attention. In a test on 10 chronic stroke subjects practicing for 3 days, we found that inter-quartile range of motion did not show improvement in movement range. However, distribution analysis using multivariate Gaussians revealed greater complexity of movement patterns by the end of training. Furthermore, linear discriminant classification analysis revealed that each movement distribution could be uniquely associated with each patient. Interestingly, this analysis indicated greater distinction in acceleration data compared to position or velocity. These results show that distribution analysis provides more powerful tools for detecting differences in movement deficits. The impact of this work could be in improving therapy by incorporating distribution analysis in the design of customized interventions.



(A) Contour plots of acceleration histograms (for two typical subjects) versus multivariate normal functions with 1, 2, and 5 components, reveal new movement patterns from Day-1 and Day-3 (Red/blue indicates greater/lesser observations). (B) Contrasts of histograms versus model functions indicate lower contrast with increasing components (columns), and higher contrast on Day-3 compared to Day-1. The color gradation (red/blue) indicates differences (greater/lesser) in the data compared to the models. These results show irregular changes in movement distribution across workspace.

Abstract: Stroke is the leading cause of physical disability and presents enormous societal and economic costs. Recovery, is driven by neuroplasticity - an intrinsic property of the brain that attempts to compensate for damaged motor networks. For about half of stroke survivors, recovery is not complete and the associated neurological symptoms, and the recovery dynamics, can be related to pathophysiological motor and compensatory networks that have arisen from the reorganization process. Recently, such networks have been monitored in vivo using connectivity analysis performed on functional MRI/PET data. The emerging consensus is that connectivity analysis will be key to our future understanding of stroke recovery. An especially exciting possibility is the application of this knowledge for the development of new, neurobiologically-informed treatment strategies. Current connectivity methods, however, are not suited to monitoring task-dependent networks during clinically relevant motor assessment tests, due to the practical constraints of MRI/PET. In addition, their intrinsically poor temporal resolution does not capture well, the transient changes in network coupling which are important for a comprehensive description of the motor program dynamics. To overcome the shortcomings of current approaches we propose a new methodology for simultaneous capture of brain and behavior using a combination of functional EEG neuroimaging and motion capture during standard clinical motor assessments. We present initial data collected from 128 channel EEG and full motion capture of the upper limb using a subset of the Wolf Motor Function Test with healthy subjects. We identified clear brain dynamics localized in the motor cortices which demonstrated beta suppression after onset of the right arm movement. The subsequent

multivariate vector auto-regressive analysis further revealed that the information flowed more from the left to the right hemisphere. The results demonstrate the feasibility of producing interpretable brain and behavior data during standard clinical assessments used to evaluate upper extremity motor deficits.

Title: Bilateral priming accelerates recovery of upper limb function at the sub-acute stage after stroke

Authors: *W. D. BYBLOW[1], C. M. STINEAR[2], M. A. PETOE[2], P. A. BARBER[2], S. ANWAR[3];
[1]Ctr. for Brain Res. and Dept of Sport & Exercise Sci., [2]Ctr. for Brain Res. and Dept of Med., Univ. of Auckland, Auckland, New Zealand; [3]ADHB, Rehab Plus, Auckland, New Zealand

Abstract: The ability to live independently after stroke depends on the recovery of upper limb function. We hypothesised that bilateral priming with active-passive movements before upper limb physiotherapy would promote re-balancing of corticomotor excitability and accelerate upper limb recovery. A single-centre randomised controlled trial of priming with patients at the sub-acute stage after first-ever ischaemic stroke. The bilateral priming group made rhythmic mirror symmetric bimanual movements using a mechanical device for 15 minutes before undertaking 30 minutes of upper limb physiotherapy, every weekday for 4 weeks. The control group were given 15 minutes of intermittent cutaneous electrical stimulation of the paretic forearm before 30 minutes of physiotherapy. Measures of stroke severity, upper limb impairment and function were made at baseline, 6, 12 and 26 weeks. Transcranial magnetic stimulation was used to evaluate motor evoked potential measures in paretic and non-paretic wrist extensor muscles and MRI obtained to determine corticospinal tract integrity. The primary endpoint was relative % recovery of upper limb function at 12 weeks, measured with the Action Research Arm

Test. Intention to treat and per protocol analyses were conducted. Bilateral priming was suitable for 80% of patients who required upper limb therapy. Primed participants were 3 times more likely than controls to achieve at least 75% of their maximum recovery within 12 weeks, and a greater proportion of primed participants achieved at least 75% of their maximum score by 12 weeks (all $P < 0.05$). Primed participants exhibited greater re-balancing of corticomotor excitability than controls, evidenced by the slopes of stimulus-response curves at 12 and 26 weeks (both $P < 0.05$), and ipsilateral silent period at 26 weeks (both $P < 0.05$). Bilateral priming promoted neurophysiological reorganisation and accelerated recovery of upper limb function in the initial weeks after stroke. Further studies are required to determine if bilateral priming will increase the efficiency of rehabilitation.

Title: Simulated human arm motion drives perception-action learning in post-stroke individuals

Authors: *J. J. BUCHANAN[1], N. ROBSON[2], J. RAMOS[3];
[1]Texas A & M Univ., COLLEGE STA, TX; [2]Mechanical Engin., California State Univ., Fullerton, CA; [3]Mechanical Engin., Texas A&M Univ., College Station, TX

Abstract: Post-stroke individuals have varying degrees of hemiparesis in the arm contralateral to the lesion. This study was designed to evaluate if tracking computer simulated rhythmic arm actions can facilitate motor and visual perceptual learning in post-stroke individuals. Three individuals with varying degrees of hemiparesis that reduced elbow- wrist flexion-extension motion in the arm contralateral to the stroke participated. A visual perception rating task was given before and after motor training. The perceptual rating task required the individuals to rate 12 simulated elbow-wrist flexion-extension motion patterns. In the animation, the upper-arm remained stationary (forearm supine) and the sagittal plane elbow-wrist motion patterns were defined by 12 relative phase (ϕ) values (0°, ±30°, ±60°, ±90°, ±120°, ±150°, 180°), a constant elbow amplitude (92°), and a varying wrist amplitude (largest for $\phi = 0°$ and smallest for $\phi = 180°$). The simulated arm motions were rated as being easy (score 10) or hard (score 1) to produce. Participants did not move during the rating task. Between the pre- and post-training ratings, the individuals tracked animation patterns of $\phi = +60°$ and $\phi = +120°$ for three days with the arm contralateral to the stroke. Participants tracked the animation (12 cycles in 30 seconds) and concurrently received visual feedback in the form of a virtual stick figure of their arm. The level of hemiparesis influenced motor learning. Participant 1: characterized with mild hemiparesis demonstrated significant motor learning (in both ϕ and joint amplitudes). Participant 2: characterized by moderate to severe hemiparesis (wrist motion limited more than elbow) demonstrated motor learning in terms of upper-arm stability and elbow amplitude changes. Participant 3: characterized with severe hemiparesis (limited elbow and no wrist motion) did not demonstrate significant motor learning, yet responded to the animation. The level of hemiparesis influenced motor learning in the arm contralateral to the stroke. The visual motor training significantly impacted the visual perception of motor actions. Before training, the 0° and 180° patterns were rated as the easiest to produce and ±60° to ±120° were rated as the hardest. After training, the three participants rated the animated motions of ±60° to ±120° as easier to produce with ±90° rated as the easiest. The change in perceptual rating was similar to a group of younger adults that underwent similar motor training. In conclusion, simulated arm motion can serve as a visually relevant source of action information that can drive motor learning and in turn may enhance more traditional rehabilitation protocols.

Title: Robotic-assisted assessment of neurologic function in patients suffering from minor traumatic brain injury

Authors: *J. J. KORFHAGEN[1], J. M. MEUNIER[2], V. SUBBIAN[3], F. R. BEYETTE[3], G. J. SHAW[2];
[1]Neurosci. Grad. Program, [2]Emergency Med., [3]Sch. of Electronic and Computing Systems, Univ. of Cincinnati, Cincinnati, OH

Abstract: Introduction
About 1.2 million patients annually present to a U.S. Emergency Department (ED) with a minor traumatic brain injury (mTBI). Generally, these patients undergo a clinical neurological examination and a CT scan as part of their assessment. After ED discharge, 38-80% of these patients can experience chronic symptoms such as headache, fatigue, and difficulty concentrating; this is denoted ‘ postconcussive syndrome (PCS)’. Currently, there is no test to predict which mTBI patients develop PCS.
The Kinarm (BKIN Technologies Inc.) has been developed to utilize robotic technologies for objectively assessing neurologic function in humans and can detect subtle neurologic deficits not apparent in the standard neurological exam. The main goal of this project is to determine the relationship between ED-Kinarm scores and prevalence of PCS in mTBI patients. It is hypothesized that patients suffering from mTBI with abnormal Kinarm scores are more likely to develop PCS three weeks post-injury.
Methods
Patients are drawn from the population of a 90,000 visit per year Level 1 urban trauma center. Potential subjects are screened by clinical study assistants (CSAs) for clinical diagnosis of mTBI. Inclusion criteria include: Glasgow Coma Scale (GCS) score of 13-15, at least 18 years of age, blood-alcohol level lower than 100 mg/dl, and is physically capable of using the Kinarm device. The Kinarm device is composed of two robotic arms linked to a video screen and a computer interface. The computer controls the robots and monitors handle position. The screen displays interactive tests requiring the person to move the handles to complete a task. Five standard tasks measuring cognitive and sensorimotor function are used to determine neurologic status.
Three weeks post-injury, the patient completes the Rivermead Postconcussive Symptoms Questionare (RPQ) and Acute Medical Outcomes SF-36v2 Health Survey (SF-36) to determine if PCS is present.
Results
To date, 9 patients have been enrolled with 4 completing the study. Preliminary results show that 2 of these 4 patients have symptoms which may be consistent with PCS. Both of these patients

performed poorly on three of the five tasks while the other two performed poorly on one task.
Conclusion
Neurologic function of ED patients suffering from mTBI can be assessed using the Kinarm robot during their ED presentation. PCS at three weeks may be associated with worse Kinarm performance in these patients.

Title: Motor learning via low dimension remapping as a marker for spasticity and dystonia in cererbal palsy

Authors: *C. LOPEZ-ORTIZ[1], J. M. S. SIMKOWSKI[3], K. DOSHI[4], W. GOMEZ[5], D. GAEBLER-SPIRA[2];
[1]SMPP/PM&R, Rehabil. Inst. of Chicago/Northwestern Univ., CHICAGO, IL; [2]SMPP/PM&R, Rehabil. Inst. of Chicago/Northwestern Univ., Chicago, IL; [3]Biomed. Engin., Northewstern Univ., Chicago, IL; [4]Col. of Med., Univ. of Illinois, Chicago, IL; [5]Loyola Univ., Chicago, IL

Abstract: Children with cerebral palsy (CP) present atypical muscle tone and reduced selective motor control resulting in abnormal movements and postures. We tested a novel motor learning paradigm with feedback of reduced dimension in a virtual reality display as a marker for spasticity and dystonia in CP. All procedures were approved by the local IRB. 14 typically developing (TD) children and 14 age matched children with CP (mean age = 9.6 years, standard deviation (SD) = 1.4) and GMFCS I-II volunteered to participate in this study. 10 children participated in the spastic group (SG) and 4 children participated in the dystonic group (DG). Both groups completed the same training consisting of two matching games set to music. Both groups trained 3 times per week for 2 weeks and of 10-15min per game. Each child wore 8

reflective markers to track their movement with the NaturalPoint system at 100Hz (OptiTrack, Corvallis OR). The TD children performed a sequence of ballet postures requiring selective shoulder joint control in task 1 and additional hip joint control in task 2. Using statistical principal component analysis (PCA), the 24-dimensional space of the body trackables was reduced to a 2-dimensional space. The children in the SG and DG received continuous feedback about their own movement on a VR screen while aiming to match fixed target points from the TD group. After training, the children with both spastic and dystonic CP demonstrated motor learning by increasing the total number of matches with the targets from the first to the last training session in both tasks. Two-tailed t-tests showed a significant increase in the number of exact matches (alpha=0.05) for the SG (p=0.0019) and the DG (p=0.0433) in Task 1. In Task 2, significant improvement was seen in the spastic group (p=0.0015). Analysis of trajectory smoothness was computed using the spectral arc length metric based upon the Fourier magnitude spectrum of the movement speed. In Task 1, the group of children with spastic CP demonstrated significantly increased (alpha=0.05) smoothness of trajectory in 7 of the 8 trackables and in Task 2 for one trackable representing the right hand. The DG had no significant improvement in either task. Additionally, they had less trajectory smoothness by the last training session in Task 2. This presentation discusses the quantitative evaluation of selective motor control using classical ballet technique combined with low dimension remapping of body motions as quantitative marker to discriminate spastic and dystonic components in CP so as to optimize their clinical classification and therapeutic interventions.

Title: Assessing cognitive-motor integration in preclinical Alzheimer's disease: A discriminant analysis and investigation of neural correlates

Authors: *K. M. HAWKINS[1], L. E. SERGIO[2];
[2]Kinesiology and Hlth. Sci., [1]York Univ., Toronto, ON, Canada

Abstract: The objectives of our research are 1) to characterize how the ability to integrate cognition into action is disrupted by Alzheimer's disease (AD) in its early stages and 2) to examine the neural correlates of impaired cognitive-motor integration in preclinical AD. We propose that measuring visuomotor integration under conditions that place demands on visual-spatial and cognitive-motor processing may provide an effective behavioural means for the early detection of underlying neuropathology. To this end, we have tested participants both with and without AD risk-factors on four visuomotor transformation tasks (standard, feedback reversal, plane dissociated, and plane dissociated + feedback reversal) using an Acer Iconia dual-touchscreen tablet. Comparisons between high AD risk participants (n=22) and both young (n=22) and old (n=22) healthy control groups have revealed significant performance disruptions in at-risk participants as task demands increase. A stepwise discriminant analysis was used to distinguish between high and low AD risk groups based on the outcome measures from our cognitive-motor integration assessment. The resulting classification accuracy was 86.4% (sensitivity: 81.8%, specificity: 90.9%).
We suggest that the impairments observed in high AD risk participants may reflect early neuropathology disrupting the intricate reciprocal communication between hippocampal, parietal, and frontal brain regions required to successfully prepare and update complex reaching movements. Currently, we are examining the underlying structural and functional connectivity in relation to AD risk and cognitive-motor integration performance in these participants. To date, seven at-risk participants and six age-matched controls have undergone anatomical, diffusion weighted, and resting-state functional connectivity scans. Preliminary analysis of these data has revealed significant correlations between peak activations in regions of the default mode network and task performance, as well as between the mean fractional anisotropy in white matter tracts and task performance. These data support our hypothesis that disruptions in cognitive-motor integration performance are associated with identifiable brain alterations.

Title: Modeling movement duration based on target-dependent differences to assess reaching movement recovery post-stroke

Authors: *H. PARK, S. KIM, J. GORDON, N. SCHWEIGHOFER;
Biokinesiology & Physical Therapy, USC, LOS ANGELES, CA

Abstract: According to the well known Fitts' law, distance and accuracy constraints (target size) affect reaching movement duration. In addition, the arm's biomechanics is known to influence duration, with movements in the direction of the largest inertia at the hand being the longest (Gordon et al. 1994). A possible third effect is that often practiced movements are faster (Keetch et al. 2005). We thus hypothesized that 1) movement distance, deviation from largest inertia, and the deviation from midline will predict reaching movement duration in healthy subjects, 2) reaching movements post-stroke will be longer in duration than those of healthy subjects and will depend on these three factors to a lesser extent, and 3) re-training will decrease movement duration and will increase the roles of these three factors in determining duration.
Six right handed non-disabled participants (2M, 4F, 50.2 ± 6.0 yrs) and five participants with stroke (3M, 2F, 59.8 ± 21.9 yrs, FM 42.4 ± 16.2; at least 1 year post-stroke) were asked to reach circular targets (diameter 3 cm) with the index fingers of their dominant or paretic hands as accurately and quickly as possible. The stroke group were asked to visit the laboratory for three consecutive days: on the first two days they received intensive training of 600 movements per day on 5 targets arrayed on an arc ranging from 30 to 150 degrees at 25 cm from the home position, as well as a pre- and a post-test. On the third day they received only a test. In each test, 35 targets were presented at different locations on a two-dimensional horizontal workspace arrayed from 30 to 150 degrees and at 10, 15, 20, 25, and 30 cm. The model of movement duration was fitted from data recorded in the tests, and is given by: $MD = a * \log2((2*D/size) + 1) + b * \cos(3*\pi/4 - q) + c * (1-\cos(\pi/2 - q)) + d$, where MD, D, size, and q represent the movement duration, the target distance from the starting position, the target size, and the target angle from the starting position in radians, respectively. a, b, c, and d are parameters to be estimated. Stepwise regression analysis was used for each test.
In the healthy group, mean movement duration was 290±60.0 ms and all parameters (a, b, and c) were statistically significant ($p < 0.02$) for all subjects, with a good average fit ($R2 = 0.73$). In the stroke group, movement duration decreased from 604±244 ms in the pre-test of day 1 to 458±154 ms in the post-test of day 2, but increased to 506±230 ms in the 24 hour retention test. Only distance accounted for the movement duration ($p < 0.009$) for all subjects in both group and all tests.

Title: transcranial direct current stimulation for improving motor symptom in patients with Parkinson's disease

Authors: *Y. SALIMPOUR[1], Z. MARI[2], R. SHADMEHR[1];
[1]Dept. of Biomed. Engin., [2]Neurol. Dept., Johns Hopkins Sch. of Med., Baltimore, MD

Abstract: Transcranial direct current stimulation (tDCS) is a promising noninvasive cortical stimulation method for adjunctive treatment of movement disorders. Here, we performed an experiment to quantify the effects of tDCS on PD motor symptoms. We considered an isometric task in which subjects held the handles of two robotic arms, one in each hand. The goal was to push on the left and the right robotic arms in order to move a cursor toward targets distributed around a circle. The position of the cursor was the sum of the force vectors produced by each arm. For each direction of target the subjects chose how much force to produce with their right and left arms. This choice was remarkably consistent over repeated days, suggesting that consistent cost dominated the choice of action. We hypothesized that the choice that people made was due to a cost that had two components: a cost for variability, and a cost for effort. To measure variability, in a unimanual task we measured variance of force for each arm at each direction of force. To measure effort, we measured the maximum voluntary force for each arm and each direction.We applied cathodal tDCS to M1 of the affected hemisphere and anodal in contralateral side of PD patients. This produced an immediate reduction in variance on the affected side in the unimanual task. That is, in PD cathodal stimulation of M1 reduced the variance for control of movements on the contralateral side. Consistent with this, the patients altered the choices that they made in the bimanual task: cathodal tDCS made their choices more similar to healthy controls. In contrast, the effect tDCS was very different in healthy controls: the reverse polarity (anodal M1 stimulation) of the electrodes in controls induced changes in bimanual behavior as we saw in PD patients with cathodal M1 stimulation. The laterality and flexion-extension indexes showed that PD patients were more responsive to tDCS in comparison to normal healthy controls. The results of applying tDCS in multi-session experiments also showed marked reduction in the motor subscore of the Unified Parkinson's Disease Rating Scale (UPDRS).In summary, we found that motor choice PD patients make is due to a cost analysis that has two components: variance, and effort. On the affected side, variance is significantly increased with respect to controls, and the choices of PD patients are generally consistent with this increased variance. We can improve unimanual variance of the PD patients using tDCS. This produces an immediate improvement in their actions in bimanual tasks. The repeated session of applying tDCS might improve motor symptom of Parkinson's Disease by decreasing the UPDRS and thus be therapeutically relevant.

Title: Relative proprioceptive distance is used for movements towards visual targets

Authors: *M. C. VAN DER GRAAFF, E. BRENNER, J. B. J. SMEETS;
MOVE Res. Inst. Amsterdam, Fac. of Human Movement Sci., VU Univ., Amsterdam, Netherlands

Abstract: When we want to make accurate hand movements to for instance a visual target, it is assumed that we combine visual and proprioceptive information to localize our hand precisely. It has been suggested that you do the same for visual targets. In this case, visual localization is based on the target's position relative to your fovea, and proprioceptive localization is relative to your hand. If you cannot see your hand, this proprioceptive target information will degrade, as updating the location of the target relative to your moving hand adds noise. If this proprioceptive estimate of the target is relevant, movements will become more precise and accurate if we are able to keep a proprioceptive estimate, for instance by placing the other (invisible) hand near the target. This unseen hand does not add new information; it only copies the visual information to proprioception. We tested this prediction by asking subjects to repeatedly move their right index finger between several visual targets on a table. We repeated the experiment after the subjects put their left index finger under one of the target locations (without any feedback). Subjects made considerable errors in positioning their invisible right finger. As predicted, adding a non-informative finger improved the accuracy of the movements (by about 20%). The bias of the invisible right hand after repetitive movements was on average shifted more towards the left hand's location than towards the target. When the invisible left hand was placed 10 cm to the right of the target, subjects also ended on average on a different place than the condition with no hand near the target. However now the endpoints of the invisible right hand did not simply shift in the direction of the left hand's location. This suggests that we are able to use a relative proprioceptive distance to localize a visual target.

Title: The influence of affordances on object-directed actions

Authors: *E. ROUNIS[1,2], M. DUTA[2], G. HUMPHREYS[2];
[1]Oxford Univ., Oxford, Headington, United Kingdom; [2]Dept. of Exptl. Psychology, Cognitive Neuropsychology Ctr., Oxford, United Kingdom

Abstract: Studies in non-human primates suggest that the motor system selects which action to perform by a process of 'affordance competition'. This postulates that a number of potential actions may be represented simultaneously prior to one being selected when sufficient evidence accumulates to indicate that the action lead to a desired outcome (Cisek 2007).
We designed a forced-choice paradigm in which participants were required to use an everyday object (a mug) either with a congruent or incongruent hand grasp as specified by a line positioned to the top or the bottom of the mug. We varied both the orientation of the object (upright or upside down) and the action to be performed (based on a verbal instruction : 'lift' or 'turn'). To control for affordance effects elicited by the mug, participants also performed the same task on a cylinder with identical size and weight to the mug plus an identical line indicating an upright or rotated grasp.
The two tasks were presented in counterbalanced order across participants. Responses were characterized by four separate time stamps: 1) movement initiation; 2) movement duration (from movement initiation to lifting the object); 3) object handling duration (the time between the object lift and its repositioning) and 4) the return time (the time from re-positioning the object to the return to the resting position).
We found a strong effect of grasp orientation on movement initiation time and movement duration, both of which reduced for grasps to the top of an upright mug. It addition, the object handling duration reduced when the cup was returned into an upright position, suggesting an effect of completing a familiar action goal; in contrast return times were delayed when cups were transformed to an upright position.
This study demonstrates the dynamic influence of affordances and action goals on different parts of reaching, grasping and manipulating actions. A familiar affordance, from an upright cup, speeds action initiation and duration, while the subsequent affordance from a cup turned to

upright delays a return response. The presence of a familiar goal, to turn a cup to upright, facilitates enactment of the corresponding action.

Title: The influence of arm-movement preparation on interhemispheric beta synchronization in the medial motor areas

Authors: *T. NAKAJIMA[1,2], H. ARISAWA[1], R. HOSAKA[3,4], K. SHIMA[1], H. MUSHIAKE[1,2]; [1]Dept Physiol, Tohoku Univ. Sch. Med., Sendai, Japan; [2]Core Res. of Evolutional Sci. & Technol. (CREST), Tokyo, Japan; [3]Dept Appli Math, Fukuoka Univ., Fukuoka, Japan; [4]RIKEN Brain Sci. Inst., Wako, Japan

Abstract: The interhemispheric cooperation of the frontal lobes is of cardinal importance in controlling both bimanual and unimanual movements. In particular, the medial motor areas - the supplementary motor area (SMA) and the pre-SMA - seem to be pivotal regions to regulate the interhemispheric crosstalk via dense transcallosal connections. One of the measurements for the functional coupling between separate brain regions is the synchronized oscillation of field potentials. Although the beta wave (15~40 Hz) is a representative oscillation that is observed in motor-related areas including the SMA during motor preparation, its precise role concerning the interhemispheric cooperation is yet to be elucidated. To study how the beta oscillation mediates the functional coupling of the bilateral medial motor areas for the appropriate performance of manual movements, we trained monkeys to memorize and perform multiple bimanual or unimanual motor sequences. Bilateral recordings of local field potentials (LFPs) revealed significant level of interhemispheric phase synchrony in the beta band during motor preparation. We focused our analysis on unimanual sequences and found that the interhemispheric phase difference of the beta wave was modulated in relation to the intended arm use. Activity of more

than half of simultaneously recorded neurons was phase-locked to the beta oscillations, implying the presence of local generators of beta oscillations in each hemisphere. Our findings suggest that the direction of effective connectivity between the hemispheres changes in accordance with the prepared arm use and support the idea that the medial motor areas might inform the other hemisphere of intended movements.

Title: Analysing a hand movement and gazes to find whether a monkey sets via points in a free curve drawing

Authors: *Z. HE, E. MYASHITA;
Dept. Computa. Intelligence & Systems Sci., Interdisciplinary Grad. Sch. Sci. &, Yokohama, Japan

Abstract: Detecting via points in a complicated movement can provide a clue to understand the brain mechanism of motor planning. It has been reported that drawing figures consisting of lines, e.g. triangles, the via point seems to be set to each vertex. However, there are few studies about via point setting when drawing a closed curve like a circle, which has no explicitly defined vertices. To find whether a monkey sets via points in free drawing of a circle-like closed curve, we investigated relationships between saccade end-points and a hand trajectory during the drawing. Two Japanese monkeys were trained to draw the circle-like closed curve manipulating a robotic arm manipulandum and watching a cursor on a computer monitor displayed as its hand position. The monkeys' hand positions were measured by rotary encoders within the manipulandum, and their gaze points were estimated using EyeLink (Monte System Corp., Japan). We tested the drawing with two different rotation directions and 8 different starting points, which were placed every 45° on a circle with a 100 mm-radius. First we compared a performance of the same monkey in each day and found that both monkeys showed a daily

learning process with a decrease of the variance of hand position although saccades occurred rather consistently. By analyzing data in a plateau period of the learning, we found that the variance of hand position was relatively smaller at points where the saccade occurred in higher probability compared with those where it occurred in lower probability. Finally we compared the saccade with the local minimum point of the variance of hand position in time axis and found that the saccade preceded the hand movement. The findings suggest that as the polygonal drawing, the monkey may set several via points in the curve drawing, where the monkey plan to pass through, and gaze the via points in advance to make sure that the hand is moved as expected.

Title: Emergence of stereotypy in a complex movement sequence: A comparison of temporal and implementation variability in human motor learning

Authors: S. JETT, J. A. MEIER, J. KOSTEK, S. D. JAFFEE, *A. L. FANTANA;
Psychology Dept., Bowling Green State Univ., Bowling Green, OH

Abstract: Learned motor sequences are a foundation on which most human behavior is built. Skilled tasks as diverse as speaking, interacting with a computer, or playing a Bach cello sonata depend critically on the ability of the brain to activate the correct set of muscles at the correct time. Thus, an arbitrarily complex movement could be thought of as a string of motor acts triggered at specific times. One possible strategy for the brain to learn such a sequence would be to acquire these two aspects (temporal vs. gesture implementation) separately. Indeed, piano instruction often involves practicing individual finger movements separately before stringing them together and increasing the tempo to performance level. Alternatively, timing and implementation could be learned and improved on at the same time.
Here we present two longitudinal studies investigating the relationship between timing variability and movement structure variability in healthy adult volunteers learning a complex motor sequence. In both experiments, we follow the emergence of stereotyped behavior by accurately tracking movements using a high-speed (100-250Hz) and high-resolution (<1mm) 3-

D motion capture system. In the first experiment, we followed the finger movements in pianists with 15-25 years of experience over 3-6 weeks as they independently practiced a novel Beethoven prelude. We contrasted this self-timed behavior with an externally-guided sequence, a video game requiring precise movements, performed by undergraduate students with no musical training. In this experiment, the tempo of the sequence was held constant.
We found that the musicians were accurate throughout the study. Even when comparing early rehearsals, finger movements along the piano were stereotyped, both spatially ("correct notes") and temporally. While the overall tempo of the performance increased with practice, the coarse timing differences between renditions were distributed uniformly throughout the piece. However, when analyzing the detailed finger movement trajectories, we found a dramatic increase in stereotypy with practice: the motor implementation variability of the gestures decreased, and was mirrored by a corresponding reduction in temporal variability. The second experiment allowed us to separate the overall tempo from motor and uncorrelated timing errors. Here too, we observed a practice-induced parallel increase in temporal and motor precision.
Our results indicate that temporal and implementation variability show a similar time course during motor learning, whether in internally generated or externally guided movement sequences, suggesting a common neuronal origin.

Title: Reach-to-grasp: Widespread distribution in primary motor cortex of movement related potentials that vary with both reach location and object type

Authors: *A. T. ROUSSIN, A. G. ROUSE, M. H. SCHIEBER;
Neurobio. and Anat., Univ. of Rochester Med. Ctr., Rochester, NY

Abstract: In separate studies, reach direction and grasp type each have been shown to influence movement-related potentials (MRPs) in the primary motor cortex (M1). We investigated the spatiotemporal distribution of MRP variation with both reach location and grasp type. LFPs were recorded from 40 microelectrodes on 5 arrays chronically implanted in the anterior lip and bank

of the motor cortex as two rhesus monkeys performed a center-out, reach-to-grasp task. Electrode lengths ranged from 1.5 mm to 8.5 mm. Monkeys reached from a central object to grasp and operate one of four peripheral objects (sphere, button, handle, mallet) in a pseudorandom order. Each of the four objects required a different manipulation (rotate, press, pull, and pull, respectively). The locations of the objects were changed periodically, so that each object was presented at multiple locations, and multiple objects were presented at each location. Recorded LFPs were low-pass filtered, aligned at movement onset and then averaged across trials to obtain MRPs from each electrode for different combinations of reach location and object grasped.

MRPs typically were comprised of three prominent peaks: an initial positive peak between the instruction/go cue and movement onset (P1), a sharp negative peak around the time of object contact (N1), and a subsequent positive peak (P2). All three MRP peaks were widely distributed in M1. Two-way ANOVA for each of the three peaks showed that all three varied depending on both reach location and object type. Location and object effects both were present medially where ICMS evoked twitches in proximal muscles as well as laterally where ICMS evoked twitches in distal muscles.

In monkey L, object effects were stronger than location effects for all three peaks. In monkey X we found little if any P1. N1, which also was smaller in monkey X, showed stronger location effects than object effects. P2 in monkey X, as in monkey L, showed stronger effects of object than location.

M1 MRPs thus vary in relation to both reach location and object grasped. Both effects are widely distributed in the upper extremity representation.

Title: Left lateralized alpha power is associated with motor preparation of both hands

Authors: *T. KAJIHARA[1,2], M. ANWAR[1], Y. MIZUNO[1,3], M. KAWASAKI[1,4,5], K. NAKAZAWA[2], K. KITAJO[1,5,3];

of Tsukuba, Tsukuba, Japan; [5]Lab. for Advanced Brain Signal Processing, RIKEN Brain Sci. Inst., Saitama, Japan

Abstract: Covertly preparing a cued motor response decreases alpha-band (8-13Hz) electroencephalographic activity over the motor cortex. However, for the paradigm in which a cue indicates a subsequent imperative stimulus on differing probabilities, the alpha power differences between the contralateral and ipsilateral motor regions during the preparatory period remains unknown. Correcting the influences of visuospatial attention, the current study addresses the question using a variant of Posner paradigm (75% cue reliability). Right-handed participants were asked to covertly prepare a corresponding hand response (Left/Right/Non-Preparatory) based on a cue and execute it after the presentation of a target. Visual stimuli for the cue and the target were identical. The type of the cue did not significantly influence the change of alpha power activity over the motor region between the pre-cue and after-cue periods. However the cue per se, in other words regardless of the type of the cue, significantly decreased alpha power over the left motor region. Furthermore, for the after-cue period the alpha power of the left motor region was significantly lower compared to the right motor region across all the types of the cues. A previous study found, using a similar paradigm, showed that the lateralization of occipital alpha contralateral to visuospatial cue indexed visuospatial attention bias. On the contrary to our expectation, lateralization of motor preparation for one hand did not influence alpha activity over the motor-related region. Instead the preparation in general decreased alpha power in the left hemisphere. This result further consolidates the emerging view that motor-related function is rather localized to the left hemisphere for right-handed people.

Title: Implicit guidance to dynamic stability in rhythmic ball manipulation

Authors: *M. E. HUBER[1], D. STERNAD[2];
[1]Bioengineering, [2]Biology, Electrical and Computer Engineering, Physics, Bioengineering, Northeastern Univ., Boston, MA

Abstract: While rhythmically bouncing a ball with a racket is a seemingly simple task, it requires a high level of perceptually-guided coordination to be successful. In the experimental task, subjects manipulated a real table tennis racket to rhythmically bounce a virtual ball to a target height in a 2D virtual environment. Stability analyses of the model showed that dynamic stability is indicated when the racket contacts the ball during the decelerating portion of the racket's upward motion (Dijkstra et al. 2004). Dynamically stable performance implies that small errors converge back to stable performance without requiring active corrections, hence constitutes a "smart" solution that skilled performers adopt. The optimal racket acceleration at contact (RAC) for exploiting dynamic stability is approximately -3m/s^2.
The present study examined if a suitably designed perturbation could guide novice subjects negative RAC earlier in practice. The perturbation was applied to racket velocity at contact. Instead of using the actual racket velocity at contact, the calculation used the velocity value 50ms prior. When RAC was negative, the prior velocity was greater than the actual velocity, resulting in an increase in racket velocity at contact rendering higher ball amplitude for less velocity. When the RAC was positive, the reverse effect was obtained. We hypothesized that subjects learn to exploit dynamic stability faster by adding this perturbation (H1). We further hypothesized that when the perturbation is removed, subjects continue to exploit dynamic stability (H2).
Two groups of subjects performed the virtual ball bouncing task for 28 trials with each trial lasting 40 sec. The experimental group (n=6) practiced the task with the perturbation for 24 trials, followed by 4 trials under normal conditions. The control group (n=6) practiced the task without any perturbation. The objective in both conditions was to hit the ball rhythmically and accurately to the target height.
Results showed that with practice, both groups learned to reduce error between maximum ball height and the target line. However, there was a statistically significant difference in mean RAC between the two groups (p=.001). The experimental group learned to hit the ball with more negative RAC (H1). Removing the perturbation caused a statistically significant increase in mean RAC to -3.24m/s^2 in the experimental group (p=.001). This increase was towards the optimal RAC for exploiting dynamic stability of -3m/s^2 (H2). These results show that humans can be guided to exploit dynamic stability in coordinative behavior early in practice and maintain dynamic stability even when the guidance is removed.

Title: Neural correlates of intrinsic and extrinsic coordinate control following left-hemisphere stroke

Authors: *S. JAX, D. ROSA-LEYRA, L. BUXBAUM;
Moss Rehabil. Res. Inst., Elkins Park, PA

Abstract: Previous research indicates that movements are controlled in both intrinsic (body-based) and extrinsic (world-based) coordinate frames. We have previously proposed that different motor tasks may preferentially rely on control in one frame or the other, and that these task differences may partially explain the pattern of intact and impaired motor abilities in stroke patients with ideomotor apraxia. Specifically, we proposed that many apraxia symptoms may be caused by disrupted intrinsic coordinate control (Buxbaum, 2001; Jax, Buxbaum, & Moll, 2006). In this study we tested 38 chronic left hemisphere stroke survivors and 11 age-matched controls on posture imitation and grasp imitation tasks designed to differ in their putative reliance on intrinsic (posture) or extrinsic (grasp) coordinate control. We also examined the relationship of performance on these tasks to performance on standard assessments of praxis and conceptual action knowledge, as well as the participants' lesion locations. Overall accuracy was lower for the stroke group than controls, and in both groups accuracy was lower for the intrinsic task than the extrinsic task. In addition, hand configuration accuracy differences between the intrinsic and extrinsic tasks were marginally larger for the stroke group than controls. A measure of performance on the intrinsic task relative to the extrinsic task (to control for overall severity) was significantly correlated with accuracy on pantomimed tool use and conceptual action knowledge. Finally, voxel-based lesion-symptom mapping analyses indicated that poorer-than-expected performance on the intrinsic task was associated with lesions to the superior portions of the posterior temporal lobe (BAs 21, 22, and 37) as well inferior portions of the angular gyrus (BA 39). These results provide further evidence that deficits in intrinsic coordinate control may be a core perceptual-motor processing deficit in ideomotor apraxia, and that these deficits may be localized to the left posterior temporal lobe and angular gyrus.

Title: Referent control of motor actions by the corticospinal system in humans (TMS studies)

Authors: *A. G. FELDMAN[1,3], H. A. RAPTIS[2,3], N. ILMANE[2,3], S. G. SANGANI[4,3];
[2]Physiol., [1]Univ. Montreal, Montreal, QC, Canada; [3]Ctr. for Interdisciplinary Res. in Rehabil. (CRIR), Montreal, QC, Canada; [4]McGill, Montreal, QC, Canada

Abstract: According to previous studies, muscles become active in response to deviations from a threshold (referent) position of body segments. Intentional motor actions result from central shifts in the referent position that represents the origin point of the spatial frame of reference in which these actions are produced. We tested the hypothesis that corticospinal pathways set and reset the referent position of body segments in a task-specific way without pre-determining movement kinematics or/and motor commands to muscles. Using TMS of the wrist motor cortex, we evaluated corticospinal influences at wrist positions established before and after voluntary motion. Such influences were also evaluated before and after involuntary motion elicited by sudden removal of a load (the unloading reflex). To minimize the effect of changes in motoneuronal excitability on the evaluation of corticospinal influences, motor potentials elicited by TMS were evoked during an EMG silent period produced by brief muscle shortening. Although the tonic EMG levels at pre- and post-unloading wrist positions were substantially different, the corticospinal influences remained the same. These influences changed however when subjects voluntarily moved their wrist to another position. An additional analysis showed that corticospinal influences shifted the referent position at which wrist muscles were recruited when voluntary wrist motion was made but that they maintained the same referent position during unloading. Thus, central control strategies underlying the two types of motor actions are fundamentally different. In another experiment, subjects learned to diminish the post-unloading movement extent (adjusted unloading). They were required not to activate antagonist muscles before unloading or make intentional movement corrections after unloading. We compared corticospinal influences before the adjusted unloading with those before the natural unloading. Tonic EMG activity levels of wrist muscles before the two types of unloading were similar. However, corticospinal facilitation of antagonist motoneurons but not motoneurons of pre-loaded agonist muscles was higher before adjusted unloading, suggesting that the referent position of the

joint was shifted by changing the sub-threshold state of the system in anticipation of unloading. The notion that the motor cortex may control motor actions by shifting spatial frames of reference for motor actions in a feed-forward way opens a new avenue in the analysis and understanding of brain function.

Title: Oscillatory corticomuscular coupling is a negative factor of exerted force steadiness

Authors: *J. YAMADA[1], J. USHIYAMA[1,3], M. LIU[3], J. USHIBA[3,2];
[1]Grad. Sch. of Sci. and Technol., [2]Biosci. and Informatics, Keio Univ., Kanagawa, Japan;
[3]Rehabil. Med., Keio Univ. Sch. of Med., Tokyo, Japan

Abstract: Oscillatory neural activity of the sensorimotor cortex shows coherence with contracting muscular activity within the 15-35 Hz frequency band (β-band) during weak to moderate intensity steady contraction (e.g. Baker et al., 1997; Conway et al., 1995). Our previous study demonstrated that the magnitude of coherence between electroencephalogram (EEG) over the sensorimotor cortex and electromyogram (EMG) varies among 100 healthy young individuals, and shows a significant positive correlation with the extent of the β-band oscillation in EMG (Ushiyama et al., 2011). Considering this result, it is hypothesized that the strength of corticomuscular coupling is a factor regulating the steadiness of individual motor output. To test this hypothesis, we recorded the EEG over the sensorimotor cortex and EMG from the tibialis anterior muscle, when the healthy participants (n = 18, aged 20-33 yrs) performed steady dorsiflexion at 30% of maximal effort for 60s. As results, individual magnitude of EEG-EMG coherence (peak coherence) showed significant positive correlations with the coefficient of variation of force and with the sum of the power spectral density of the force within β-band (Force β-PSD) (both, $p<0.01$). Furthermore, we divided lower frequency band of force signal into 5-14 Hz (Force High α-band) and 1-4 Hz (Force Low α-band) bands, based on some previous studies which have reported the existence of physiological tremor around 10 Hz during isometric contraction in lower limb (Elble and Randall, 1976; McAuley and Marsden, 2000). The magnitude of EEG-EMG coherence also showed significant positive correlation with Force High

α-PSD ($p<0.05$) but not with Force Low α-PSD. Next, we conducted further examinations to clarify the association between the β-band EMG oscillation and the High α-band force fluctuation. By careful visual observations, we found that the amplitude of EMG rhythmic burst fluctuated within the task performed by the participants with greater EEG-EMG coherence. Further, the rhythm of bursts and the duration of silent period between two successive EMG bursts changed randomly. In such cases, force fluctuations at around 10 Hz were characteristically observed in the force signal. By contrast, EMG signals in the participants with weaker EEG-EMG coherence showed tonic activation patterns, and its amplitude was stable throughout the task. Such muscle activation patterns would lead to more precise force output. Overall, the present data suggest that the β-band corticomuscular coupling is a determinant of individual muscle activation patterns, and therefore influences the force steadiness of each participant.

Title: Decreased ability to inhibit motor response under the food craving condition

Authors: *K. YAMANAKA, F. ISHIKAWA, Y. FURUKAWA;
Showa Women's Univ., Tokyo, Japan

Abstract: Human eating behavior is driven by their craving for foods and achieved with an action of reaching for foods. Therefore, inhibiting an action is difficult when human is craving for foods. However, it remains unclear how human ability to inhibit an action is influenced by the level of food appetite. Here, we compared the performance of Go/Stop task, in which participants need to inhibit a planned action, between conditions in which the level of food appetite was distinctly different: just before and after food intake. Twenty volunteers (12 females and 8 males) have conducted two experimental sessions on separate days. All participants were invited to laboratory between 11am and 2pm. They were previously instructed to have almost the same breakfast at almost the same time on both days. After the task instruction, they performed Go/Stop task, consisting of 100 Go and 100 Stop trials. They had almost the same lunch in the laboratory on both days, but the timing is different: one was before and the other was after Go/Stop task (pre-task and post-task conditions). Just before and after Go/Stop task, their ratings

of food appetite (desire to eat, hunger, and fullness) were assessed with 50-mm visual analog scales and their perceived levels of arousal, pleasant, excite, and stress were assessed with 9×9 affect grid. In the Go/Stop task, subjects were instructed to click a computer mouse by a right index finger when an indicator moving with a constant velocity reached a target (Go trial) or to avoid the click when the indicator randomly stopped 250-100 ms before it reached the target (Stop trial). From the %correct in Stop trials and mean response time in Go trials, stop-signal reaction time (SSRT) was calculated for each participant and condition. As expected, food appetites significantly decreased in post-task condition compared with pre-task condition. On the other hand, perceived levels of 4 items were not significantly different between pre- and post-task conditions due to their large between-subject variability. SSRTs tended to decrease in the post-task condition compared with the pre-task condition, but they were not significantly different. Therefore, analysis of covariance was conducted with condition as a main factor and each perceived levels as a covariate. As a result, only when perceived stress level was included as a covariate, SSRTs in the post-task condition were significantly smaller than those in the pre-task condition. These results indicate that, considering the effect of perceived stress levels, human motor inhibitory function might change before and after the food intake and suggest difficulty to inhibit a planned action under the food craving condition.

Title: Increased task complexity leads to a decreased motor preparatory state

Authors: *N. M. DRUMMOND, E. K. CRESSMAN, A. N. CARLSEN;
Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Previous research using a startling acoustic stimulus (SAS) has shown that highly practiced simple movements are prepared well in advance (1500 ms) of the earliest go-signal during a variable foreperiod simple RT task (Carlsen & Mackinnon, 2010). The purpose of the present experiments was to investigate the level of advance preparation in the motor system while participants completed a more complex task. Specifically, participants completed a visuomotor mental rotation (VMR) task within a variable foreperiod RT framework, requiring

them to perform different movements on each trial. A trial started with the appearance of a visual cue and an instructed angle of rotation (0°, 60°, 90° or 120°) 1650-2350 ms prior to the go-signal. Participants were then required to initiate their movements to the specified location (visual cue + angle of rotation) as quickly and accurately as possible following the go-signal. Instructed angles of rotation were presented either during random or blocked conditions, such that all angles were presented within a block of trials or only one angle was presented within a block of trials, respectively. To probe motor preparation a SAS was randomly presented 500, 1000, or 1500 ms following visual cue onset (i.e., 1150, 650, or 150 ms prior to the earliest go-signal). Results revealed that subjects were consistently and reliably startled at all three SAS time points during both random and blocked trial conditions. Interestingly, in comparison to previous tasks in which participants moved directly to the same target on all trials (Carlsen & Mackinnon, 2010), results revealed a reduced level of advance motor preparation in this more complex task for both random and blocked trial conditions, as indicated by the decreased proportion of movements involuntarily triggered by the SAS at all three time points. Furthermore, results indicated no differences in the proportion of SAS-triggered movements between random and blocked trial conditions or between any of the angles of rotation. These results suggest that the complexity of the task itself may be what influences the level of motor preparation achieved. More complex tasks and their resulting movements may introduce a larger amount of neural noise into the motor system than tasks involving a more simple movement. Increased noise may then result in a lower mean level of motor preparation in order to guard against accidental early and/or errorful response initiation. We postulate that these differences in preparatory state prior to the imperative go-signal between tasks are strategic, such that humans employ a preparatory strategy that accounts for noise introduced into the motor system by task demands.

Title: Adult hemispherectomy asymmetrically affects the emotional reactivity and locomotion activity in mice

Authors: *M. C. SANTOS[1], D. PAES BRANCO[2], Y. ABREU VILLAÇA[2], A. CHRISTIAN MANHÃES[3], C. CARNEIRO FILGUEIRAS[2];
[1]Dpto de Ciências Fisiológicas, Univ. Do Estado Do Rio De Janeiro - UERJ, Rio De Janeiro, Brazil; [2]Univ. do Estado do Rio de Janeiro, Rio de Janeiro, Brazil; [3]Univ. Estadual do Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Evidence exists indicating that cerebral lateralization is a fundamental feature of all vertebrates. In humans, it has been suggested that the right hemisphere is involved in processing negative emotional information and the left hemisphere is involved in control of motor function. In rodents, evidence for hemispheric lateralization is sparse. In this regard, here, we used unilateral hemispherectomy to study the relative importance of each hemisphere in controlling emotion and spontaneous motor activity in mice. Adult male mice were submitted to right hemispherectomy (RH), left hemispherectomy (LH) or sham surgery (SHAM). To help the interpretation of results an addition sample of mice was submitted to unilateral suction of left frontoparietal area (LFP), right frontoparietal area (RFP) or sham surgery (CONT). Fifteen days after surgery, both the emotional reactivity and the spontaneous locomotor activity were assessed in the open field test 10 min (divided into 1 min intervals). The open field arena consisted of a polypropylene box in which the floor was divided into 16 same-sized rectangles. The total number of rectangles crossed was used as the measure of spontaneous locomotor activity. Considering that mice avoid open areas, the ambulation in the center and time spent in the central rectangles were used to assess emotional reactivity. Regarding locomotor activity, the two surgical techniques reveal asymmetries in opposite direction. The locomotor activity of LH, which increased along the test period, was higher than both RH and SHAM. In contrast, the locomotor activity of RFP which decreased along the test period was higher than both LFP and CONT. Regarding emotional reactivity, the LH group spent less time in the central area than both RH and SHAM groups. No differences were observed between LFP, RFP and CONT groups. Our results suggest that the two hemispheres contribute asymmetrically to control of emotional reactivity and to control of motor activity in mice. Similarly to what is observed in humans, the right hemisphere of mice was more involved in processing negative emotional information. Regarding locomotor hyperactivity, the differences observed between hemispherectomized and frontoparietal-lesioned mice suggest that multiple lateralized circuits (or systems) may underlie spontaneous locomotor activity.

Title: Social cues can acutely reverse injury-induced vocal motor impairments

Authors: *M. H. KAO, R. RAJAN, A. DOUPE;
UCSF Ctr. For Integrative Neurosci., San Francisco, CA

Abstract: Motor skills, such as speaking or typing, involve combining simple movements in novel sequences. Performance of such skills is influenced by external cues, especially when the brain is damaged by injury or disease, but the underlying mechanisms are poorly understood. Songbirds are an excellent model system for studying the generation of learned movements. In adult zebra finches, social cues strongly modulate motor output: song rate and stereotypy are greater when males produce female-directed courtship song than when they sing alone ('undirected'). Previous work has shown that microlesions of a premotor nucleus, HVC, immediately destabilize undirected song, disrupting its temporal and spectral organization. To examine whether social cues can reverse the effects of HVC damage and facilitate stereotyped song, we made partial lesions of HVC and examined the consequences on song in different contexts. We found that while lesioning 40-80% of HVC induced gross changes in the sequence and structure of song elements ('syllables') when males were alone, female presence could dramatically "repair" song. The timing, acoustic structure, and order of syllables during courtship song were similar to that of pre-lesion song, and birds with HVC lesions rapidly switched between variable, degraded undirected song and more stereotyped, mature courtship song. To examine neural mechanisms underlying the social modulation of song, we focused on a basal ganglia-thalamocortical loop known to mediate song variability in normal birds. We reversibly inactivated the cortical output (LMAN) of this loop while disrupting HVC activity, and found that LMAN inactivation prevented the destabilization of song normally induced by HVC disruption. These findings indicate that song disruption following HVC damage likely derives from aberrant activity in this loop, which can be mitigated by context. More generally, they suggest that external cues facilitate movements in patients with motor disorders by suppressing pathological activity in basal ganglia-thalamocortical loops.

Title: Frontal and parietal lesions have different effects on online updating of prehension for perturbations of object goal

Authors: E. TUNIK[1], S. T. GRAFTON[2], *S. V. ADAMOVICH[3];
[1]Rehabil. and Movement Sci., Rutgers Univ., Newark, NJ; [2]Dept. of Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA; [3]Dept of Biomed. Engin., New Jersey Inst. of Technol., Newark, NJ

Abstract: It is now known form primate physiology studies that the region in the anterior portion of the intraparietal sulcus (area AIP) and the ventral premotor cortex (area F5, PMv) contain neurons whose firing rates are tuned to the features of object shape and to the hand shape used to grasp an object. Since aIPS and PMv both encode 3D features of objects and grasp shape, we set out to test the extent to which each region contributes to updating of the entire hand shape, rather than updating a single grasp parameter (which presumably can be achieved simply by a scaling solution). To test this, 8 healthy right-handed young adults observed a rectangular target object for 200ms before vision was blocked with liquid crystal glasses. The object was initially oriented such that the bottom edge was either parallel to the table or at a 45-degree angle (square and rhombus orientation, respectively). Following the initial view period, subjects were cued to reach-grasp the object such that the four fingers were either adducted and flexed together (square object) or abducted and less flexed (rhomboid object). At the start of movement, vision was restored again for another 200ms revealing to the subjects that the object orientation either remained unchanged or was perturbed to the other orientation (rhombus-to-square or square-to-rhombus), requiring them to either maintain the planned hand shape, or to update it. Double pulse TMS (50ms apart) was used to disrupt processing in aIPS and PMv either in the second viewing interval or immediately afterward, to tease apart processes related to updating versus execution. Subjects also performed the task with Sham TMS to the vertex as a control block. Kinematic analyses revealed that scaling of peak excursion of finger abduction and flexion was significantly affected and delayed when TMS was applied to PMv and aIPS at the updating interval, but not at the execution interval. Eleven joint angles submitted to linear discriminant analysis for classifying the hand shape identified a key difference between aIPS and PMv disruption on the evolution of hand shaping. aIPS-TMS led to a delay of hand shaping that

eventually recovered to the level of the Sham-TMS condition, without increasing movement time. Conversely, PMv-TMS led to a delay and an entirely different hand shaping pattern that was also associated with ~15% longer movement times. Our findings suggest that PMv and aIPS form unique but complementary nodes required for updating in the cortical reach-to-grasp network. Based on our findings, we speculate that aIPS may be integrating sensory information while PMv may be supplying a model of the grasp shape, which if disrupted must be rebuilt de novo.

Title: Age-related changes in rat cortical motor area dedicated to tongue and jaw

Authors: J. M. WENNINGER[1], J. RUSSELL[1], H. KLETZIEN[1], A. J. SCHASER[1], J. A. KLEIM[2], N. THOMAS[2], *N. P. CONNOR[3];
[1]Surgery, Univ. of Wisconsin, MADISON, WI; [2]Arizona State Univ., Temple, AZ; [3]Univ. Wisconsin Med. Ch, MADISON, WI

Abstract: Age-related changes in sensorimotor actions for speech, voice, and swallowing may be due to alterations within cranial muscles, neuromuscular junctions (NMJ), and the central nervous system. Within the tongue and hypoglossal nucleus (HN) of an aging rat model, we have found reductions in evoked and voluntary muscle forces, alterations in NMJ morphology, alterations in serotonergic inputs to the HN, and a reduction in primary dendrites of hypoglossal motor neurons. However, it is unknown if the age-related decline in sensorimotor function involves cortical map changes.
To test the hypothesis that cortical motor areas dedicated to jaw and tongue would decrease as a function of aging, we performed intracortical microstimulation mapping experiments in young adult (9 mo, n=7) and old (36 mo, n=7) Fischer 344/Brown Norway male rats. Animals were anesthetized and placed in a stereotaxic frame and a cranial window was made extending 3-5mm rostral and 1-2mm caudal to Bregma. A photograph of the cortical surface was taken and a digital grid (squares of 250μm) was overlaid. Sites of stimulation at a depth of 1550 (±5) μm were made at grid intersections using a glass microelectrode filled with 3M NaCl and platinum

wire. Current was increased until movement was evoked (maximum stimulus 100μA), and a threshold stimulus for movement was determined. Mean areas of tongue and jaw movement were calculated.
We found that old rats had larger tongue movement representations than young adult rats (0.889±0.125 and 0.204±0.093 mm^2, respectively; p = 0.001). However, there was no difference in the size of jaw movement representations between old and young adult rats (1.08 ±0.334 and 0.666 ±0.104 mm^2, respectively; p = 0.28). Additionally, only 2 of the young adult rats had a tongue area greater than 0.06 mm^2. Thus, these results did not allow us to accept our hypothesis. While it appears that the cortical area dedicated to tongue increases with age in male rats, age-related cortical thinning may have occurred. Because stimulation was evoked at a constant cortical depth, further investigation of total cortical volume dedicated to the tongue is needed.

Title: Modulation of auditory and somatosensory event-related potentials due to speech motor learning

Authors: *T. ITO[1], J. H. COPPOLA[2], D. J. OSTRY[3,2];
[1]Haskins Labors, NEW HAVEN, CT; [2]Haskins Labors, New Haven, CT; [3]McGill Univ., Montreal, QC, Canada

Abstract: The neural mechanisms of sensory plasticity associated with speech motor learning are little understood. In arm reaching motion, motor adaptation to novel external environment changes somatosensory function and its associated cortical processes as well as motor function. Since both auditory and somatosensory function are involved in speech production and learning, speech-related auditory and somatosensory cortical processes may possibly be modified in speech motor learning. We here examined whether speech motor learning alters auditory and somatosensory cortical processes by studying event-related potentials (ERPs). We tested native speakers of American English. We applied altered auditory feedback (AAF) training as a motor learning task. When subjects repeated aloud the speech utterance “head,” the produced sound

was played back through headphones. The first formant of /ea/ in “head” was gradually decreased over 50 repetitions and held at a maximum change for a further 110 repetitions. 9 of 18 participants showed a gradual increase of the first formant frequency (F1) in their utterance repetitions, an adaptive change in response to the experimentally imposed decrease of F1 in the sounds that were played back to them through headphones. In order to evaluate the effects of this adaptation on cortical sensory processes, we recorded auditory and somatosensory ERPs using 64-channel electroencephalography before and after AAF training. Auditory ERPs were elicited by using the synthesized vowel sound “e” corresponding to /ea/ in “head”. Somatosensory ERPs were elicited by facial skin deformation similar to that which occurs in the articulatory movements in the production of “head”. We found changes to auditory and somatosensory ERPs following AAF training in individuals who showed adaptation change to altered auditory feedback, but not in individuals who did not show an adaptation effect. Auditory ERPs in post training were significantly reduced at electrodes over the right frontal regions. The changes in ERPs were correlated with the amount of adaptation in AAF training. In somatosensory ERPs, we found an enhancement of the mu rhythms in individuals who showed adaptation at the C5 electrode over left sensorimotor area. The results demonstrate that speech motor learning modulates the cortical processing of speech-related somatosensory and auditory inputs.

Title: Spatiotemporal dynamics of multiple bands of local field potentials from orofacial portion of primary motor cortex during feeding

Authors: *K. TAKAHASHI, J. IRIARTE-DIAZ, K. A. BROWN, N. G. HATSOPOULOS, C. F. ROSS;
Organismal biology and anatomy, Univ. of Chicago, CHICAGO, IL

Abstract: The orofacial area of the primary motor cortex (MIo) is involved in control of voluntary, semiautomatic and rhythmic movements of the tongue and jaw during key phases of

feeding behaviors such as ingestion, chewing and swallowing. Our previous results showed that beta oscillations (15~25Hz) of local field potentials (LFPs) increased their power immediately before swallow following a preferred unilateral chew cycle, and two bands of gamma oscillations (45~55Hz and 65~85Hz respectively) increased their power around the time of transition from food manipulation to first chewing cycle. Furthermore, we have shown previously from the hand/arm area of the primary motor cortex that prominent beta oscillations were present across the recording area of 4 mm x 4 mm, and propagated as planar waves along a rostrocaudal axis at speeds ranging from 10 ~ 30 cm/sec. To investigate if MIo exhibits similar spatiotemporal dynamics in each of the frequency bands identified from our previous study, we analyzed LFPs recorded from a Utah array implanted in MIo on the left hemisphere in each of two macaque monkeys while the monkeys were performing a manual feeding task. Tongue and jaw kinematics were captured using videofluoroscopy and a 3D motion tracking system. Most of the channels showed strong beta power at a consistent frequency, while gamma oscillations exhibited wide variations in peak frequency across the cortical surface. Beta oscillations propagated as planar waves and propagated bidiretionally along a rostrocaudal axis with speed ranging from 15 ~ 35 cm/sec. As for the gamma oscillations, only lower frequency gamma band propagated as planar waves with a unimodal direction distribution oriented towards the central sulcus and a speed distribution with a mode around 60 cm/sec. These results indicate that both beta and low gamma oscillations are spatiotemporally organized and propagate as planar waves. The spatial variations in gamma oscillation frequency across MIo suggest that gamma oscillations may be related to more localized neural activity than beta oscillations.

Title: Neuronal networks innervating the jaw-opening and jaw-closing muscles: A retrograde transneuronal tracing study with rabies virus in the rat

Authors: *N. HATANAKA[1], S. MIYACHI[2], A. NAMBU[1], M. TAKADA[3];
[1]Div. of Syst. Neurophysiol., NIPS, Okazaki, Aichi, Japan; [2]Cognitive Neurosci. Section, [3]Systems Neurosci. Section, Primate Res. Institute, Kyoto Univ., Inuyama, Aichi, Japan

Abstract: Higher-order neuron networks innervating the jaw-opening and jaw-closing muscles were examined in the rat brain by intramuscular inoculation of rabies virus (CVS-11 strain). The virus was inoculated into either the anterior belly of the digastric muscle or the masseter muscle. The survival period after the inoculation ranged from 84 hr to 120 hr with 12-hr steps. The virus was initially taken up by trigeminal motoneurons for the jaw-opening and jaw-closing muscles, and then propagated through retrograde transneuronal transfer. Five infection stages were considered based on neuronal labeling in subcortical and cortical structures. At stage 1, only the trigeminal motoneurons were labeled. At stage 2, premotor neurons that project directly to the trigeminal motoneurons were labeled in the medullary, pontine, and mesencephalic reticular formation, medial parabrachial nucleus, Kölliker-Fuse nucleus, and sensory trigeminal nuclei. At stage 3, neurons that project to the trigeminal motoneurons indirectly via the premotor neurons were labeled in the cerebral cortex, amygdala, hypothalamus, zona incerta, intralaminar thalamic nucei, entopeduncular nucleus, substantia nigra pars reticulata, deep cerebellar nuclei, central gray, superior colliculus, and red nucleus. At stage 4, neuronal labeling occurred in the cerebellar cortex (Purkinje cells), ventrolateral striatum, and globus pallidus. In most of the regions examined, the distribution patterns of these neurons labeled multisynaptically from the jaw-opening versus jaw-closing muscles were largely similar. There were some differences. For example, the dorsolateral portion of the striatum exclusively contained the neurons for the jaw-opening muscle. This suggests that the dorsolateral striatum may specifically be involved in jaw-opening behaviors.

Title: Spiking activity in the motor and sensory cortices differ during long-term learning

Authors: *F. I. ARCE[1], N. G. HATSOPOULOS[1], J. C. LEE[2], C. F. ROSS[1], B. J. SESSLE[2]; [1]Dept. of Organismal Biol. and Anat., Univ. of Chicago, Chicago, IL; [2]Fac. of Dent., Univ. of Toronto, Toronto, ON, Canada

Abstract: The sensorimotor cortices have long been implicated in the acquisition of novel motor skills. However, it is not known whether learning-related changes differ between the motor and

sensory cortices. To address this issue, we used chronically implanted microelectrode arrays to track neuroplastic changes in the activity of simultaneously recorded neurons in the face somatosensory (SIo) and motor (MIo) cortices and compared the changes between the two areas. Over a period of 9-11 weeks, two naïve monkeys (Macaca mulatta) learned to protrude the tongue onto a strain gauge and apply isometric force at the level cued by target positions. The two monkeys exhibited similar learning rates early in training. As task parameters became stricter, the monkeys significantly differed in their performance level.
We analyzed single unit activity recorded from MIo and SIo of each monkey related to 2 epochs during a task trial, i.e. preparatory (0.5 s after target onset) and movement (0.5 s after force onset). Single units were deemed task-modulated when their firing rates during a hold period (0.5 s before target onset) differed significantly from firing rates during the preparatory or movement epoch (Paired t-Test, $p<0.01$). The proportion of MIo and SIo neurons that were task-modulated significantly increased over the training period (Binomial test, $p<0.05$). However, the degree of modulation observed in MIo neurons significantly decreased (ANOVA, $p<0.01$) but such a decrease was not apparent in SIo. In both monkeys, trial-by-trial variability of the neural activity in MIo during the preparatory epoch progressively decreased over time (ANOVA, $p<0.01$) and exhibited a higher rate of change compared to the trial-by-trial variability of the neural activity during the movement epoch. In SIo, the response variability reflected the monkeys' performance. The high-performing monkey exhibited progressive reduction in the response variability during the preparatory and movement epochs (ANOVA, $p<0.01$) while the low-performing monkey showed increased response variability (ANOVA, $p<0.01$). Finally, pairs of MIo and SIo neurons showed significant modulation of coherent activity (2-6 Hz) regardless of monkeys' performance level. For the population of neuronal pairs, the peak of the coherent activity of MIo neuronal pairs was observed 0.25 s before force onset and was significantly earlier than that of SIo which was observed at the time of force onset (t-Test, $p<0.01$). Overall the results show neuroplasticity of both MIo and SIo cortices during long-term learning and point to differences in the way MIo and SIo neurons may contribute to the control of movement parameters as learning progresses.

Title: Decreased face primary motor cortex (face-M1) excitability induced by noxious stimulation of the rat molar tooth pulp is dependent on the functional integrity of face-M1 astrocytes

Authors: *L. AWAMLEH[1], H. PUN[1], J. LEE[1], B. SESSLE[1], L. AVIVI-ARBER[1,2];
[1]Oral Physiol., [2]Prosthodontics, Fac. of Dentistry, Univ. of Toronto, Toronto, ON, Canada

Abstract: * Awamleh and Pun contributed equally
Acute dental pain is a common clinical occurrence that is often associated with altered sensory and motor orofacial functions. We have previously shown that application of the small-fiber excitant and inflammatory irritant mustard oil (MO) to the rat molar tooth pulp results in central sensitization of trigeminal medullary dorsal horn (MDH) (and thalamic) nociceptive neurons that can be modulated by MDH application of the astrocytic inhibitor methionine sulfoximine (MSO) (e.g. Chiang et al., J. Neuroscience, 2007). The objectives of the present study were to determine whether: 1) MO application to the rat molar tooth pulp also affects face-M1 excitability manifested as an altered intracortical microstimulation (ICMS) threshold required to evoke electromyographic (EMG) activity in the right anterior digastric (RAD) -a jaw-opening muscle-; and 2) MSO application to face-M1 can modulate the MO effect on face-M1 excitability. Under Ketamine general anaesthesia, the right maxillary first molar tooth pulp was exposed with a high speed dental drill, and EMG electrodes were implanted into the RAD of Sprague-Dawley male rats. Following surgical exposure of the left hemisphere, a microelectrode was positioned at a face-M1 site from which ICMS (35ms train, 12x0.2ms pulses, 333Hz) evoked low-threshold ($\leq$30μA) RAD EMG activity. This baseline stimulation threshold was monitored every 15 min for 30 min; then MO (n=24) or saline (n=17) was applied to the exposed molar tooth pulp and ICMS thresholds were monitored every 5 min for 15 min. MSO (0.1mM, n=9) or saline (n=7) was then applied to the left face-M1 and ICMS thresholds were monitored every 10 min for 180 min. Data were analyzed by repeated-measures ANOVA followed by post-hoc Bonferroni as appropriate ($p<0.05$). Within 15 min of MO (but not saline) pulp application, RAD ICMS thresholds increased significantly as compared to baseline (49.9%$\pm$5.7%, Mean$\pm$SEM; $p<0.001$). One hour following MSO (but not saline) application to face-M1, elevated RAD ICMS thresholds decreased considerably towards baseline levels (14.2%$\pm$4.5%; $p<0.05$). These novel findings suggest that acute inflammatory dental pain is associated with decreased face-M1 excitability that is dependent on the functional integrity of face-M1 astrocytes and may be related to the mechanisms by which acute dental pain is associated with limited jaw movements.

Title: Early and progressive oromotor and swallowing dysfunction in a PINK1 knock-out model of Parkinson Disease

Authors: *M. R. CIUCCI, L. M. GRANT, C. A. KELM-NELSON;
Surgery-Otolaryngolgy, Univ. Wisconsin, MADISON, WI

Abstract: Parkinson disease (PD) is devastating to oropharyngeal swallowing. However, the onset, progression and neural correlates of PD-related dysphagia are poorly understood. To address this, we used a transgenic rat model of PD and hypothesized that oromotor and swallowing deficits would manifest early in the disease process, progress, and be related to pathologies in brain structures associated with cranial sensorimotor function.
Rats with homozygous and heterozygous knock-out (KO) of PINK1, and WT controls (n=48;) were studied. Bite force and timing characteristics were measured during consumption of a 7cm piece of pasta at 4 and 8 months. Lingual force and timing control was measured during a complex licking task at 2, 4, 6, and 8 months. Videofluoroscopy was used to evaluate swallow function at 4 and 8 months (analysis ongoing). Tissue analysis is ongoing for key neurotransmitters and alpha-synuclein aggregates in brainstem, basal ganglia, and cortical regions important to oromotor function and swallowing. To determine differences between groups for biting and lingual forces/timing variables, a repeated measures ANOVA and Fishers Least Significant Difference tests were used (alpha<0.05).
Results show that rats in the PD models demonstrate increased interbite intervals regardless of age [$F(3, 96)=16.74$, $p<0.01$]. Contrary to our hypothesis, homozygous KO rats had increased lingual forces compared to WT ($t(46)=5.24$, $p<0.001$) and heterozygous ($t(46)=3.358$,$p=0.003$) at all-time points. However, there was an age by genotype effect for timing (average force over time)[$F(6,99)=9.7$, $p<0.001$] that shows homozygous rats press harder for the first 30 seconds of the task, then forces decayed during the task, and this deficit worsens as a function of age. Overall results indicate that transgenic PD rats, especially with homozygous KO of PINK1, demonstrate early oromotor and swallowing dysfunction, and that lingual deficits reflecting fine control and timing of licking behavior is progressively impaired. Full data sets will be presented for functional swallowing and pathology. Defining pathophysiology related to swallow deficits is essential to develop new treatment targets for PD-related dysphagia.

Title: Kinematics of the pharyngeal swallow following palatal anesthesia in infant pigs: Evidence of motor learning

Authors: *R. Z. GERMAN[1], S. HOLMAN[2];
[1]Anat. and Neurobio., NEOMED, Rootstown, OH; [2]Sch. of Dent., Univ. of Maryland, Baltimore, MD

Abstract: Adaptive motor learning during swallowing occurs in adults, but its existence or prevalence in infants is unknown. A reduction in palatal sensation due to local anesthesia (PLA) injection is known to produce an increase in both hyoid elevation and jaw opening during swallowing. In some animals (Group A), there were no significant differences in kinematics after PLA. In others, however, the response was a distinct qualitative and quantitative change in hyoid, jaw and tongue kinematics (Group B). We examined the potential for motor learning or a feed forward mechanism during infant feeding using the Group B animals and measuring the time course of the swallowing motor response to palatal anesthesia. If motor learning occurred in the hyoid muscles, we would see a return to baseline hyoid elevation over time in the first feeding, and overshoot when the anesthetic wore off in subsequent feedings. On day one four infant pigs were fed during two sessions two hours apart that lasted 15-30 seconds and recorded with lateral videofluroscopy to assess normal kinematics. On day tow they were given palatal anesthesia and fed every 20 minutes for 15-30 seconds until normal suckling was observed. Over the course of each feeding session we measured hyoid and mandibular movements as well as airway protection with the Infant Mammal Penetration/Aspiration Scale. In all four pigs 30 minutes after PLA there was abnormal feeding, characterized by significantly more hyoid elevation and jaw opening, with no signs of returning to baseline levels, or adaptive learning. In three of four pigs, when normal sucking, characterized by normal jaw movement, returned 50-90 minutes after the anesthesia injection, the hyoid remained elevated early in the feeding and decreased over time. Jaw opening, however, immediately returned to baseline levels. This is the

first evidence that infant mammalian swallowing may also be capable of motor learning. Such evidence may provide the basis for the development of strategies for pediatric rehabilitation of dysphagia.

Title: Effects of targeted strength training in a unilateral vs. bilateral 6-hydroxydopmine model of Parkinson's disease

Authors: *E. K. PLOWMAN, B. RIVERA, K. DONOGHUE;
Communication Sci. and Disorders, Univ. of South Florida, Tampa, FL

Abstract: Background: Recent evidence suggests that motor training may be beneficial for slowing the onset of motor impairments in Parksinson's disease (PD). Aims: The aims of the current investigation were to: 1) determine the differential effects of unilateral versus bilateral striatal dopamine depletion on oral motor and limb motor function and 2) Determine the differential responses of oral and limb motor function in PD to targeted motor rehabilitation. Methods: Thirty-six male Long Evans were randomized to either a control (n=12), unilateral 6-OHDA (n=12) or bilateral 6-OHDA (n=12) group. Baseline performance of limb (reaching) and oral (licking) motor function were established prior to and six-weeks following intrastriatal 6-Hydroxydopamine (6-OHDA) infusions. Animals were then randomized to be in either a progressive forelimb strength training group or a progressive lingual resistance training group (n=6 in each rehab group) and underwent daily resistance training of either the tongue or forelimb. Following rehabilitation, motor performance was reassessed for a third and final time. High liquid protein chromatography was performed to determine levels of striatal dopamine depletion. Results: Both unilateral and bilateral 6-OHDA groups demonstrated significant reductions in lingual and forelimb force post-lesion ($p<0.05$). Progressive lingual resistance training had a significant treatment effect for bilateral 6-OHDA animals with noted increases in lick force following treatment. Unilateral 6-OHDA animals, however did not show improvements in lick-force impairments following eight-weeks of progressive lingual resistance training. A significant increase in forelimb force was noted for both the control and bilateral 6-

OHDA animals undergoing progressive forelimb strength training, however unilateral 6-OHDA animals did not improve forelimb force impairments post strength training. Conclusions: These data show that in a bilateral rodent model of PD, progressive strength training of both limb and oral motor function is effective for improving motor impairments.

Title: Noxious tooth pulp stimulation decreases rat face primary motor cortex (Face-M1) excitability by modulating medullary astrocyte function

Authors: *H. PUN[1], L. AWAMLEH[1], L. AVIVI-ARBER[1,2], B. SESSLE[1];
[1]Oral Physiol., [2]Prosthodontics, Fac. of Dent. Univ. of Toronto, Toronto, ON, Canada

Abstract: H.P. and L.A. contributed equally to this work.
Dental pain is a common symptom forcing patients to seek dental or medical treatment, and is often associated with disruption of orofacial motor function. Application of the inflammatory irritant mustard oil (MO) to the molar tooth pulp in rats has been shown to induce central sensitization in medullary dorsal horn (MDH) nociceptive neurons that is dependent on MDH astrocyte function (e.g. Chiang et al., 2007). We hypothesized that such noxious stimulation of the tooth pulp would also result in altered face-M1 excitability that is dependent on the functional integrity of medullary astrocytes. To test our hypothesis, we examined if MO application to the rat molar tooth pulp affects face-M1 excitability manifested as an altered intracortical microstimulation (ICMS) threshold required to evoke electromyographic (EMG) activity in the right anterior digastric (RAD), a jaw-opening muscle, and if application of an astrocyte inhibitor (methionine sulfoximine, MSO) to MDH can modulate the MO effect. Under ketamine general anaesthesia, male Sprague-Dawley rats were implanted with EMG electrodes in the RAD. A high-speed dental drill was used to expose the right maxillary first molar tooth pulp. Following a craniotomy and cervical laminectomy, a microelectrode was positioned in the left face-M1 (<2.4mm depth) at a site from which ICMS (35ms train, 12x0.2ms pulses, 333Hz)

evoked low-threshold (≤30μA) RAD EMG responses. Baseline ICMS thresholds were monitored for 30 min, then MO (n=26) or vehicle (n=17) was applied to the tooth pulp. In some of these rats, 0.1 mM MSO (n=8) or vehicle (n=5) was applied to the MDH 15 min after MO application to the pulp. ICMS thresholds were monitored every 10 min for 200 min after MO or vehicle pulpal application. Changes in ICMS thresholds were analyzed by repeated-measures ANOVA followed by post-hoc Bonferroni-adjusted pairwise comparisons as appropriate, and are reported as mean ± standard error ($p<0.05$). RAD ICMS thresholds significantly increased within 15 min of MO pulp application (49.9% ± 5.7%, $p<0.001$) compared to vehicle application or baseline levels. However, within 15 min of MDH application of MSO, but not vehicle, the MO-induced elevated RAD ICMS thresholds decreased significantly towards baseline thresholds (9.7% ± 5.2%, $p<0.02$). Our findings suggest that motor disturbances arising from dental pain may involve decreased face-M1 excitability that is modulated by MDH astrocytes.

Abstract: Age-related changes in the central nervous system may generate cognitive and motor decline, such as reduction of memory, learning, balance, gait and complex motor skill. These deficits can be mitigated with physical exercise. However, little is known about the mechanisms involved in this neuroplastic improvement. The aim of this study was to analyze the expression

of the structural proteins microtubule-associate protein 2 (MAP2) and low molecular weight neurofilament (NF68), and synaptic proteins synapsin I (SYS) and synaptophysin (SYP) in the motor cortex, striatum and cerebellum of aged rats submitted to treadmill exercise (TE) and acrobatic exercise (AE). We used aged (18-month-old) male Wistar rats, divided into 3 groups: control-sedentary (SED, n=11), treadmill exercise (TE, n=13) and acrobatic exercise (AE, n=15). In the TE group, the rats were trained on a treadmill with maximum speed of 0.5 Km/h for 40 minutes, 3 times per week for 4 weeks. In the AE group, the rats went through circuits composed of various obstacles during the same period of time that the TE were trained. After 4 weeks of training, analyses of protein expression were carried out by immunoblotting and immunohistochemistry, and data were submitted to statistical analysis using ANOVA and Tukey post-test when appropriate. The level of significance was $p<0.05$. Immunoblotting and immunohistochemistry both revealed that trained animals, regardless of the type of exercise, showed distinct changes in structural and synaptic protein expression in the areas studied. AE and TE groups showed significant increase of MAP2, NF68 and SYS, with a decrease of SYP in the motor cortex, but the changes for the AE were bigger than those for TE, and were found with both techniques. In the striatum, both AE and TE generated an increase of NFs and SYP, with a significant decrease of MAP2 and SYS revealed by immunohistochemical data. The molecular and granular layers of the cerebellum responded with an increase of MAP2 and a decrease of NFs, SYS and SYP immunostaining. Immunoblotting data were unchanged after either AE and TE. These data suggest that the motor cortex of aged rats presents larger plastic responses than the other structures studied, and which were more evident after AE than TE, suggesting a larger participation of the motor cortex in neuroplasticity.

Title: Thenar cortical representation in humans associated with cellular-phone texting ability

Authors: *Z. A. RILEY[1], N. HOSEINI[2], J. MAO[2], N. R. ECKERT[2];
[1]Kinesiology, Indiana University- Purdue Univ. Indianapolis, Indianapolis, IN; [2]Indiana Univ., Bloomington, IN

Abstract: There is re-organization with motor learning that results in a change in the topographic motor 'map' or the distribution and connectivity of M1 neurons where representative areas expand or contract. These mechanisms enable the nervous system to adapt and consolidate practice of a task to improve performance. A novel way of studying motor skill learning and associated M1 plasticity is with cellular phone text messaging, where in the United States alone ~68% cell phone owners use texting as a means of communicating (mobiThinking.org). The purpose of the present study was to investigate changes in the motor cortical organization of a thenar muscle with transcranial magnetic stimulation (TMS) in individuals relative to their performance of a functional texting task (FTT) on a cellular phone keyboard. Stimulation-induced motor evoked potentials (MEPs) were examined in eight healthy subjects (6 males; range: 20-34 yrs) before and after a functional texting task (FTT). The FTT consisted of completing as many 45-character long phrases as possible in 2-minutes and served as a baseline measurement of the subject's texting ability. After the FTT the subjects were taken to an adjoining room and were seated comfortably in an upright position with the right arm resting on a padded table and placed in 60° shoulder abduction and 90° elbow flexion. TMS was used to stimulate an area over the left motor cortex corresponding to the representation for the right APB muscle, serving to map the motor cortex excitability. Subjects then completed a 10-minute practice FTT and finally the motor mapping procedures were repeated to examine any short-term changes that may have occurred with practice of the FTT. Texting score, indicating texting proficiency, was negatively correlated with the normalized map volume of the APB ($r = -0.78$, $p = 0.022$) and number of active stimulation sites ($r = -0.83$, $p = 0.009$). With texting practice there was a negative correlation between the subject's original texting score and the change in the Center-of-Gravity (CoG) ($r = -0.81$, $p = 0.014$). The results suggest there is an increased efficacy of existing synaptic connections in individuals that frequently use text messaging. It can also be demonstrated that a short-term adaptation to practicing a texting task is to move the CoG by 'unmasking' intracortical circuits. The biomedical significance of repeated cellular phone texting may serve in a manner to promote recovery of thumb control and dexterity, for example in stroke patients, in a manner similar to virtual reality gaming simulations.

Title: Influence of BDNF polymorphism on I-wave TMS (ITMS) plasticity and neurophysiology in human motor cortex

Authors: *R. CASH, K. UDUPA, R. CHEN;
Dr Chen's Res. Lab., Toronto Western Res. Inst., Toronto, ON, Canada

Abstract: INTRODUCTION:
The influence of genetic variation in the brain-derived neurotrophic factor gene (BDNF) on human cortical neuroplasticity has recently attracted much interest. Motor cortical plasticity can be probed using repetitive TMS protocols including I-wave TMS (ITMS). Bidirectional modulation of cortical plasticity is possible with ITMS: ITMS(+) at ~1.5ms leads to LTP-like effects while ITMS(-) at ~2ms leads to LTD-like effects, attributed to phase-dependent plasticity mechanisms (PDP; Cash et al, 2012).
In the present study, we investigated the influence of single nucleotide polymorphism (SNP) BDNF Val66Met on ITMS plasticity, and additionally compared this with previously reported influence on Paired Associative Stimulation (PAS) plasticity. We also investigated the influence of ITMS (and genetic variation) on cortical inhibition neurophysiology, and compared this with PAS effects.
METHODS:
Ten subjects have thus far been studied: 5 Val homozygotes and 5 Met allele carriers. ITMS was optimized to individual I(1)-wave peaks and troughs for LTP-like ITMS(+) and LTD-like ITMS(-) protocols respectively (Sewerin et al, 2011). PAS(+) was likewise optimized to individual N20 latency and delivered at N20+2ms (Ziemann et al, 2004). Unconditioned single pulse motor evoked potential amplitude (MEP) and short and long interval intracortical inhibition (SICI and LICI respectively) were measured pre-and post-intervention.
RESULTS:
As anticipated, group results indicated that ITMS(+) led to an increase in MEP amplitude of ~150% post-intervention while ITMS(-) led to a reduction of MEP amplitude of ~20% compared to pre-intervention baseline. These changes were sustained for at least 30 minutes before returning to baseline between 45-60 minutes. ITMS(-) effects on MEP amplitude, SICI and LICI were more sensitive to BDNF genotype than ITMS(+), with Met allele carriers demonstrating reduced plasticity. PAS(+) effects were also greater in Val homozygotes.
DISCUSSION:
ITMS(-) LTD-like plasticity is more sensitive to BDNF Val66Met SNP than ITMS(+) LTP-like plasticity. This is consistent with the finding from cellular studies that LTD-like PDP is less robust than LTP-like PDP, and thus likely to be more sensitive to internal drivers of plasticity. The results furthermore suggest that ITMS optimized to individual I-wave latency may considerably increase the duration of ITMS after effects. Influences on inhibition will be discussed.

Title: Visuomotor adaptation and retention in the young, elderly and people with Parkinson's disease

Authors: M. PANOUILLÈRES, R. JOUNDI, J.-S. BRITTAIN, P. BROWN, *N. JENKINSON;
Dept. of Clin. Neurosciences, Univ. of Oxford, Oxford, United Kingdom

Abstract: Motor adaptation is an essential process for the acquisition and refinement of motor skills and, importantly, for the recovery of motor function in neurological disease or after injury. Adaptation relies on plastic mechanisms in the brain which are known to be less efficient in healthy elderly people compared to young individuals. Transcranial direct current stimulation (TDCS) can improve motor learning and shows promise as an adjunctive therapy for motor rehabilitation. In this study, we explored the effects of TDCS on motor learning in healthy young and elderly subjects and in patients with Parkinson's disease (PD). Specifically, we measured visuomotor adaptation and retention of the adapted state after subjects received either sham or anodal TDCS over the primary motor cortex during adaptation. The task involved using a joystick-controlled cursor to follow a target that jumped from the centre of a computer screen to one of 8 locations situated concentrically about the screen. After an initial baseline phase where the relationship between the joystick and cursor was veridical, a visuomotor adaptation phase started, in which, the cursor movements were rotated counter-clockwise by 60° relative to the joystick movements. Subjects quickly adapted to the rotation and rapidly reduced the error between the cursor and the target over successive trials. Following the adaptation phase, subjects rested for 50 minutes. They then performed the task again with the same cursor rotation (60°), to assess short-term retention of the adaptation. The session ended with a washout phase, in which the movements of the cursor and the joystick were restored to normal. In this phase, subjects

started with large errors in the clockwise (opposite) direction but again quickly adapted back to the veridical joystick relationship. People with PD showed a similar ability to adapt to the visuomotor rotation as healthy aged controls, though the extent of adaptation in both elderly and PD groups was lower than that seen in young adults. PD patients showed impaired short-term retention compared to the elderly group and the young adults, who demonstrated the best retention. TDCS improved adaptation in all groups of participants. It also improved short-term retention, but only in elderly participants and people with PD. In sum, TDCS applied over M1 during visuomotor adaptation improved the ability of elderly and PD subjects to adapt and improved their subsequent short-term retention of the adapted state. Retention was not altered in young adults. Our results suggest TDCS may be an effective adjunctive tool for enhancing motor plasticity in patients with PD and the elderly.

Title: Training, transfer and tDCS: Are training and tDCS effects generalizable, or effector and sequence specific?

Authors: *G. PRICHARD, C. VAROTSIS, S. WATERS-METENIER, J. DIEDRICHSEN; Inst. of Cognitive Neurosci., Univ. Col. London, London, United Kingdom

Abstract: Training on finger sequence tasks leads to a decrease in the time taken to complete a sequence at a comparable error rate. Whether and how this skill gain generalizes across effectors is uncertain. For sequences, there are multiple possible ways a learnt sequence could show inter-manual transfer of skill: extrinsically, according to an external reference frame (e.g. the untrained hand pressing the same keys on a piano keyboard, achieved by making non-symmetrical muscle movements), or intrinsically, according to an internal reference frame (e.g. the untrained hand making mirror-symmetric movements, but pressing different keys on the piano). Alternatively, skill gains could benefit the other hand for any sequence, whether learnt or novel. We examined

whether and how the brain transfers learnt skills to new effectors. Furthermore, we applied bihemispheric transcranial direct current stimulation (tDCS), known to improve learning, in order to assess how well the motor learning gains from brain stimulation generalize. Two groups (sham, tDCS) learned a set of sequences on the left hand for four days. Participants were then tested for two days with learnt sequences on the both hands, both in extrinsic and intrinsic reference frames, and on novel sequences. A further control group performed sequences on both hands for two days without training or tDCS. Both groups who received training performed better on the untrained hand than the group without training, however this effect was not specific to the intrinsically or extrinsically transformed sequences. tDCS improved the execution of the learnt sequences on the trained hand, and this effect generalized across hands, as well as to novel sequences. The representation of specific sequences does not appear to transfer across effectors, however training does result in more general task improvements, which are further enhanced by tDCS.

Title: Compensatory changes in neuronal firing in the perilesional motor cortex: A single unit recording study in the macaque monkey

Authors: *N. HIGO, N. KUNORI, I. TAKASHIMA;
Systems Neurosci Group, Human Tech. Res. Inst, AIST, Tsukuba, Japan

Abstract: We previously reported that motor training after lesioning of the primary motor cortex (M1) induces recovery of dexterous hand movements in macaque monkeys (Murata et al., 2008; J Neurophysiol, 99, 773-786). Our recent brain imaging and reversible pharmacological inactivation studies suggest that the recovery involves both the ipsilesional ventral premotor cortex and perilesional M1 (Murata et al., 2012; Soc Neurosci Abstract, 185.04). In the present study, we performed single unit recording in the same M1-lesion model to investigate

compensatory changes of the perilesional motor cortex after M1 lesion at a single neuron level. Single unit activity was recorded during a small-object retrieval task in which the monkey reaches for, grasps and retrieves an object, and moves the hand toward the mouth to eat the food morsel. The movement representation of the recording sites was then confirmed by conventional intracortical microstimulation (ICMS, 1-100 μA, 200 μs in duration, monophasic cathodal pulses at 333 Hz). Before lesion, response property of M1 neurons largely corresponds to the movements of the body part represented in the ICMS-derived movement representation map; e.g., neurons in the digit representation have a peak activity during grasping/retrieving while those in the proximal representation a peak activity during reaching. After the lesion in the hand digit area of M1 by ibotenic acid injection, monkeys could not perform the retrieval task because of the hand paralysis including a complete loss of digit movement. Functional recovery of hand movements was observed, and the number of successful trials in the small-object retrieval task progressively increased during the first month after the lesion. Unexpectedly, the ICMS threshold for inducing the body movements increased in perilesional area after recovery, and there was large area in which ICMS up to 100 μA elicited no movement. Nevertheless, single unit recording after recovery indicated that the percentage of neurons in the perilesional area that have a peak activity during grasping/retrieving was higher than that in the same area before lesion. The present results suggest that the compensatory changes in neuronal firing occurs in the perilesional area, and the changes may underlie functional recovery of hand movements after lesion in the hand digit area of M1.

Title: Enlarged striatal brain volume in individual top athletes

Authors: *M. TAUBERT[1], U. WENZEL[2], B. DRAGANSKI[3], S. KIEBEL[1], P. RAGERT[1], J. KRUG[2], A. VILLRINGER[1];
[1]MPI Leipzig, Leipzig, Germany; [2]Inst. of Gen. Kinesiology and Athletics Training, Univ. of Leipzig, Leipzig, Germany; [3]Dept. des neurosciences cliniques, Univ. of Lausanne, Lausanne, Switzerland

Abstract: Behavioral studies have shown that many characteristics of elite performers, once believed to reflect innate talent, are actually the result of intense practice extended for a minimum of 10 years (Ericsson et al., 1993). Interestingly, already a short period of motor practice induces structural changes in the brain (Draganski et al., 2004). Since highly automatic movements are coded in the cortico-striatal system (Doyon & Ungerleider, 2002), we assessed morphological differences in striatal regions between top athletes and normal controls.
We employed a case-control study design with 92 male control subjects and two male track and field athletes at an international level. The first athlete was a javelin thrower with a personal best mark > 80 m. He/She is a former national champion in javelin throw and participated in international tournaments including Olympic Games. The second athlete is a long jumper with a personal best mark of > 8 m. He/She is a former national vice-champion in long jump and participated in international tournaments including a World cup.
T1-weighted MRI data from all subjects were acquired on a 3T scanner. MRI data from the javelin thrower was acquired two times separated by two years (Olympic Games in between). T1-data was used to investigate sub-cortical grey matter volume (GMV). For each athlete, we used 46 control subjects from the local database (max. number of matched control subjects from the database). Control subjects were carefully matched for gender, age (± 2 years) and education (German A-Level). Control subjects participating in competitive sports or playing a musical instrument were not included in the study. T1-weighted images were preprocessed using VBM 8 (DARTEL). We compared each athlete's GMV map with those of 46 control subjects using a two-sample t-test (Mühlau et al., 2009). FWE correction was used for multiple comparison correction at $p<.05$ (voxel-level).
Compared to 46 control subjects, larger GMV in the javelin thrower was seen in left and right ventral striatum. No reductions were observed. Striatal increases were also seen two years after the first MRI scan. Furthermore, in the long jumper, larger GMV was observed in the right striatum. No reductions could be identified.
Although limited by the cross-sectional design of our study, we interpret the differences as effect of training on brain structure. The predominant change within the ventral striatum might be related to the mental effort of long-term deliberate practice (Erickson et al., 1993). To the best of our knowledge, this is the first study describing prominent features in brain structure of internationally known track and field athletes at an individual level.

Title: Dose-response effects of anodal transcranial direct current stimulation (tDCS) on cortical excitability in rats

Authors: H. J. HULSHOF, J. REIS, A.-K. GELLNER, C. WEILLER, *B. FRITSCH;
Univ. of Freiburg/ Neurocenter, Freiburg, Germany

Abstract: Anodal transcranial direct-current stimulation (tDCS) has been shown to modulate cortical excitability and improve motor learning. By convention human tDCS studies are generally conducted with low stimulation intensities of approximately 0.4-0.8 A/m² to ensure safe levels. Since higher stimulation levels might further improve plasticity, i.e. learning, dose-response studies on functional measures of cortical excitability and possible adverse effects of tDCS are highly desirable. In the current study we aimed to assess the dose-dependent effects of anodal tDCS on cortical excitability in an in vivo rat model of tDCS by studying the effects on sensory evoked potentials (SEP; low stimulation intensities: 0.8 and 8.0 A/m2) and EEG architecture (higher intensities: 8.0 - 47.8 A/m2).
For this purpose, adult male Sprague-Dawley rats were equipped with electrodes for tDCS stimulation above the left primary motor cortex and the chest region. Furthermore, EEG electrodes were surgically placed above the somatosensory cortices and the cerebellum (grounding electrode). In separate sessions, rats were exposed to anodal tDCS of different intensities for a period of 20 min. EEG and SEPs were continuously recorded prior to, during and after tDCS, in freely moving or anaesthetized animals, respectively.
Anodal tDCS at low stimulation intensities (0.8 and 8.0 A/m2) had no significant effect on SEPs or EEG architecture. Mild EEG alterations, with more spiky waves and higher amplitudes, were first observed at a stimulation intensity of 15.9 A/m². This change in EEG patterns was reflected in total EEG power, which showed a significant, short-term increase during stimulation, attributed to changes in the delta, theta and alpha frequency bands. This change in EEG power also appeared to be time-dependent. At an intensity of 15.9 A/m2 a longer stimulation period was required to significantly increase EEG power when compared to stimulation intensities of 31.8 and 47.8 A/m2. Furthermore, whereas in the 31.8 A/m2 group EEG power stayed increased during the second half of the stimulation period, EEG power already decreased during the last 10 minutes in the 47.8 A/m2 group.
In conclusion, the current data show that anodal tDCS affects cortical excitability in a dose-dependent manner, visible as EEG changes but not as SEP changes (only low stimulation intensities were applied in the SEP experiment). While higher simulation intensities showed an increase in cortical excitability, thereby probably improving plasticity, the decrease in EEG power in the highest intensity group might suggest a negative influence of this intensity on cortical excitability.

Title: Cortical adaptations within and between the primary motor cortices after bimanual training and theta burst stimulation to the left dorsal premotor cortex

Authors: *J. L. NEVA[1], M. VESIA[2], A. M. SINGH[1], R. J. IBEY[1], W. R. STAINES[1,3]; [1]Dept. of Kinesiology, Univ. of Waterloo, Waterloo, ON, Canada; [2]Div. of Neurol. and Krembil Neurosci. Ctr., Toronto Western Res. Inst., Toronto, ON, Canada; [3]Heart and Stroke Fndn. Ctr. for Stroke Recovery, Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada

Abstract: Bimanual visuomotor training (BMT) augments the excitability of cortical areas involved in motor preparation [1] and execution [2]. These changes in excitability are characterized by an increase in the cortical territory of the trained muscles within the left primary motor cortex (lM1) [2]. The specific neural mechanisms underlying this effect are unclear, but may involve transcallosal connections between homologous M1 representations and/or connections from the left dorsal premotor cortex (lPMd). Intermittent theta burst stimulation (iTBS) enhances motor evoked potentials (MEPs) and short-interval intracortical inhibition (SICI), with no effect on intracortical facilitation (ICF), when applied to the stimulated M1 [3]. Further, cTBS applied to lPMd suppresses MEPs, with no effect on SICI or ICF in lM1 [4]. Recently it has been found that MEP amplitude of the entire ECR representation in lM1 is enhanced due to iTBS to lPMd. This study investigates the possible intracortical and interhemispheric modulations of the extensor carpi radials (ECR) in M1 bilaterally due to: 1) BMT, 2) iTBS to lPMd, and 3) the combination of these interventions. This study tests three related hypotheses: 1) BMT will enhance excitability within and between M1 bilaterally, 2) iTBS to lPMd will primarily enhance lM1 excitability, and 3) the combination of these interventions will cause a greater enhancement of bilateral M1 cortical excitability. This study will quantify MEPs, SICI, ICF, long-interval intracortical inhibition (LICI), cortical silent period (cSP), and interhemispheric inhibition (IHI) for the ECR in M1 bilaterally. Preliminary results indicate that MEPs are facilitated in both hemispheres, with a decrease in ICF and IHI in both hemispheres

due to BMT. These results demonstrate the possible neural mechanisms that may underlie the early indications of rapid functional plasticity associated with BMT, which may be related to a decrease of inhibition between the M1 homologous representations and modulation of intracortical excitability locally within M1. The intracortical and interhemispheric effects of iTBS to lPMd and the combined effects of iTBS to lPMd with BMT are currently being tested.

Title: Representation of motor speed in the cerebellar anterior lobe

Authors: *U. WENZEL[1,2], M. TAUBERT[3], P. RAGERT[3], A. VILLRINGER[3], J. KRUG[1]; [1]Univ. of Leipzig, Leipzig, Germany; [2]Friedrich Schiller Univ., Jena, Germany; [3]Max Planck Inst. for Human Cognitive and Brain Sci., Leipzig, Germany

Abstract: In athletics, motor performance is determined by different abilities such as technique, endurance, strength and speed. Based on animal studies the latter is thought to be encoded in the basal ganglia, sensorimotor cortex and the cerebellum (Turner et al., 2003). Especially the cerebellum seems to play a major role for speed performance since correlations between discharge rate of Purkinje cells and movement velocity have been observed (Hewitt et al., 2011). The question arises whether there is a unique structural feature in the human brain, which allows power athletes to perform a simple movement significantly faster than endurance athletes.
We acquired functional and structural brain imaging data from 32 track-and-field athletes. 16 of whom were “power athletes” requiring high speed foot movements (sprinters, jumpers, throwers) and 16 were endurance athletes (distance runners). We tested maximum movement velocity of plantarflexion (PF-Vmax) by 3D-movement-analysis. fMRI scans were used to identify speed specific regions of interest during fast and slow foot movements and T1-weighted scans to assess structural grey matter volume (voxel based morphometry).

fMRI indicates that fast plantar flexions are accompanied by increased activity in cerebellar anterior lobe ($p < 0.05$; FWE corr.). The same region shows increased grey matter volume for the power athletes compared to their endurance counterparts ($p = 0.002$; FWE corr.). Behaviorally, a significant difference between the two groups of athletes was noted in the maximum speed of plantar flexion (2.03 ± 0.34 m/s power and 1.79 ± 0.20 m/s endurance athletes; $p = 0.007$). Furthermore there was a significant correlation between the regional cerebellar grey matter volume and PF-Vmax. Our results suggest that motor speed of plantar flexion is represented in the anterior lobe of cerebellum and that there are speed-dependent morphological differences between power and endurance athletes. Grey matter differences may be a structural manifestation of the continuously higher demand to generate high discharge rates of Purkinje cells and explosive muscle contractions.

Title: Motor cortex ensemble dynamics imaged during motor learning

Authors: *A. PETERS, T. KOMIYAMA;
UCSD, La Jolla, CA

Abstract: The motor cortex is capable of substantial plasticity during learning to flexibly control movements. Previous studies have examined short-term plasticity on the neuronal scale and long-term plasticity on a global scale. Our study is designed to investigate long-term changes within large populations of layer 2/3 neurons accompanying the learning of a skilled motor task. The genetically encoded calcium indicator GCaMP 5G was injected into transgenic mice expressing a red fluorescent protein in all inhibitory neurons, allowing for simultaneous activity recording and classification of excitatory and inhibitory neurons. Mice were fitted with a chronic cranial window over the forelimb area of the motor cortex to allow for weeks of stable imaging. Following recovery, the animals were simultaneously imaged and trained in a cued forelimb task for two weeks. An auditory cue marked a period where the mice could press a piezoelectric lever under the forelimb contralateral to the imaged cortex for a water reward. Animals' performance of the task improved during the first week and stabilized thereafter. Activity of motor cortex neurons was highly correlated to movement. The activity of inhibitory neurons matched the activity of excitatory neurons on a movement-by-movement basis. Over the course of learning, the populations of excitatory neurons associated with movement changed over time, while those of inhibitory neurons remained relatively stable. Within the early learning phase of the first few days, the population of movement-related excitatory neurons significantly increased. Following this initial increase, the number of movement-related neurons decreased to a stable fraction near the end of the training sessions. This population change consisted largely of transient newly-recruited neurons during the early sessions, followed by the pruning of the movement-related pool. In addition to these changes in the identity of movement-related neurons, the temporal structure of ensemble activity became progressively more stable during learning. These results suggest that the stabilization of spatiotemporal activity patterns of motor cortex ensembles is a major component of motor learning.

Title: The effects of skill learning versus skill repetition on cortical organization and behavioral output: A computational model

Authors: *A. S. BAINS, N. SCHWEIGHOFER;
USC, Los Angeles, CA

Abstract: Motor cortex area M1 in rodents and primates consists of a somatotopic map that represents the ability of neighborhoods of neurons, when stimulated, to elicit responses from various body parts. In the example of primate reaching and grasping, specific neighborhoods driving the hand, wrist, and more proximal limb segments have been identified (Nudo et al 1996). It is widely accepted that these neighborhoods in the map can change size and shape in response to motor skill repetition, even in adults. To elicit such changes, the repetition must lead to learning a new skill, likely through Hebbian plasticity-like LTP (Rioult-Pedotti et al 2000), and not simply be repetition of an already-learned skill. For instance, monkeys repeatedly retrieving a food pellet from a small well, requiring learning of a dexterous action, exhibited map changes, while monkeys repeatedly retrieving food from a large well, requiring no new skill learning, did not exhibit changes (Plautz et al 2000, Dancause and Nudo 2011).
Other investigations have conversely suggested that learned-skill repetition may lead to further learning or adaptation. This was shown in a study in which participants repeatedly reached in directions close to a fixed target without exact error feedback, but with a "bonus score" feedback dependent in part on how close they moved to the target. This skill was already well-learned; however, it was found that when the participants reached towards targets in different directions from the original target, their movements were biased towards the original (Verstynen and Sabes 2011). The authors explained this finding using a neural network model with Hebbian learning that transformed target directions to reach directions. The Hebbian learning expanded the representations in the network of recently-repeated target directions on a fast time scale.
Here we attempt to reconcile these observations- that repetition of learned skills does not alter the M1 somatotopic map significantly, while biases driven by such repetition could be explained by Hebbian learning-dependent increases in those skills' representations. We propose a neural network model in which reward-gated Hebbian learning further strengthens defined synaptic pathways when a learned skill is repeated- in this case reaching to a target using a feedback-controlled model arm. This causes bias towards that skill's execution but little change in the motor output map of the network. However, a combination of reward-gated Hebbian learning and exploration of new network activity patterns acts to more fundamentally change the existing synaptic pathways only when a new skill is learned, leading to larger changes in the output map.

Title: Individualising theta burst stimulation to optimise motor cortex plasticity

Authors: *P. BROWNJOHN, J. N. J. REYNOLDS, N. MATHESON, J. FOX, J. B. H. SHEMMELL;
Univ. of Otago, Dunedin, New Zealand

Abstract: Theta burst stimulation (TBS), consisting of trains of high frequency 50Hz stimulation repeated in a 5Hz theta pattern, has been shown to modulate excitability of the human motor cortex and corticospinal tract when applied using transcranial magnetic stimulation. Intermittent TBS (iTBS) and continuous TBS (cTBS) induce opposing facilitation and inhibition of the motor cortex, through processes thought to be linked to long term potentiation and long term depression, respectively. While a theta frequency of 5Hz is commonly employed in TBS applied to the human motor cortex, this frequency derives from the firing rates of hippocampal neurons in rats, and fails to consider the firing rate of human cortical neurons or subject-to-subject variations in cortical rhythms. To address this we compared the effects of standard 5Hz iTBS and cTBS with individualised TBS paradigms on corticospinal excitability and inhibitory cortical circuits, with the 5Hz theta frequency component of the TBS intervention replaced by the dominant cortical frequency for each individual. Ten healthy volunteers were treated with standard and individualised iTBS (iTBS 5; iTBS I) and cTBS (cTBS 5; cTBS I), and sham TBS, in a randomised order. The effects of these interventions on motor evoked potential (MEP) amplitude, a measure of corticospinal excitability, and short interval cortical inhibition (SICI) and cortical silent period (CSP) duration, measures of inhibitory cortical circuits, were assessed. Both iTBS 5 and iTBS I interventions significantly facilitated MEP amplitude to a similar extent when compared with sham treatment. Unexpectedly, neither cTBS 5 nor cTBS I intervention depressed MEP amplitude when compared with sham, and moreover, cTBS 5 had a mild facilitatory effect. None of the TBS protocols had any significant effects on inhibitory pathways when compared with sham, as assessed by SICI and CSP measurement. Hypothesising that an interaction between cTBS and voluntary muscle activity required for CSP measurements was nullifying the expected cTBS-induced inhibition of corticospinal excitability, we performed an additional session of cTBS 5 in 5 of the 10 subjects, in which CSP measurement was omitted. Under these conditions, cTBS 5 again increased MEP amplitude. We report that individualising facilitatory iTBS to a subject's underlying cortical rhythm had no effect on the magnitude of

corticospinal facilitation induced. Furthermore, in our hands, reportedly inhibitory cTBS protocols produced mild facilitation of corticospinal excitability.

Title: Timing- and activity- dependent plasticity of indirect cortico-motoneuronal pathways in humans

Authors: *T. NAKAJIMA[1], T. KOMIYAMA[2], H. OHTSUKA[2], S. SUZUKI[2], G. FUTATSUBASHI[2], Y. OHKI[1];
[1]Dept. of Integrative Physiol., Kyorin Unversity Sch. of Med., Mitaka City/Tokyo, Japan; [2]Chiba Univ., Chiba, Japan

Abstract: We previously reported that repetitive combined stimulation (RCS) of pyramidal tract and peripheral nerve induces the long-term potentiation (LTP) of indirect cortico-motoneuronal (C-M) excitations which would be mediated via. cervical propriospinal neurons (PNs) in humans. However, underlying mechanisms of the effects are still unclear. Therefore, we further examined characteristics of the modulation of C-M excitations after RCS.
Healthy volunteers, who all gave written informed consent, participated in the experiments. Electromyograms were recorded from the right biceps brachii (BB) and first dorsal interosseous muscles. RCS intervention (0.2 Hz) was performed for 10 min, during which transcranial magnetic stimulation (TMS) to the contralateral motor cortex was delivered in conjunction with the right ulnar nerve stimulation, with or without weak contraction of BB. Interstimulus interval (ISI) for the combined stimulation was set at -10, 2 or 10 ms (negative value: TMS ahead), though simultaneous inputs by both stimuli on PNs was thought to be obtained at an ISI ~7.0 ms. Stimulus strengths were determined to observe the maximum spatial facilitation effect in BB before the intervention, by converging inputs on PNs with a ISI of 10 ms. To observe LTP in C-M excitations in BB, motor evoked potentials (MEPs)

were evoked by TMS at ~0-70 min after the intervention. As reported previously, MEP amplitudes were enhanced after RCS (ISI 10 ms) with BB contraction, which lasted for 20-60 min. However, long-term depression (LTD), instead of LTP, was observed after the RCS without contraction. Furthermore, even with BB contraction, LTP (ISI 10 ms) and LTD (ISI -10 and 2 ms) could be observed under different ISIs after RCS. These findings suggest that plastic changes in the indirect C-M pathways could be induced by RCS, which were strongly timing- and activity- dependent. These changes were resembled the characteristics of synaptic plasticity in CNS. The timing to observe LTP indicates that the changes took place in synapses at the pyramidal tract on cervical PNs.

Abstract: Motor performance improves with repetitive training, and it has been proposed that this is mediated by functional and structural reorganization of the motor cortex. However, it is poorly understood how different cortical neuronal activities in layers 2/3 and 5a are reorganized during learning of a motor task. In this study, we used mice performing a self-initiated lever-pull task (Hira et al., 2013) to show that the neuronal activities that predict the lever trajectory are dynamically reorganized in layer-specific manners during long-term training. Two-photon calcium imaging in layers 2/3 and 5a of the primary motor area was conducted while mice practiced the motor task for 14 consecutive days. In layer 2/3, **no overall change in the accuracy of neuronal ensemble prediction of lever trajectory was detected** during sessions. At the single-neuron level, neurons that increased the prediction accuracy were counterbalanced by those that decreased it, and a subset of neurons maintained high prediction ability. In layer 5a, the ensemble prediction steadily improved and one-third of neurons slowly improved their prediction ability and strongly contributed to the ensemble prediction by the late stage of learning. Our results provide a novel microcircuit model that consists of distinct intermediate layers upstream of layer 5b with the motor output activity. The balanced dynamic network in layer 2/3 may represent coordination of signals from other areas and combination of motor primitives, whereas the downstream layer 5a may constitute the evolving dynamic network that represents a well-learned movement. Layer 5a in the primary motor cortex may be a major site for long-term motor memory.

Title: Modulation of paired associative stimulation-induced plasticity following aerobic exercise

Authors: *A. M. SINGH[1], J. L. NEVA[1], W. R. STAINES[1,2];
[1]Univ. of Waterloo, Waterloo, ON, Canada; [2]Heart and Stroke Fndn. Ctr. for Stroke Recovery, Sunnybrook Hlth. Sci. Ctr., Toronto, ON, Canada

Abstract: The effects of aerobic exercise on primary motor cortical (M1) excitability are unclear. Given the beneficial effects of acute exercise on cognition, there is strong interest in the ability of exercise to promote cortical plasticity, particularly when paired with skilled tasks. Research from our lab indicates that aerobic exercise can facilitate excitability changes associated with motor learning; however, the outcomes are variable. Thus, in this study, we employed paired associative stimulation (PAS), an established technique shown to induce short-term plasticity in the motor cortex, in order to remove variations in performance and examine the effect of exercise on the induction of plasticity in M1. In addition, we sought to correlate changes induced by PAS with modulations of short-interval intracortical inhibition (SICI), long-interval intracortical inhibition (LICI) and intracortical facilitation (ICF). It was hypothesized that a single bout of moderate intensity aerobic exercise would lower intracortical inhibition and result in a greater modulation of M1 plasticity associated with PAS. Following identification of the motor hotspot of the abductor pollicis brevis (APB) muscle, transcranial magnetic stimulation (TMS) was applied over the left hemisphere APB representation at varying intensities in order to generate an input-output curve. Subsequently, paired-pulse TMS was used to probe SICI, LICI, and ICF at the central site. All subjects underwent two sessions at least one week apart, consisting of either PAS alone or PAS preceded by exercise. The PAS protocol comprised 180 pairs of median nerve stimulation (at 300% of perceptual threshold) at the right wrist followed by a single suprathreshold TMS pulse over the right APB hotspot, delivered at 1 Hz with a 25 ms inter-stimulus interval. In the control condition, excitability was assessed at the hotspot before, immediately after, and 30 minutes after PAS. In the exercise condition, participants performed 20 minutes of moderate-intensity stationary biking at 65-70% of their age-predicted maximum heart rate prior to undergoing PAS, with identical pre- and post-measurements. Changes were quantified in the amplitudes of motor-evoked potentials (MEPs) in the input-output curves, and the degree of SICI, LICI and ICF at each timepoint. Preliminary results from input-output curves indicate that that the combination of exercise and PAS can facilitate plasticity to a greater degree than PAS alone, and that such changes are associated with greater modulations in intracortical inhibition. The findings presented have implications for both learning-related and rehabilitation-focused plasticity.

Title: CB1 receptor signaling affects motor map expression in rodents

Authors: *K. A. SCULLION, A. T. HUSSIN, M. N. HILL, Q. J. PITTMAN, G. C. TESKEY; Hotchkiss Brain Inst., Univ. of Calgary, Calgary, AB, Canada

Abstract: Motor maps are the topographical representation of movements in the motor cortex and are derived by stimulating pools of layer 5 pyramidal neurons that give rise to the cortical spinal tract. Previously it has been shown that motor map expression can be altered by experience, as well as by the quantity and type of neurotransmitters present in the neocortex. The balance between cortical excitation and inhibition determines motor map expression. Previous research has demonstrated that an increase in cortical inhibition results in an increase in movement thresholds and smaller forelimb motor maps.

Endocannabinoids are retrograde neurotransmitters that regulate neurotransmitter release at many different types of synapses and may therefore modulate cortical excitability. Endocannabinoids and the cannabinoid (CB) receptors are found in layer 5 of the neocortex, the source of the cortical spinal tract.

We examined the role of CB1 receptors on the expression of cortical forelimb motor maps and on activation of layer 5 pyramidal neurons in motor cortex slices. We tested the hypothesis that activation of CB1 receptors in the motor cortex causes an increase in cortical inhibition.

We made the following 3 predictions: 1) CB1 receptor knockout mice will have lower forelimb movement thresholds than wildtype mice, 2) Arachidonoyl 2-chloroethylamide (ACEA), a CB1 receptor agonist, will increase forelimb movement thresholds while 1-(2,4-Dichlorophenyl)-5-(4-iodophenyl)-4-methyl-N-1-piperidinyl-1H-pyrazole-3-carboxamide (AM 251), a CB1 receptor antagonist, will decrease forelimb movement thresholds, 3) ACEA will increase, while AM 251 will decrease the activation threshold of pyramidal neurons in layer 5 of the motor cortex in response to intracortical microstimulation (ICMS).

To test the first and second predictions, adult mice and rats underwent high-resolution ICMS to map forelimb (digit, wrist, elbow, shoulder) movement representation areas. To test the third

prediction, whole cell voltage and current recordings were carried out in motor cortex slices. Afferents to these layer 5 pyramidal neurons were stimulated using the same in vivo ICMS parameters ("slice ICMS") to study the effects of CB1 receptor agonists and antagonists on single-cell electrophysiological properties and stimulation responses.
Our results indicate that CB1 receptor activation reduced excitatory responses in layer 5 pyramidal cells while inactivation had either the opposite or no effect. Taken together our results indicate that endocannabinoid CB1 receptors play an inhibitory role on motor map expression.

Title: Transient directed microglia motility and activation by direct current stimulation (DCS): Simultaneous DCS and two photon *In vivo* imaging

Authors: *A.-K. GELLNER, C. WEILLER, J. REIS, B. FRITSCH;
Neurol., Univ. of Freiburg/ Neurocenter, Freiburg, Germany

Abstract: Introduction: Direct current stimulation (DCS) is a widely used experimental tool for non-invasive modulation of cortical excitability and learning. Some light has been shed on neuronal effects of DCS. However, the vast majority of brain cells, glia, has been shown to participate in neuroplasticity and to be electrically active but mechanistically neglected so far. Fluorescent neocortical cells can be monitored through a cranial window by 2-photon in vivo microscopy (2PM). To monitor online effects of DCS on microglia we established combined DCS and 2PM in transgenic mice with fluorescent microglia (heterozygous Cx3Cr1(+/-)-GFP mice). Mechanistically we also utilized homozygous Cx3Cr1(-/-)-GFP mice, which bear a reduced capability of microglial activation.
Methods: Adult transgenic mice were equipped with a combined chronic cranial window -DCS electrode preparation over the left primary motor and somatosensory area. After 14-28 days imaging of microglia in layer II/III by 2PM started. Pre-intervention day: 1 hr of baseline imaging; intervention day: 20 min of pre-, during- and post-DCS imaging each; post-intervention day: 1 hr of imaging. Stimulation polarity was assigned randomly and performed in a cross-over

design with a minimum of 5 days in-between.
Changes in microglial motility including the direction in relation to the stimulation electrode and morphology were analyzed by ImageJ.
Results: DCS electrodes can be successfully implemented in a chronic cranial window preparation and enable longitudinal 2PM including image acquisition during DCS. We found a significant increase in microglia motility during anodal and cathodal DCS. Directed migration occurred towards the cathode and away from the anode. Motility was normalized to baseline values 1 day after DCS. Analysis of cell morphology revealed remarkable signs of activation within the 40 min of DCS and post-DCS. This effect was more pronounced in slightly pre-activated microglia compared to those in resting state. All of these features were inhibited in Cx3Cr1(-/-) mice.
Conclusion: For the first time we demonstrate feasibility of combined DCS and 2PM. Our study reveals the capability of DCS to increase microglial motility with polarity dependent features and to induce activation. The inhibition of these effects in Cx3Cr1(-/-) genotype suggests a mechanistic role of fractalkine-signalling in DCS induced microglial activation. Further studies elucidating the potential role of microglia as contributor to DCS mediated neuroplasticity are needed.

Title: Neurofeedback training over the premotor cortex increases the activation of motor related areas

Authors: *E. C. RODRIGUES[1,2], T. F. MARINS[3,4], A. ENGEL[3], I. BRAMATI[3], R. BASILIO[3], R. LENT[4], J. MOLL[3], F. TOVAR-MOLL[3,4];
[1]D'Or Inst. For Res. and Educ., Rio De Janeiro, Brazil; [2]Augusto Motta Univ. (UNISUAM), Rio

de Janeiro, Brazil; [3]D'Or Inst. for Res. and Educ., Rio de Janeiro, Brazil; [4]Federal Univ. of Rio de Janeiro, Rio de Janeiro, Brazil

Abstract: Real-time functional magnetic resonance imaging (fMRI) neurofeedback (NFB) allows individuals to voluntarily achieve control and modulate different areas of their own brains. The NFB can be associated with motor imagery, that is the mental rehearsal of a motor act, without overt body movement. This combination can potentially modulate the activation of cortical areas that are typically involved in motor planning and execution. The objective of this work was to investigate if the activity of the left premotor cortex (PM) could be modulated by motor imagery of the right hand finger tapping with NFB training. The PM was selected as the region of interest because it is an important motor related area that may play a key role in rehabilitation after brain injury. Twenty right-handed healthy volunteers were included in the study and divided into 2 groups, NFB (n=10) and controls (n=10). The experimental design was composed by a pre-training session and a 3T MRI acquisition, including high-resolution spin-echo anatomical sequence (T1-weighted image) and a fMRI protocol (EPI single-shot (TR / TE, 2000 / 22 ms; voxel size: 3,75 x 3,75 x 5 mm3). The fMRI protocol encompassed (i) a motor run (real finger tapping movement) and (ii) three imagery runs. Each imagery run comprised 8 blocks containing 30s motor imagery of the right hand finger tapping, and 20s of a baseline condition (i.e., visual imagery of a scene). All participants viewed through a mirror on top of the head coil a screen presenting a bar graph with dynamically raising or falling content. In the NFB group the changing bar graph was related to the hemodynamic response in the left PM area during motor imagery, providing participants a feedback of their own ongoing brain activation. NFB group was instructed to increase the activation level during training. In the control group, the movement of the bar was random during motor imagery and participants were asked to pay attention to the graph bar. The entire session lasted 45 minutes. An accelerometer was positioned over the thumb to ensure that no overt movement occurred during motor imagery. NFB volunteers were able to increase the left PM cortex activation throughout training session. In addition, direct comparison between the last and first NFB runs showed increased activation in other motor-related brain areas, such as ipsilateral PM cortex, supplementary motor area, basal ganglia and cerebellum for the NFB group, but not for the control one (fixed-effect analysis; $p<0.05$ FWE). In conclusion, NFB training can induce functional plasticity in motor related areas. This finding can be particularly important for clinical application in motor rehabilitation in neurological disorders.

Title: Constructing a hodological map for the mouse forelimb muscles

Authors: *E. M. STRAIT, M. BANNECK, Y. ZUO;
MCD, Univ. of California, Santa Cruz, Santa Cruz, CA

Abstract: The motor cortical area representing task-related muscle movements expands during repetitive practice of motor skills. Using in vivo imaging, our previous studies have shown that motor learning promotes formation of new synapses onto layer 5 pyramidal neurons in the motor cortex and these new learning-induced synapses are selectively stabilized with repeated practice of the same task. However, how learning-induced synaptogenesis contributes to circuitry remodeling of the motor system and how projection trajectories of cortical neurons change during the learning process remain unknown. Using multi-colored, retrograde transneuronal pseudorabies viruses (PRVs), we have recently developed a method to identify cortical neurons controlling particular forelimb muscles. We found that it took 3 days for PRVs to reach the cortex after they were injected into forelimb muscles. At this time, only layer 5 cortical neurons were infected in the cortex, with the majority of labeling observed in the contralateral motor cortex. One day later, more layer 5 cortical neurons were infected on both hemispheres and the infection also spread out to other cortical layers. In the cortex, only neurons were infected by the virus, implying faithful transneuronal transport of PRVs. We are currently examining the hodological maps for different muscle groups and determining how such maps change in response to motor skill learning.

Title: Training strategies in the elderly may differentially affect the speed accuracy trade-off during motor skill learning

Authors: M. ELWENSPOEK[1], G. PRICHARD[2], A. SCHÖCHLIN-MARX[1], B. FRITSCH[1], *J. REIS[1];
[1]Dept. of Neurol., Univ. of Freiburg, Freiburg, Germany; [2]UCL London, London, United Kingdom

Abstract: Acquisition of a new motor skill results in an increased level of motor performance. Motor skill learning on a sequential visual isometric pinch force task results in a shift in the speed-accuracy trade-off function (SAF) in young subjects (Reis et al., 2009). When subjects move through speed-accuracy space, different strategies may be utilized (e.g. mostly increasing speed while maintaining accuracy, or increasing accuracy while maintaining a chosen speed). Hence, similar levels of skill can be reached with different strategies. These strategies have not been investigated so far in elderly subjects. Here we investigated whether a constrained training mode (fast speed versus high accuracy) would result in a specific shift of the speed-accuracy trade-off function relative to an unconstrained mode.
42 healthy elderly subjects practiced the sequential visual isometric pinch task in three different training modes (n=14 per group; as fast as possible versus as accurate as possible versus fast+accurate in unconstrained mode) for 3 consecutive days. We assessed skill by probing the SAF in testing sessions one day before and after the training period.
The SAF probes showed that training resulted in improved accuracy for given speeds encountered during training, but also for speeds never reached during training in all three training modes (generalization). Moreover, our preliminary analysis revealed a more pronounced shift in those speeds assigned to (speed group) or chosen (accuracy group) during training.
These preliminary results suggest that in elderly people: 1) Skill generalizes during training, as untrained speeds can be better performed afterwards. 2) Training strategies may be visible by a change in particular aspects of the SAF. Hence, constrained training strategies may facilitate different components of motor skill learning. These results are of relevance for behavioral and sports science as well as neurorehabilitation.

Abstract: Robotic technology is increasingly used for rehabilitation and the potential exists to enhance use-dependent plasticity with non-invasive motor cortex stimulation specifically timed with the practiced reaching movements. The objective was to determine how the timing of stimulation influenced neuroplasticity associated with robotic reaching. Sixteen participants completed 3 separate sessions with different stimulation timings (pre-movement, EMG triggered, random) during a repetitive reaching intervention using a planar robot with 480 trials of movement. Sub-threshold, single-pulse transcranial magnetic stimulation (TMS) was delivered at: pre-movement - 120-150ms prior to movement onset; EMG triggered - when muscle activity exceeded threshold; or randomly - anytime between visual cue and movement completion. Five assessments included the amplitude and direction of TMS evoked movements with corresponding motor evoked potential (MEP) recordings from the biceps, triceps, anterior and posterior deltoid muscles. Each assessment included 10 averaged trials and MEP data were organized into elbow and shoulder agonist and antagonist groups. Change scores from the initial assessment were calculated as follows: % change in amplitude, absolute change in direction (0-180 degrees), and change in MEP amplitude (normalized to amplitude at movement threshold). Data were analyzed using a general linear model with repeated measures for time and a between subjects effect for stimulation conditions. The evoked movements significantly increased in amplitude following the pre-movement and random conditions, but not following EMG triggered condition ($p < 0.05$). The TMS evoked directions significantly changed following all conditions ($p < 0.05$), and no differences between groups were observed. There was a significant difference between conditions for shoulder and elbow agonist MEPs with a general increase in amplitude following pre-movement and a significant decrease following the EMG triggered condition ($p < 0.05$). These findings demonstrated that stimulation delivered during pre-movement and EMG triggered conditions influenced neuroplasticity with a robotic reaching intervention, yet the mechanism by which these changes occurred appeared to differ. The direction of plasticity may change rapidly and selectively during the planning and production of movement. This dynamic change in plasticity shapes the way in which practice results in motor system changes.

Title: The effects of hand immobilization on motor imagery: A multimodal study

Authors: *L. MARSTALLER[1], P. SOWMAN[1], A. RICH[1], M. WILLIAMS[1], G. SAVAGE[2], H. BURIANOVÁ[1];

Abstract: Neural plasticity in somatosensory cortex has been investigated extensively in patients with stroke (Hallet, 2001; Pascual-Leone et al., 2005) or phantom limbs (Ramachandran et al., 1996; Karl et al., 2001), and in healthy populations after hand immobilization or motor training (Liepert et al., 1995; Ngomo et al., 2012; Zanette et al., 2004). The aim of this study was to investigate the effects of short-term hand immobilization on motor imagery, and specifically immobilization-related plastic changes in the primary motor cortex (M1). Using a novel motor imagery paradigm (Burianova et al., 2013), we tested 16 healthy, right-handed adults, assessing neural changes in M1 with functional magnetic resonance imaging (fMRI) and related oscillatory changes in the beta frequency band with magnetoencephalography (MEG). We measured resting motor thresholds (RMTs) and motor map areas (MMAs) with transcranial magnetic stimulation (TMS), thus attaining a direct index of the immobilization effect. The results show that after 24 hours of right hand immobilization, RMTs and MMAs increased significantly in the contralateral motor cortex. In addition, fMRI and MEG results show a significant reduction in BOLD activation and beta desynchronization in M1 contralateral to the immobilized hand. The results suggest that short-term hand immobilization has a direct and rapid effect on motor imagery in M1, which can be reliably assessed using multimodal neuroimaging methods.

Title: Enhancing effector-independent representations of motor skill with transcranial direct current stimulation (tDCS) to primary motor cortex (M1): Behavioral and neuroimaging effects

Authors: *S. WATERS-METENIER[1,2], T. WIESTLER[1], J. ALLEN[3], M. HUSAIN[1,2,4,5], J. DIEDRICHSEN[1];
[1]Inst. of Cognitive Neurosci., [2]Inst. of Neurol., [3]Sch. of Med., Univ. Col. London, London, United Kingdom; [4]Nuffield Dept. of Clin. Neurosciences, [5]Dept. of Exptl. Psychology, Oxford Univ., Oxford, United Kingdom

Abstract: It has been hypothesized that it is behaviorally advantageous to *increase contralateral* M1 activity and simultaneously *decrease ipsilateral* M1 activity, thereby reducing interhemispheric inhibition of contralateral M1. Indeed, a bihemispheric tDCS montage--with the anode over contralateral and cathode over ipsilateral M1--facilitates motor performance better than unihemispheric tDCS, in which the cathode is above non-motor structures (Vines et al., 2008). To test whether the advantage of bihemispheric tDCS really arises from a suppressive effect on ipsilateral M1, we trained 42 healthy, right-handed subjects for 4 days on a finger sequence task, while applying double-blind sham or bihemispheric tDCS with the anode over contralateral M1 (bi-anodal) or ipsilateral M1 (bi-cathodal). Training was conducted with *either* left or right hand, and tDCS (2mA) was applied during the first 25 min of a 1hr training session. We expected that bi-cathodal tDCS would attenuate learning with respect to sham, as it should not only directly suppress contralateral M1, but also increase ipsilateral M1 activity, further inhibiting contralateral M1. Contrary to this prediction, we found that both bihemispheric tDCS groups achieved ~40% faster movement times than sham recipients, as well as ~20% faster movement times than eight anodal unihemispheric tDCS recipients. This indicates that the additional benefits conferred by bihemispheric relative to unihemispheric tDCS are achieved due to increases in plasticity in *both* hemispheres, rather than suppression of ipsilateral M1. Consistent with this idea, we also found that tDCS-associated learning gains, regardless of montage, near completely generalized to the untrained hand. Further, intermanual generalization was most pronounced in the bi-cathodal group, indicating that this montage particularly influenced effector-independent representations. Finally, we studied the neural effects of tDCS-

coupled training in the same participants using fMRI. We observed that both bihemispheric tDCS groups exhibited ipsilateral increases in % BOLD signal change (as well as contralateral increases), whereas sham recipients showed characteristic ipsilateral deactivation. In conclusion, we propose that, irrespective of polarity, bihemispheric tDCS facilitates dual hemisphere coding of effector-independent representations, whereas unihemispheric tDCS (which is half as effective) enhances such encoding in one hemisphere.
Vines BW, Cerruti C, Schlaug G (2008) Dual-hemisphere tDCS facilitates greater improvements for healthy subjects' non-dominant hand compared to uni-hemisphere stimulation. BMC Neurosci 9:103.

Title: Microstructural changes of motor tracts in healthy ageing

Authors: R. LINDENBERG, A. WILLERT, M. MEINZER, *A. FLOEL;
Neurol., Charite Univ. Med., Berlin, Germany

Abstract: Studies on stroke patients have demonstrated that so-called alternate motor fibers (aMF), which may comprise the cortico-rubro-spinal system, can compensate for damage to the pyramidal tract (PT). While it is well documented that the PT undergoes degeneration with age, no data are available with regard to aMF. Using diffusion tensor imaging (DTI), we examined

microstructural properties of PT and aMF in groups of young and older healthy subjects. We hypothesized that aMF may undergo plastic changes in order to compensate for the previously described age-related degeneration of the PT.
36 healthy older subjects (18 women, mean age 68.0±5.3 years, all right-handed) and 90 healthy young subjects (45 women, mean age 25.1±3.7 years, all right-handed) underwent MRI at 3T. We acquired a DTI sequence (10 b0, 64 b1000, isotropic voxels sized 2.3x2.3x2.3 mm3) in order to extract fractional anisotropy (FA) of the pyramidal tract (PT) and so-called alternate motor fibers (aMF). FSL was used for pre-processing and probabilistic tractography. For both PT and aMF, waypoint masks were used in the posterior limb of the internal capsule and the hand knob of the primary motor cortex. The anterior pons served as seed region to reconstruct the PT, whereas ROIs applied to the posterior pons were used for aMF. We extracted mean FA and mean intensities of the reconstructed tracts in either hemisphere in order to compare values between the two groups. In addition to this tract-specific approach, a slice-by-slice analysis allowed us to investigate potential regional differences between the age groups.
With regard to tract-specific FA, significant between-group differences were found in right PT (lower FA in older adults) and left aMF (higher FA in older adults). The slice-by-slice analysis revealed that FA reductions in the right PT of older compared to younger subjects could be observed throughout the tract, from its origin in the cortex to the brainstem. In contrast, regional differences in left aMF (higher values of older compared to young participants) appeared to be greater in the midbrain and brainstem than in the white matter cranial to the internal capsule.
In conclusion, aMF may not only play a compensatory role in case of PT damage due to lesions such as stroke, but also in physiological ageing. In line with previous studies on stroke patients, our data are suggestive of plastic changes in the vicinity of midbrain and brainstem nuclei of corticofugal motor tracts (e.g., the red nucleus), potentially as a result of age-related PT degeneration. Our study sheds light on reorganization processes of the motor system in ageing, which may be of value for the development of restorative treatments.

Title: Unilateral activation of the less affected limb to task-failure facilitates the ipsilesional hemisphere post-stroke

Authors: *C. PATTEN[1], E. WHITE[2], N. LODHA[3];
[1]Univ. of Florida, GAINESVILLE, FL; [2]Occup. Therapy, [3]Applied Physiol. & Kinesiology, Univ. of Florida, Gainesville, FL

Abstract: Unilateral movements activate multiple brain regions bilaterally, leading to cross-transfer effects between limbs. Previous investigations suggest the magnitude of bilateral activation scales with contraction force. Here we investigated concurrent neurobehavioral effects of unimanual gripping and to observe acute adaptations in cortical and interhemispheric circuits. We studied 6 persons (63.7±3.8 yrs) with post-stroke hemiparesis (UEFMA 53.5±2.9/66 pts) and 6 age-matched (60±7 yrs) controls.
Participants performed repeated submaximal (30% maximal age-referenced norm) isometric power grip to task-failure. Maximal voluntary isometric grip force (MVIC) was assessed at: baseline and following every 10th submaximal repetition (10 repetitions = 1 block). Single-pulse transcranial magnetic stimulation was used to elicit cortical (cSP) and ipsilateral (iSP) silent periods and motor evoked potentials (MEPs) at: baseline, immediately following, 30 and 60minutes post-task-failure. The more (MA) and less (LA) affected limbs of participants post-stroke were studied in separate sessions one week apart. The non-dominant hand was studied in Controls (C).
At task-failure MVIC grip force was reduced similarly among MA, LA and C hands (range 21.3 - 28.9%, $p > .05$). In contrast, time to task-failure was significantly prolonged (203.5 blocks) and reduced (18 blocks) in LA and MA, respectively, relative to C (120 blocks) hands ($p < .05$).
In activated hemispheres normalized MEParea (i.e., MEParea/Mmax) increased modestly immediately following (Stroke-Ipsilesional (IL), 47.6%), post30 and post60 (C, 74-79%) (p's <.05). In the resting, IL, hemisphere, however, normalized MEParea increased markedly (85.2%, $p < .005$) immediately following LA hand activity to task-failure. This IL hemisphere facilitation was both sustained and extended for up to one hour following activity (post30, 125.6%; post60, 160%, p's <.0002). Concurrently, iSP duration measured in the IL hemisphere, indicating interhemispheric inhibition (IHI) from IL-to-CL, was significantly increased (post, 51%) and sustained for up to one hour (post30, 48%; post60, 64%; p's <.05). Taken together, these results suggest that systematic activation of the LA hand (CL hemisphere) facilitates the IL hemisphere and improves IL-to-CL IHI, reducing inter-hemispheric competition known to occur following stroke. Rather than force magnitude, per se, these effects appear to be mediated by activation to task-failure. Persistence of these neural adaptations for up to one hour may offer a novel therapeutic opportunity for effective rehabilitation of paretic limbs.

Title: Physiological changes in the cerebellum and primary motor cortex during skill learning

Authors: *D. SPAMPINATO[1], A. BASTIAN[2,5], P. CELNIK[3,4];
[1]Biomed. Engin., Johns Hopkins Unviersity Sch. of Med., Baltimore, MD; [2]Neurosci., [3]Physical Med. and Rehabil., [4]Neurol., Johns Hopkins Univ. Sch. of Med., Baltimore, MD; [5]Kennedy Krieger Inst., Baltimore, MD

Abstract: Learning motor tasks is associated with excitability changes in the cerebellum (CB) and primary motor cortex (M1). Two important types of motor learning include adaptation and skill learning. Adaptation refers to an error-based learning of sensorimotor calibrations, whereas skill learning requires performance improvements with repeated practice via reinforcement mechanisms. Although these two forms of learning have been linked to different neural substrates and physiological changes, it is likely that learning certain skills tasks have an initial component of acquiring a new sensorimotor calibration. Previously, we have shown that CB-M1 connectivity decreases early on when participants experience adaptive motor learning (Jayaram et al., 2011; Schlerf et al., 2012), whereas skill learning results in occlusion of LTP-like plasticity at the end of the practice session (Cantarero et al., 2013). Thus, we predict that if learning a skill involves in its early stages forming a new sensorimotor calibration then CB-M1 connectivity should be reduced early during skill learning but not late, once the calibration has been fully learned. Similar, we would expect that occlusion of LTP-like plasticity should be more prominent late but not early during the skill learning process.
We used a pair-pulsed transcranial magnetic stimulation (TMS) technique to assess the changes in CB-M1 connectivity before, during, and after participants trained on an isometric finger-pinch sequence skill task. In addition, we assessed the magnitude of occlusion early and late during skill training, using anodal transcranial direct current stimulation (TDCS).
We found a reduction in CBI only initially when participants began to learn the skill task ($p<0.05$). However, with further practice, CBI returned to baseline levels despite improvement in performance. Interestingly, we found that CBI changes were proportional to early skill

improvement (R2=0.58, $p<0.05$). In addition, we found that occlusion of LTP-like changes over M1 occurred late but not early during skill learning ($p<0.05$). Importantly, a control group that trained on a randomized form of the task showed no changes in CBI or occlusion of M1. These findings indicate that CB-M1 connectivity changes occur early on during the initial acquisition of a skill, whereas M1 role in skill learning becomes more prominent as the skill is practiced. This suggests that skill learning, which relies in reinforcement practicing mechanisms, also incorporates early on adaptation mechanisms.

Title: Visual attention load modulates motor cortical plasticity through sensory-motor projections

Authors: *J. L. MIRDAMADI, L. Y. SUZUKI, S. K. MEEHAN;
Sch. of Kinesiology, Univ. of Michigan, Ann Arbor, MI

Abstract: Repetitive transcranial magnetic stimulation (rTMS) has been shown to induce neural plasticity, providing a potential means of enhancing learning and rehabilitation. However, the efficacy of this technique remains uncertain due its state-dependent nature. Previous work suggests a role for attention in mediating plasticity of the motor cortex. Although, whether attention works directly on the motor cortex or indirectly through altering sensory processing remains uncertain. Here, we addressed this issue by delivering 2-second trains of theta burst stimulation (TBS) over either the motor or sensory cortex under varying attention loads. It was hypothesized that increased attention load would reduce motor cortical excitability changes induced from TBS over the motor cortex, as previously reported. In contrast, we expected that TBS over the sensory cortex would enhance motor cortical excitability, regardless of attention load. 2-second trains of TBS (3 pulses at 50 Hz repeating every 200 msec, 80% AMT) were delivered over either the motor cortical representation of the first dorsal interosseous muscle or the corresponding sensory cortex. During TBS, participants were engaged in a visual detection task that required either high attention or low attention. Motor cortical excitability was quantified using motor evoked potential (MEP) amplitude elicited by single pulses of TMS (120% RMT) before TBS and at 2-second intervals after TBS for 20 seconds. 12 trials were delivered over

each stimulation site (sensory cortex, motor cortex) and for each attention load (low load, high load). As a control, the procedure was repeated without any TBS. Preliminary results (N=8) suggest that 2 seconds of TBS increased MEP amplitude regardless of TBS site. However, the increase in MEP amplitude was greater following sensory TBS compared to motor TBS. For both sites of TBS high attention load reduced MEP amplitude compared to low attention load. Interestingly, MEP amplitude was similar for motor TBS with low attention load and sensory TBS with high attention load. Motor evoked potentials in the absence of TBS demonstrated no change in amplitude regardless of attention load. These results suggest that attention may influence plasticity in the motor cortex, reflected by increased MEP amplitude, indirectly through altering sensory-motor projections. These results may have important implications for maximizing the benefits of TBS in both healthy individuals and potential rehabilitation interventions.

Title: Hardware simulation of excessive cortical drive results in increased motoneuron excitability and presents features of spasticity

Authors: *S. NANDYALA, C. M. NIU, T. D. SANGER;
USC, Los Angeles, CA

Abstract: Childhood-onset spasticity can typically take an upwards of 10 years to develop before symptoms present. Disease onset in this time frame suggests there is involvement of a long-term plasticity component in response to the descending motor drive. A biorealistic, hardware simulation of the spinal motor loop over a period of 10 years of simulation time was used to investigate the effects of long-term excessive descending drive on the excitability of alpha and gamma motoneurons. Synaptic plasticity was modeled using the spike-timing dependent plasticity (STDP) and Bienenstock-Cooper-Munro (BCM) learning rules. By using a hardware emulation, we are able to accelerate emulation time to 365x faster than real time, allowing us to investigate these long-term plasticity effects in a reasonable time frame. Using this model, we emulated a variety of stretch reflex responses at a single joint. The emulated

EMG response shows good correspondence with the known velocity-dependent spastic EMG patterns as reported in Jobin et al. 2000. The emulated joint torque response shows good correspondence with known spastic torque responses as reported in Schmit et al. 1999. These results suggest that increased motoneuron excitability in response to excessive cortical drive can explain the causation of some forms of childhood-onset spasticity.

Title: Trial-to-trial variability of PM and M1 cortical neurons encodes directional learning control task factors

Authors: *J. SI, H. MAO, T. KETCHUM;
Arizona State Univ., TEMPE, AZ

Abstract: Trial-to-trial variability is recently found informative in neuronal encoding of sensory and motor parameters, though the nature of the variability is elusive. To provide insight on the issue, we studied trial-to-trial firing rate variability of PM and M1neurons as rats learned to associate light cues with appropriate directional control strategies.
A rat would press a center lever to start a trial at his own will. One of five cue lights would appear. The rat could press either a left or right control lever to “move” the cue light to the right or left by one position, respectively. The goal was for the rat to “move” the light to the center for a food reward. By trial and error, rats could reach an accuracy of 80% or above in about 30 sessions on average. Single units in PM and M1 were recorded along with behavioral parameter. In each session/day, trials were grouped as L-L subset (left movement in response to the left side cue) and R-R (right movement to the right side cue). According to trial outcomes, the trials were grouped as P-S (post a previously success trial) and P-E (post a previously error trial). Neuronal spike counts in a 100 ms window sliding at a 20 ms step were computed. The L-L and R-R trials were compared, and direction selectivity (DS) was defined if significant differences were observed (Mann-Whitney *U*-test, $p<0.01$). Similarly, previous outcome selectivity (POS) was

recognized between P-S and P-E trials. A neuron was labeled as DS if direction selectivity was observed in at least 20% of the time from 200 ms to 2000 ms after cue onset, and similarly POS neurons were identified. Among the 678 neurons recorded from all sessions of 8 rats, 24.0% were DS, 26.5% were POS, and 6.6% showed both types of selectivity.
Trial-to-trial neural variability was calculated as spike count variance over mean (Fano factor, FF) in L-L and R-R trials of DS neurons, and P-S and P-E trials of POS neurons, respectively. Decreased FF values were found in L-L, R-R, and P-S trials from 1.76, 1.73, and 2.89 before cue onset to 1.38, 1.52, and 2.47 after (*U*-test, $p<0.01$), respectively. But it was not in P-E trials when FF changed from 2.43 to 2.48 (*U*-test, $p>0.5$). Meanwhile, P-S and P-E trials had higher FF values than L-L and R-R trials.
These results demonstrated that trial-to-trial firing rate variability carried task related information. This variability may suggest different levels of coding demand, where movement parameter coding required relatively more precise rate coding while performance monitoring was coded less precisely on a daily basis.

Title: Motor cortical activity tracks the position of a brain-machine interface cursor

Authors: *S. D. STAVISKY[1], J. C. KAO[2], P. NUYUJUKIAN[3,4], S. I. RYU[6], K. V. SHENOY[5,2,4];
[1]Neurosciences Program, [2]Electrical Engin., [3]Sch. of Med., [4]Bioengineering, [5]Neurobio., Stanford Univ., Stanford, CA; [6]Dept. of Neurosurg., Palo Alto Med. Fndn., Palo Alto, CA

Abstract: Brain-machine interfaces (BMIs) continue to move towards restoring movement to individuals with paralysis or limb loss. However, little is known about how the sensorimotor system incorporates BMIs into its motor control strategy. We tested whether a well-described property of arm control - that motor cortical activity is modulated by hand position (Caminiti et al. 1991) - also holds when a task is done with a BMI rather than with the arm. During arm reaches, hand position is linked to neural activity through mechanisms including proprioception, postural tonic output, visual feedback, and efference copy. Moving a cursor via BMI, without arm movements, minimizes the influence of proprioception and postural tone and reveals whether the cursor's position still affects neural activity.

Two macaques were implanted with multielectrode arrays in primary motor (M1) and premotor (PMd) cortex. They performed a 2D task in which a cursor either followed the monkey's fingertip (arm control) or was driven by a BMI that decoded multiunit activity into cursor velocity. During BMI use both arms were restrained. The monkey moved and held the cursor over a target appearing at a random location. We linearly regressed the multiunit firing rate during these hold epochs against hand or cursor position to measure how much neural variance was explained by position. In a representative dataset, during arm control the hand position explained significant variance ($p < .001$, shuffle test) on 118/161 movement-modulated channels ($R^2 \in [0.012, 0.531]$). In BMI control, cursor position explained significant variance on 77 channels ($R^2 \in [0.006, 0.196]$). Since the BMI controlled only cursor velocity, modulation of neural activity due to cursor position suggests that visual feedback and/or an internal model affect the motor system during BMI use. Further work must test if gaze differences contribute to this effect, but we note that our result holds in M1 and that prior studies found weak correlates of free gaze in PMd (Cisek & Kalaska 2002).

We further show that a decoder that accounts for neural modulation expected due to the current cursor position (Gilja et al. 2012) outperforms decoders that instead account for actual hand position (81% longer acquire times) or omit this step (14% longer acquire times). These results are consistent with a feedback controller view of motor cortex in which the BMI cursor is the task-relevant effector whose state is tracked by the sensorimotor system. It provides principled justification for applying an online control perspective to neural-control algorithm development and motivates future studies of how sensory feedback is incorporated into the neural state during BMI use.

Title: Microfabrication and finite element modeling of micro and macro sieves for use in targeted peripheral nerve regeneration

Authors: *J. PARDO, E. ZELLMER, D. MORAN;
Biomed. Engin., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: While human peripheral nerves are known to regenerate following damage, the restoration of normal nerve function following injury has remained, at best, an elusive aim. Withal, it has been suggested and evidenced that modulation of nerve afferent plays a central role in the mechanisms that are important for learning and executing motor tasks. Previous work has shown that peripheral nerve axons regenerate through vias in polyimide sieve guides. Furthermore, electrodes can be integrated onto the polyimide sieve to make a complete multichannel neural interface. A major challenge is the optimal design and fabrication of these sieves to ensure the best possible regeneration. The present study presents the on-going development of a next-generation integrated and flexible sieve interface for use in targeted peripheral nerve regeneration. First, a process technology was developed to fabricate a multilayer sieve device with micron sized features meeting mechanical, electrical and biocompatible requirements. Additionally, the process is shown to be adaptable to multiple geometric designs (micro and macro) which can be tested in terms of regeneration performance. Second, a myelinated mammalian peripheral nerve segment was modeled with a microsieve electrode device, using finite element analysis, to evaluate the spatial selectivity the microsieve electrode, as well as, explore the novel stimulation paradigms that been found useful in increasing selectivity in the previously developed macrosieve electrode.

Abstract: Interest in the use of implanted microelectrode arrays for neural prosthetic applications has increased. Implanted neural interfaces are also utilized clinically to relieve the symptoms of neurological disorders such as essential tremor, Parkinson's, and obsessive-compulsive disorder via electrical stimulation. The utility of neural implants may be limited by the degradation of their performance in detecting neural signals over time. Such degradation may partly result from the brain's immune response, which is activated by penetration of the blood brain barrier. This response is characterized by immediate microglia/macrophage activation which signals increased upregulation of glial fibrillary acidic protein in astrocytes and formation of a glial scar that encapsulates the probe. However, the extent of this reaction varies greatly and is dependent on the size, shape, and insertion rate of the implant. According to some reports, this tissue response is coincident with a significant loss of neurons proximal to the device, but this mechanism remains unclear. To date, this putative neurodegenerative response has primarily been investigated through post-mortem labeling of neurons at different time points.
Here we report an in vivo optogenetic assay to detect changes in neuronal function and physiology throughout the course of the neuroinflammatory response to implanted devices. We used a chronic optogenetic stimulation protocol to provide repeatable controlled stimulation over many weeks of implanted time without susceptibility to electrode contact degradation mechanisms. Single-shank optrodes (Neuronexus Technologies, A16) were implanted into the primary motor cortex of adult male B6.Cg-Tg(Thy1-COP4/EYFP)18Gfng/J mice. The probes were inserted so as to position the end of the fiber optic cable flush with the surface of the brain, and the recording sites throughout the cortical depth. After one week of recovery from implantation, weekly recordings were performed from awake, freely moving mice. Each session consisted of recording spontaneous activity for 10 minutes, followed by 10 minutes of optical stimulation with 5-100ms pulses at frequencies from 1-40 Hz. Delivered light was from a DPSS 473 nm laser with power emission of 1-50 mW. Electrophysiological recordings continued until 4 months post implant, or until discernible spikes could not be recorded. Preliminary data showed optically driven activity in both spiking and lower frequency bands. Properties of the spontaneous and optically-evoked activity were tracked longitudinally to assay for the presence of viable neurons, even in the absence of spontaneous or behavior-locked activity.

Title: Evaluation of chronically implanted microelectrode arrays for brain-machine interface

Authors: *P. TAKMAKOV[1], S. JAROUDI[1], E. F. CIVILLICO[2], K. T. WACHRATHIT[2], V. KRAUTHAMER[2], C. G. WELLE[2];

Abstract: Neuroprosthetics with brain-computer interface provides an alternative motor functionality for paralyzed patients and amputees by directly linking the brain to artificial limbs via cortical implants that sample neural activity from a motor cortex. Currently, the chief roadblock for this technology is the decrease functionality of the implants with time. Experiments in primates and human patients have indicated degeneration of the device performance manifested as a decline both in amplitude and number of recorded neural spikes. It is unclear whether this degeneration pertains to the death or silencing of the adjacent neurons and encapsulation of the electrodes or to the failure of the implants due to chemical degradation. The neural implants are invasive high-risk medical deviceswich require extensive evaluation of their safety and efficacy is needed before this technology is common for the patients.
Electrochemical impedance spectroscopy (EIS) is the most efficient technique to assess the condition of the neural implant in vivo. Traditionally, only impedance at 1 kHz is reported and used to characterize the device. In this work, we evaluated the performance of cortical neural implants from several commercial manufacturers during chronic implantation in mice. Periodic recordings of action potentials along with EIS were performed for a period of up to one year. EIS recordings were conducted using wide band spectra from 1 Hz to 1 MHz to establish which frequencies best correlate with the observed decline in the electrophysiological signals. Our data indicates that using wide range of frequencies provides a more reliable prediction of the implant condition.
Additionally, we performed thorough characterization of the neural implants after they were removed from the animals. We developed a cleaning protocol based on mild cleaning agents including surfactants and digestive enzymes used to remove biological deposits. Characterization of the integrity of the neural implants was performed with EIS and scanning electron microscopy. In sum, evaluation of the electrode characteristics both in vivo and post-explant

elucidates associations between the functional decline in the device performance and the physical degradation of the implants.

Title: A wireless neural recording system for freely behaving primates

Authors: F. ASGARIAN, M. HASHEMI, W. CARTAGENA, S. HAO, *K. G. OWEISS; Michigan State Univ., EAST LANSING, MI

Abstract: Wireless neural recording from awake behaving subjects has received much interest in recent years due to continued interest in improving our understanding of neural coding mechanisms outside of the pristine lab environments, and the urgent need for cosmetically acceptable solutions in clinical applications. Implantable microelectrode arrays that record spiking activity from ensembles of neurons, however, require ultra-high bandwidth links that preclude wireless telemetry with conventional electronics. A wireless system that enables high fidelity information transmission, while animals move freely in their natural surrounding is highly desirable. Here, we report on the first generation of our wireless, head-mounted neural interface for continuous intracortical neural recording from 96-channel Utah electrode arrays in primates. Besides being compatible with commercially available connectors/adaptors, the system has a configurable hardware platform, permitting calibration “on demand” depending on user-specific needs and experimental design.
The head mounted (transmitter) part consists of a Neural Interface Node (NIN) connected to the implanted array, while the receiver part consists of a Manager Interface Module (MIM) interfaced with a base workstation for programing and calibration purposes. The NIN processes neural data from 96 microelectrodes with a programmable sampling rate (up to ~23 KHz/channel) at 16-bit/sample resolution. The NIN further compresses and packetizes the data to enable wireless transmission over a 2-Mbps link (for each block of 32 channels) without compromising information about spike timing and identity on any given electrode. The system is battery powered, with a life time of 10~25 hours, depending on the enclosing case design. One

design features a case-battery (measures 35.5×53×24 mm^3), while another design features a backpack-battery with a subcutaneous cable extending to the skull (measures 50×54×36 mm^3). The MIM transfers data wirelessly to and from NIN, and is connected to the PC through USB. A Graphical User Interface (GUI) has been designed for display and programming purposes. The real-time processing capability of the system has been bench-tested with pre-stored monkey neural data. A fully implantable version is currently under development. Taken together, the system provides the most essential elements for recording from freely behaving subjects, and paves the way for fully implantable systems in Brain-Machine Interface applications.

Title: Evaluation of long-term stability of atomic layer deposited Al2O3 and Parylene C bi-layer encapsulated Utah electrode array based neural interfaces

Authors: X. XIE[1], L. RIETH[1], L. WILLIAMS[3], *S. NEGI[1], R. BHANDARI[3], R. CALDWELL[2], M. DIWEKAR[1], R. SHARMA[1], P. TATHIREDDY[1], F. SOLZBACHER[1]; [1]Electrical and Computer Engin., [2]Bioengieering, Univ. of Utah, Salt Lake City, UT; [3]Blackrock Microsystems, Salt Lake City, UT

Abstract: Long-term stability and functionality of neural interfaces is a big challenge for chronic implantation. We present a novel encapsulation scheme that combines atomic layer deposited (ALD) Al2O3 and Parylene C for biomedical implantable. Our approach combines the highly effective moisture barrier properties of ALD alumina, and Parylene as a barrier to many ions and for preventing contact of alumina with liquid water. 52 nm of Al2O3 was deposited by plasma-assisted (PA) ALD on assembled Utah electrode arrays (UEAs) at 120 °C. A 6-µm thick Parylene-C layer was deposited by CVD using Gorman process on top of Al2O3 and A-174 (Momentive Performance Materials), an organosilane, was used as adhesion promoter. Hybrid methods were used to de-insulate the tips of the UEAs in order to interact with neurons for

recording and stimulation, including 200 laser pulses with fluence of 1400 mJ/ cm2, 2 minutes of oxygen plasma, and 8 minutes of buffered oxide etch etching. The tip exposure was ~ 35 µm. The devices were then put into saline solution for soak testing. The neural interfaces coated with 52 nm of Al2O3 and 6 µm of Parylene C were immersed in phosphate saline solution at 57 °C for accelerated lifetime testing. The median tip impedance of the bi-layer encapsulated wired Utah electrode array increased from 60 kΩ to 160 kΩ during the 960 days of equivalent soak testing at 37 °C. The loss of tip metal iridium oxide and etching of silicon in PBS solution contributed to the increase of impedance. Also bi-layer coated fully integrated Utah array based wireless neural interfaces had stable power-up frequencies at ~910 MHz and constant RF signal strength of -50 dBm during the 1044 days of equivalent soaking time at 37 °C. Bi-layer coated Utah arrays had steady current drawing of about 3 mA during 228 days of soak testing at 37 °C. The relatively stable tip impedance, constant power-up frequencies and signal strengths, and low current drawing suggested that the alumina and Parylene C bi-layer coating is very suitable for encapsulating chronic implantable devices.

Title: A longitudinal study of comparative neural implant recording efficacy in awake behaving mice

Authors: *E. F. CIVILLICO, K. T. WACHRATHIT, A. JAIN, V. KRAUTHAMER, C. WELLE;
Office of Sci. and Engin. Laboratories, Div. of Physics, FDA, Silver Spring, MD

Abstract: The development of more reliable neural interfaces will benefit from a thorough characterization of the stability of electrophysiological features over lengthy chronic

implantations. Current intracortical neuroprosthetic systems transform the modulation of neuronal activity into command signals for prosthetic devices. Studies using both human and animal neuroprosthetic systems find a decline in quality of the recorded neural signal over time, reducing its information content for neuroprosthetic control. This decline may result from a complex tissue response, changes to the physical integrity of the electrode array, or a combination of both. To understand the factors determining electrode efficacy, we have developed a test platform consisting of a set of complementary surgical, recording, histological, and data analysis protocols for neural interface characterization in awake mobile mice. Microelectrode arrays are tested by surgical implantation, followed by biweekly 15-minute electrophysiological recordings from 2 weeks until 5 months postimplantation, followed by tissue sectioning and histology. Here we report results from various electrode form factors that are commercially available for research purposes, including silicon shank style arrays, microwire arrays, floating microelectrode arrays, and platinum-iridium arrays. All arrays were targeted to the motor cortex. A mixture of custom and off-the-shelf analysis routines was used to quantify activity. Measured quantities included RMS of the recorded signal from each site, amplitude and rate of multiunit activity, amplitude of putative single unit waveforms, number of single units identified, and stability of nonspiking signal components such as gamma-band power. Where appropriate, comparisons were made between different re-referencing methods and measurements are reported for multiple methods.
Preliminary analysis in a subset of recordings made with silicon probes showed declines in the multiunit event rate between 100 and 180 days postimplant. This decline did not track precisely with the amplitude of detected spike events. Immunohistochemical methods were used to examine the expression of foreign-body response-related markers such as GFAP (astrocytes), Iba-1 (microglia), and Nissl substance (neuronal somata), in the vicinity of the electrode. Preliminary histology data from mice successfully recorded for over 100 days showed minimal loss of neuronal cell bodies within 100 um of the electrode, as well as a mild microglia response. The results of these regulatory science studies will inform the evaluation of novel diagnostic and therapeutic medical devices in the CNS.

Title: Keep your attention on the ball, a small twist on the old adage

Authors: *J. NORTON[1], S. HAAS[3], C. BESHERS[4], S. UMUNNA[1], T. BRETL[2];
[2]Aerospace Engin., [1]Univ. of Illinois, Urbana, IL; [3]Urbana High Sch., Urbana, IL; [4]Univ. High Sch., Urbana, IL

Abstract: In her collected works, "Perception, Cognition, and Decision Training", Joan Vickers reveals the importance of focusing on the ball immediately before a golf swing. Using eye tracking, Vickers is able to show that the series of steps leading up to a successful stroke culminates in a period of intense focus on the ball immediately prior to the backswing. In this brief moment, elite golfers focus their eyes directly on the point of contact between the ball and the putter. While the "quiet eye" has revealed a great deal about the sequence of events leading to a golf swing and the role of gaze, it has not dissociated gaze information from active attentional focus. Is the quiet eye simply a coupling of eye movements and motor activity or is there an attentional component? In order to investigate attention's role in performance, we use Steady State Visually Evoked Potentials (SSVEPs), a neural response that is known to be an index of attention. Results reveal that stroke performance is correlated with the allocation of attentional resources.

Title: Multi-channel recording system with UWB wireless data transmitter for ECoG-BMI

Authors: *T. SUZUKI[1], H. ANDO[1], T. YOSHIDA[2], K. MATSUSHITA[3], M. HIRATA[3], T. YOSHIMINE[3], K. TAKIZAWA[1];
[1]Natl. Inst. of Information and Communications Technol., Osaka, Japan; [2]Hiroshima Univ., Hiroshima, Japan; [3]Osaka Univ., Osaka, Japan

Abstract: As a source signal for clinical Brain-Machine Interface (BMI), the electrocorticogram (ECoG) has recently attracted attention because of its good balance of features. It is less invasive but stabler than penetrating electrode methods and has a higher spatial resolution than the normal EEG. We have been developing a fully implantable human ECoG-BMI system that has 128 channels for clinical applications. To improve the accuracy of estimating motion intention and to achieve more precise control of a multi-joint prosthetic arm, it is necessary to increase the number of recording channels; however, there are several barriers, especially in the electrode array, amplifier, and wireless transmitting. In this research, we report a novel multi-channel recording system for ECoG based-BMI in which 1024 channels of ECoG signals are recorded, amplified, and transmitted wirelessly by UWB(Ultra Wide Band). In the proposed system, recorded signals are amplified and converted to digital (maximum sampling rate of the ADC is 1kHz per channel) by using a LSI chip, which has 64-ch low-noise amplifiers and ADCs. Then, the signals from 16 chips (1024-ch) are multiplexed by MUX units and transmitted wirelessly to the control unit located outside of the body by an UWB unit that is designed to use a frequency band that can be used internationally. The transmitting rate of the unit in the air is 133 Mbps. Evaluation experiments of the system with a body phantom system and animals are undergoing.

Title: Wireless electrocorticographic (ECoG) recording system

Authors: *D. R. MERRILL, R. ASKIN, C. F. SMITH, R. E. MADSEN, Jr., D. MCDONNALL, K. S. GUILLORY;
Ripple, Salt Lake City, UT

Abstract: We describe the design and development of a wireless recording system for short-term electrocorticographic (ECoG) monitoring. Reliable monitoring is necessary to guide accurate resection of cortical seizure foci in epilepsy patients who do not respond to drug therapies, but who are candidates for surgical treatment. State-of-the-art monitoring relies on percutaneous leads which may be a source of infection, and relatively stiff electrode arrays which may cause

hemorrhaging and unacceptable foreign body response. Percutaneous leads and stiff electrodes together have hindered the widespread deployment of this otherwise meaningful tool, resulting in only 0.5% - 1% of surgical candidates receiving treatment. The system described here comprises a wireless transcutaneous system using infrared data transmission which mitigates infection risk, and a manufacturing system for production of highly flexible electrode arrays which mitigates the foreign body response of traditional electrodes, together allowing the appropriate substantially larger epilepsy patient base to receive surgical treatment. Although the system design targets an underserved epilepsy population, the solutions offered by these technologies are also well-suited to providing a long-term brain-machine interface.
The flexible electrode manufacturing process is based on robotic deposition of alternating layers of nonconductive polymers, and polymers doped with electrically conductive particles forming the electrodes and interconnections. This process facilitates production of composite structures with trace and space pitches down to 300 μm, and supports synthesis of the electrode array and encapsulation of integrated electronics at low cost. We have performed flexural testing on electrodes, demonstrating electrical and mechanical reliability for over 14 million flexions. Signals from the flexible electrodes are routed to a subcutaneous electronics package where they are amplified and digitized. Data from the implant are then transmitted transcutaneously from an infrared emitter to a detector in the external transceiver. Robust data transmission is supported at rates of at least 10 Mbit/s with a power efficiency of 38% or greater. The implant is inductively powered from the external transceiver. Optimization of the coil driver circuit allows low voltage and low power operation, minimizing interference of the RF field in the optical detector.

Title: Cortical representation of cognitive load in a graded-difficulty BCI task

Authors: *J. D. WANDER[1], T. BLAKELY[1], J. G. OJEMANN[2], R. P. N. RAO[3];
[1]Bioengineering, [2]Neurosurg., [3]Computer Sci., Univ. of Washington, Seattle, WA

Abstract: When executing motor actions, the nervous system dynamically modulates a wide variety of control parameters based on the expected precision requirement of the task being executed. To perform effectively in the face of diverse task requirements, brain-computer interfaces (BCIs) must modulate control parameters in a similar fashion, but without direct knowledge of the task being executed, cues for this modulation may need to be derived from neural activity. Two electrocorticography subjects were trained on a simple 1-D BCI task and then presented with a variant of that task involving targets that either did or did not require precision control. The amplitude of activity in the high-gamma band (HG, approx. 70-100 Hz) recorded at a single electrode over primary motor cortex was mapped to cursor velocity in the control dimension. In both subjects, we observed increases in HG activity near the controlling electrode in the pre-feedback task phase (two-sample t-test, $0.0012 < p < 0.0622$). In S1, we observed decreases in HG activity in pre-frontal cortex (PFC) and supplementary motor area (SMA) only when the precision requirement of the task was low and trial success was imminent ($0.0005 < p < 0.001$). These preliminary data suggest that, there exist neural correlates of both pre-trial and in-trial cognitive engagement corresponding to successful precision control of a BCI that could be leveraged in closed-loop BCI architectures to modify control parameters in real-time.

Caption:

Title: Performance improvements in fully-integrated small form-factor wireless neural interfaces

Authors: *L. RIETH[1], D. WARREN[2], A. SMITH[4], R. HARRISON[5], P. TATHIREDDY[3], X. XIE[3], H. OPPERMANN[6], G. CLARK[2], F. SOLZBACHER[3];
[1]Electrical and Computer Engin., Univ. of Utah, Salt lake city, UT; [2]Bioengineering, [3]Electrical and Computer Engin., Univ. of Utah, Salt Lake City, UT; [4]Univ. of Washington, Seattle, WA; [5]Intan Technologies, Los Angeles, CA; [6]Microintegration, Fraunhofer IZM, Berlin, Germany

Abstract: The Integrated Neural Interface Program (INIP) has continued to make significant progress on our fully-integrated wireless neural interface system in terms of device lifetime, telemetry performance, and performance of the ASIC to accurately detect neural signals. Significant in-vivo recordings will also be presented to demonstrate the overall efficacy of the system. We have previously reported the improved performance of the 9th (INI-R9) version of the wireless ASIC, which demonstrate improved spike detector stability, better telemetry reliability, robust command reception, and a 2-level spike detection system. This report presents

the in-vitro and in-vivo performance characterization of the fully integrated devices, that includes fully wireless powering of the device through the integrated coil, and wireless telemetry of the recorded signals.
The integrated system consisted of a modified Utah Electrode Array (UEA) designed to be flip-chip bonded with the INI-R9 ASIC, capacitors, and gold coil, and be the platform for the encapsulation. The INI-R9 ASIC was developed with a 0.35 µm CMOS process fabricated using the X-Fab process. The ASIC utilizes a frequency-shift keyed (FSK) telemetry radio operating in the 910 MHz ISM band, with an aggregate bandwidth of 345 kbps, to transmit the spike-detected and single full bandwidth data streams. The ASIC is powered and data is telemetered to the device through a 2.765 MHz carrier that is amplitude-shift keyed (ASK). The integrated 5.5-mm diameter gold coil has an inductance of ~25 µH, and received power from 25 mm Class-E driving coil. The system was encapsulated using novel atomic layer deposited alumina layer, in conjunction with the Parylene and silicone encapsulation that has been previously reported. Details of the performance of this encapsulation are reported in a separate poster (Xie et al.)
This ASIC includes a diagnostic register to detect errors in the received commands, and was used to assess the command reception reliability. The command reception performance depended on position of the driving coil, medium surrounding the devices, and the characteristics for the amplitude modulation utilizes. Typical conditions used a 15% signal modulation. The command reception reliability of >90% could be achieved for testing in air or in PBS solution under optimized conditions. We achieved a typical bit-error-rates of 10^{-3}, and could achieve < 10^{-4} under optimized conditions. The recording performance of these devices in a feline peripheral nerve will be collected and analyzed as part of this poster presentation.

Title: Assessing awareness after traumatic brain injury (TBI) using spatially-constrained independent component analysis (ScICA)

Authors: *D. GUPTA[1,2], G. SELIGER[3,4], G. FIORENZA[3], D. ZEITLIN[3], B. ZOLTAN[3], L. TENTEROMANO[3], T. M. VAUGHAN[1,3];
[1]Brain Computer Interfacing, Wadsworth Ctr., Albany, NY; [2]Albany Med. Col., Albany, NY; [3]Helen Hayes Hosp., West Haverstraw, NY; [4]Columbia Univ., New York, NY

Abstract: This study seeks to detect awareness in patients with a profound disorder of consciousness following traumatic brain injury. We are using an electroencephalography(EEG)-based brain computer interface (BCI) protocol to determine whether a spoken command produces an EEG response. The long-term goal is to determine the prognostic value of such an analysis and to evaluate BCI communication in these patients.
The patient is asked to imagine specific hand and feet movements while EEG is recorded from 32 locations. We assess correlations between the instruction and the amplitudes and scalp distributions of specific EEG rhythms.
EEG activity is assumed to reflect a finite set of separate independent CNS or artifactual sources (overlapping in space, frequency, and time). Spatial filters (e.g., common average reference (CAR), Laplacian) are often used to isolate these sources. The effectiveness of a given filter is affected by electrode number, source orientations, and spatial spread, and may vary across subjects.
We are applying spatially-constrained Independent Component Analysis (ScICA) to extract the underlying sources from the EEG. ScICA exploits prior knowledge (e.g., likely spatial or spectral characteristics of the sources). It imposes constraints on the model to guide the ICA solution toward the expected source. As used here, it relies heavily on expected spatial topography, and optimizes a penalty function to find sources that have the expected topographies.
We are analyzing data from 4 subjects 30-60 days after traumatic brain injury (JFK coma score ≤10). The ScICA algorithm has spatial constraints favoring smooth topographies centered at Cz (feet motor imagery), or at C3 or C4 (hand motor imagery). The coefficient of determination (R2) is calculated for specific 3-Hz frequency bands from 2-45 Hz. We compare R2 for ScICA, for CAR filtering, and for unfiltered (i.e., ear-referenced) EEG. Initial results suggest that ScICA may improve real-time detection of an EEG response in patients with traumatic brain injury who are otherwise unresponsive.

Title: Rotations of neural population state present in scalp EEG recordings during human movement

Authors: *K. NATHAN, H. AGASHE, J. L. CONTRERAS-VIDAL, Ph.D;
Univ. of Houston, Houston, TX

Abstract: A recent article by Churchland et al. (Nature 2012) proposed that motor commands may be represented in cortex by operating on a system in which the oscillation parameters (e.g. phase, amplitude) of the population response are functionally related to the behavioral and kinematic parameters. This dynamical model suggests that the neural responses might reflect the underlying dynamics of the system, and that previously believed tuning models are merely incidental effects. The new model also found robust rotational structure in the transformed principal components (termed the jPCs) of the population response in the motor cortex of nonhuman primates during movement, both rhythmic (as in walking) and non-rhythmic (during reaching). However, it has not been shown whether these oscillatory features are represented in human cortex, or whether the rotational structure can be obtained by means other than intra-cortical spike recordings. Here we present evidence of similar rotational structure in whole-scalp electroencephalography (EEG) recordings from humans during walking and reaching tasks. EEG data were previously recorded from healthy human subjects and subjects affected by chronic stroke performing various walking and reaching tasks, and were analyzed using the same methods outlined by Churchland et al. Plotting the top two jPCs against each other revealed continuous circular structure for walking, whose speed was correlated with the amplitude of the rotations; remarkably, this result was also evident albeit slightly distorted in the stroke subjects. The EEG recorded during reaching tasks also had the similar brief rotational structure as previously reported in primate studies. Studies involving EEG recordings have often been criticized for having insufficient information content, particularly for brain-machine interface applications, despite the great benefits of the signals being acquirable without invasive surgery. Showing that the parameters of the rotational structure generated from the dynamical model can be obtained non-invasively reaffirms the consistency of the model across different recording methods and species. Furthermore, the evidence of the structure within EEG supports the use of EEG as a source signal for decoding and BMI applications just as invasive recordings.

Title: Large field study of ultra-low cost BMI using intention decoding from eye movements for closed loop control

Authors: *W. W. ABBOTT[1], A. A. FAISAL[2];
[1]Bioengineering, [2]Bioengineering & Computing, Imperial Col. London, London, United Kingdom

Abstract: Developments in the field of brain machine interfaces (BMI) hold the hope to restore independence to patients with severe motor disabilities via neuroprosthetics. However, current technology is either highly invasive or suffers from long training times, low information transfer rates, high latencies and high clinical costs (Tonet et al., 2008, J. Neurosci. Methods). We propose a non-invasive and ultra-low cost alternative - intention decoding from 3D gaze signals (Abbott & Faisal, 2012, J. Neural Eng.). Eye movements provide a high frequency signal directly relevant for neuroprosthetic control and are retained by patients with serious motor deficiencies, paralysis and limb amputation (Kaminski et al., 2002, Ann. N. Y. Acad. Sci.; Kaminski et al. 1992, Ann. Neurol.). Our system allows read-out bit rates of 43 bit s-1, well beyond conventional BMIs (EEG 1.63 bit s-1, MEA 3.3 bit s-1, EMG 2.66 bit s-1 , making our task-level BMI suitable for closed loop control of neuroprosthetics (Tonet et al., 2008, J. Neurosci. Methods; Abbott & Faisal, 2012, J. Neural Eng.). In the present study we performed a large-scale field study (n=867) to determine if naïve subjects could use our BMI to compete in an arcade video game (Pong - computer tennis). Two arcade cabinets with our embedded BMI system were built that allowed members of the public to briefly calibrate and then to play a game of pong (first to 5 points), controlling the paddle using just their eyes. Their opponent was either an AI computer player or another human player using a conventional control pad (up-down) input. During game play, the eye position, gaze estimation, control position and game state were recorded. Following a 30 second calibration, games lasted 76±34 seconds and subjects successfully returned 6.5±6.2 shots against their opponent (mean ± standard deviation). The average score when the subjects lost was 0.7±1.1 compared to the opponent average losing score of 2.1±1.4. Surprisingly, 20% of players could actually beat their opponent, despite total naivety to gaze-based interfaces before the trial, showing the intuitive nature of our system's control. Our study demonstrates the straightforward applicability of using the eyes as a BMI compared to other non-invasive methods that require significant training such as EEG and EMG. We also propose the game pong as a benchmark for the BMI field as it is a well-known easily accessible video game, which unlike

many BMI demonstrations, requires real-time closed loop control, vital for subject acceptance in neuroprosthetic control.

Title: Brain-Muscle-Computer Interfaces: The effect of audio feedback

Authors: *I.-M. SKAVHAUG, C. DAO, B. VERNON, S. S. JOSHI;
Mechanical and Aerospace Engin., Univ. of California, Davis, Davis, CA

Abstract: We are developing a novel Brain-Computer Interface that we call a Brain-Muscle-Computer Interface (BMCI), in which participants learn to control a cursor on a computer screen by manipulating the surface electromyography (sEMG) at one single muscle site (i.e. two control channels achieved from one recorded signal). Two-dimensional control was achieved by simultaneously adjusting the partial power in two separate frequency bands. Through the aid of visual feedback of cursor position, participants demonstrated a gradual improvement in target-hitting accuracy throughout four one hour-long testing sessions. In the current pilot study we investigated whether participants would be able to perform the cursor-to-target task when the feedback is auditory rather than visual. Auditory feedback was presented in the form of two tones of different auditory frequencies, one to the right ear and one to the left ear. The tones indicated to the participants the proximity of the invisible mouse cursor to the target's x- and y coordinates, respectively, by sounding at increasing temporal rates the closer the cursor got to the target in each dimension. This means that the participants received two sets of one-dimensional feedback that they had to integrate in order to hit the targets on the screen. The preliminary results show that participants in the audio group could learn to control the BMCI following four testing sessions, although more work must be carried out in order to establish whether the performance is comparable to that of groups receiving visual feedback and a combination of auditory and visual feedback. Our observations thus far are promising as there are situations in

which visual feedback to BMCI users is not convenient or even possible - for example in cases where the user is visually challenged.

Title: Activation of a Gq-coupled membrane estrogen receptor rapidly attenuates alpha 2-adenoceptor-induced antinociception via an ERK I/II-dependent, non-genomic mechanism

Authors: *D. M. HECKARD[1], S. NAG[2], S. S. MOKHA[2];
[2]Neurosci. and Pharmacol., [1]Meharry Med. Col., Nashville, TN

Abstract: Sex differences in pain and analgesia are known, however, underlying mechanisms still remain elusive. We reported estrogen-induced attenuation of α_2-adrenoceptor-mediated antinociception, however, selective contribution of membrane estrogen receptors (mER) and mER-initiated non-genomic signaling mechanisms remains unknown. Hence, we selectively targeted spinal mERs in ovariectomized female rats using E2BSA (membrane impermeable estradiol), PPT, DPN, G1 and STX, selective agonists at ERα, β, G-protein coupled receptor 30 (GPR30), and Gq-coupled mER (Gq-mER), respectively. The effect of mER activation on clonidine (an α_2-adrenoceptor agonist)-induced antinociception was determined using nociceptive tail flick test. Tail flick latencies (TFL) were quickly assessed and expectedly, significantly increased by intrathecal (i.t.) clonidine. While i.t. PPT, DPN, and G1 failed to significantly alter, E2BSA or STX rapidly and dose-dependently attenuated clonidine-induced increase in TFL. This effect was reversible by, ICI 182,780, an estrogen receptor antagonist. Inhibition of *de novo* protein synthesis using anisomycin failed to alter the effect of E2BSA or STX suggesting unlikely contribution of genomic mechanisms. Immunoblotting of spinal tissue revealed mER activation-induced increased phosphorylated extracellular signal regulated kinase (ERK) I/II but not protein kinase A (PKA) or C(PKC) levels. Finally, *in vivo* inhibition of ERK I/II with U0126 blocked the effect of STX and restored clonidine antinociception. We provide strong evidence that Gq-mER may solely mediate estrogen-induced attenuation of clonidine

antinociception via a rapid, ERK I/II-dependent, non-genomic mechanism. Gq-mER blockade strategies may improve analgesia in females. Moreover, widespread distribution of α_2-adrenoceptor and mERs implicate our novel findings to cognitive, cardiovascular, and reproductive functions.

Title: Human electrocorticography based stimulation

Authors: D. K. SU[1], J. D. WANDER[2], L. A. JOHNSON[1], D. SARMA[2], *K. E. WEAVER[3], J. D. OLSON[4], E. E. FETZ[5], J. G. OJEMANN[1];
[1]Neurosurg., [2]Bioengineering, [3]Radiology, [4]Rehabil. Med., [5]Physiol. and Biophysics, Univ. of Washington, SEATTLE, WA

Abstract: Introduction:
Numerous experiments using non-invasive cortical stimulation have demonstrated transient increases in motor cortical plasticity and improved functional rehabilitation in humans. We examined the feasibility and the effects of performing repetitive human electrocorticography (ECoG) based stimulation in an activity-dependent manner.
Methods:
4 epileptic patients undergoing subdural ECoG grid implants were enrolled in this study. Electrical stimuli were triggered by spontaneous movement leading to upper extremity electromyographic (EMG) activity, or increases in ECoG high gamma (HG) power overlying motor cortex, exclusively. An FDA-approved EMG stimulator was used to provide 5000 stimuli over 30 minutes; afterwards, ECoG recordings were taken while the subject performed cued motor tasks. No subjects experienced any adverse events.
Results:
A consistent decrease in event-related high-gamma activity after conditioning was seen. One subject, who had received 2 sessions of 5000 stimuli, also demonstrated a broadband increase in

HG power and a decrease in low frequency band (LFB) power during the resting state. These spectral changes were more apparent at sites closer to the stimulated electrodes, and lasted for at least 30 minutes. No significant changes in resting motor thresholds or correlation values between stimulation sites and the rest of the grid were noted. Latencies calculated for EMG-trigger to stimulation pulse delivery were normally distributed with a mean of 31-32ms.
Conclusions:
These surprising results suggest that, with this stimulation paradigm, repetitive electrical stimulation caused blunting of the normal HG response seen during motor movement. In the subject with the sustained broadband resting state changes, the prolonged effects perhaps suggest physiologic phenomena such as changes in neuronal resistivities or local neurotransmitter levels, or potentially reflect local charge build-up on the ECoG grid. This experiment demonstrates that invasive activity-driven human cortical stimulation is safe, feasible to accomplish within the window for spike timing dependent plasticity, and underlines the need for further investigation.

Title: Prelocalization of a bipolar electrode using fMRI enables a minimally invasive ECoG-based Brain Computer Interface

Authors: *N. F. RAMSEY, M. BLEICHNER, A. TORRES VALDERRAMA, Z. FREUDENBURG, B. VERWEIJ, M. VANSTEENSEL, E. AARNOUTSE;
Dept Neurol. & Neurosurg., Rudolf Magnus Institute, Univ. of Utrecht, Utrecht, Netherlands

Abstract: Invasive Brain-Computer Interface (BCI) technology promises many advantages over non-invasive BCI, but general acceptance is dependent on a minimal invasive approach. We envision a minimally invasive BCI with one surface electrode recording ECoG. Two major

problems arise to implant such a BCI: 1) how to non-invasively localize the areas where electrodes are placed and 2) where to place a reference electrode. We have solved these problems by using an fMRI protocol to localize placement of a bipolar electrode.
Eight patients with intractable epilepsy who were scheduled for surgery preoperatively performed a calculation task while 3T functional MRI images were collected. fMRI data was analyzed with SPM8 using GLM analysis. After implantation of 80-120 surface electrodes, all patients performed a BCI cursor task, during which they used mental arithmetic to control the cursor. The feature selected for control was high gamma power (65-95 Hz).
Six of the patients had successful BCI control (> 85%) using a unipolar electrode over the dorsolateral prefrontal cortex (DLPFC), re-referenced to the common average of all implanted electrodes. We analyzed retrospectively whether we are able to select a bipolar electrode (i.e. an electrode pair with a maximum inter-electrode distance of a few centimeters) the signal of which would give comparable results to a unipolar electrode referenced to the common average in terms of their discrimination between mental calculation and resting brain activity (r-squared measurement).
The coordinates of the strongest activating voxels within a predefined Region of Interest (DLPFC) were identified. Bipolar electrodes closely matching the fMRI coordinates were selected. We found significant differences in high gamma power between mental arithmetic and rest using the selected bipolar electrodes with inter-electrode distances of 1-3 cm for all six patients.
The preoperative localization of a suitable bipolar electrode was validated in the remaining two subjects. The coordinates of a bipolar electrode were identified before BCI experiments by defining a line of 4 cm through the fMRI foci with strongest activation. The selected bipolar electrode gave a high performance on the BCI cursor control task in both patients (70-94% and 92% respectively.). Post hoc comparison between uni- and bipolar signals revealed that the pair chosen yielded the highest r-square during the task of all tested pairs and for all unipolar signals for those electrodes.
In conclusion, fMRI prelocalization of bipolar electrodes yields high performance in BCI control. This method paves the way for minimally invasive BCI implants.

Title: Acceleration of TRH and TRH-like peptide release in rat brain and peripheral tissues during proestrus/estrus

Authors: A. SATTIN, *A. E. PEKARY;
Res., VA Greater Los Angeles Hlthcare Syst, LOS ANGELES, CA

Abstract: The two major estrogen receptors, ERα and ERβ, mediate reproductive, metabolic, behavioral, neuroprotective, cognitive, neuroendocrine, immunomodulatory, and neurodevelopmental functions of estrogenic steroids. ERβ mediates more of the cognitive and neuroprotective effects of estrogens and less of the more familiar reproductive, metabolic and secondary sexual responses mediated by ERα. ERβ-selective agonists for the treatment of major depression, PTSD, and other anxiety disorders are the focus of pharmacologic development and clinical testing. Women are at greater risk for these disorders. Estradiol and its metabolites contribute to the neuroprotective effects of this steroid class, particularly in men, due to local conversion of testosterone to estradiol in key brain regions which are predisposed to neurodegenerative diseases. We have used young adult female Sprague-Dawley rats to assess the role of TRH and TRH-like peptides, with the general structure pGlu-X-Pro-NH_2 where "X" can be any amino acid residue, as mediators of the neurobiochemical effects of estradiol. TRH and TRH-like peptides have neuroprotective, antidepressant, anti-epileptic, and analeptic properties. The levels of TRH and TRH-like peptides during proestrus and/or estrus in the 12 brain regions analyzed were significantly decreased 87 times but increased only 8 times when compared to the corresponding levels during diestrus day 1 or 2. These changes, listed by brain region in the order of decreasing number of significant decreases (↓) and/or increases (↑) , were: medulla oblongata (15↓), striatum (14↓), hypothalamus (13↓), entorhinal cortex (9↓,4↑), cerebellum (9↓,2↑), amygdala (10↓), hippocampus (8↓), posterior cingulate (6↓), nucleus accumbens (2↓,1↑), frontal cortex (1↓,1↑), piriform cortex (0), and anterior cingulate (0). In peripheral tissues peptide decreases (accelerated release) during proestrus and estrus were observed 35 times while increases, all within the pancreas, occurred 7 times: ovaries (15↓), adrenals (11↓), uterus (8↓), and pancreas (1↓,7↑). Fluctuations in the levels of TRH and TRH-like peptides in brain and peripheral tissues observed during the female estrous cycle are most likely the combined effects of altered posttranslational processing of precursor peptides and their release/clearance by the excitatory glutamatergic nerves of the central and peripheral nervous system. We conclude that these peptides may be downstream mediators of some of the therapeutic effects of estrogen.

Title: The suprachiasmatic nucleus regulates the ovarian steroid secretion and the ovulatory response in an asymmetric way

Authors: D. A. RAMIREZ, A. GONZÁLEZ, H. JIMÉNEZ, E. VIEYRA, L. MORALES, *R. DOMINGUEZ;
UIBR, FES Zaragoza UNAM, Mexico City DF, Mexico

Abstract: The disruption of the circadian system in the Hypothalamus-Pituitary-Ovaries axis may be a factor affecting fertility. The suprachiasmatic nucleus (SCN) of the hypothalamus represents the circadian pacemaker in mammals, participating in the regulation of preovulatory release of gonadotropins releasing hormone (GnRH), since neurons located in preoptic area (that contains the largest concentrations of GnRH cell bodies in the rat brain) are innerved by efferent projections from the SCN. In rats, the bilateral lesion of the SCN results in lower progesterone and estradiol serum levels, disruption of LH timing secretion and ovulation. In hamsters exposed to constant light, the asymmetric activation of the GnRH neurons of the preoptic area correlates with the asymmetric activity of the SCN. Such results support the idea that the activity of the oscillators in each SCN can be different. Present study analyzes the effects of the unilateral lesion of the SCN at the day of proestrus on steroid ovarian secretion and ovulation response. For this purpose, cyclic female rats of the CII-ZV strain at 11:00 hours on proestrus were subjected or not (control) to a left (SCN-L) or right (SCN-R) lesion of the SCN, left (Sham-L) or right (Sham-R) sham surgery. The animals were sacrificed one or 24 hours after surgery. At autopsy, we assessed progesterona and estradiol serum levels by RIA. Spontaneous ovulation was analyzed in those animals sacrificed 24 hours after surgery. Sham-surgery did not modify ovulation, but results in changes in the ovarian hormones secretion, which depends on the side on which the electrode is inserted, as well as post-surgery period. The ovulation rate by rats with lesion of the SCN-R was lower than in Sham-R (2/5 vs. 5/5) as well as the number of ova shed 2.5±0.5 vs. 5.7±0.3, $p<0.05$). One hour after the lesion of the SCN-R, the progesterona levels were higher than Sham-R (39.4±3.6 *vs.* 28.5±2.2 ng/ml, $p<0.05$), while it was lower in rats with SCN-L 24 hours post-surgery (8.9±1.2 *vs.* 14.1±1.4 ng/ml, $p<0.05$). The estradiol levels were higher in the animals with lesion SCN-R than sham-R one hour after surgery (185.0±34.6 *vs.* 117.8±9.5 pg/ml, $p<0.05$). Present results suggest that the SCN-R modulates in a stimulatory

way the ovulatory process by the ipsilateral ovary. It is possible that the increase in estradiol levels can be the cause of a possible decrease in LH levels due to the inhibitory effect of estradiol, and therefore a decrease in ovulation. In conclusion, the activity of SCN-R regulates ovarian functions at 11:00 hours of proestrus day, whereas the SCN-L plays such regulation at other hours of the day.

Title: Ovulatory response and monoamines concentration in the celiac-superior mesenteric ganglia and ovaries in rats with polycystic ovarian syndrome

Authors: R. LINARES[1], G. ROSAS[1], M. I. NAVARRETE[1], M. E. AYALA[1], *C. MORAN[2], R. DOMÍNGUEZ[1], L. MORALES[1];
[1]BRRU, FES Zaragoza-UNAM, Mexico City, Mexico; [2]Inst. de Ciencias, Univ. Autonoma de Puebla, Puebla, Mexico

Abstract: The polycystic ovary syndrome (PCOS) is the most common endocrine abnormality in women during their reproductive years. It is characterized by ovulatory failure, amenorrhea, increased plasma androgen concentrations, and lower plasma capacity for binding sex hormone and, higher concentrations of estrogens. The PCOS etiology has been associated with disorders at the hypothalamic-pituitary level. In the last decades, it has been shown that the development of the syndrome also involves the sympathetic nervous system. The ovaries of animals treated with estradiol valerate (EV) increased noradrenergic tone which depends on the integrity of the superior ovarian nerve (SON). In rats with PCOS induced by EV injection or cold stress exposure the tyrosine hydroxylase activity and noradrenaline (NA) levels in the celiac ganglion (CG) were higher than in control. The unilateral or bilateral section of the vagus nerve (VN) restores ovulation in rats with EV induced PCOS. The VN has synaptic connections with the neurons originating the SON at the CG. To test the hypothesis that there is a relationship

between the catecholaminergic and serotonergic system level of the CG and the ovaries in PCOS rats, we assessed the concentration of NA, dopamine (DA), serotonin (5-HT) and their metabolites in the CG and ovary of rats with PCOS, induced by EV or stress. 10 day-old female rats of the CIIZ-V strain were injected with corn oil (Vh) or 2 mg of EV. The rats exposure to cold stress were placed from 24 days of age in a room at 4°C for 3 h/d for 8 wk (monday to friday) until sacrifice at day 80 of age. The VE-treated rats did not ovulate (EV 0/11 vs. Vh 12/12). NA levels in the CG of EV injected rats was higher than Vh (7.3±1.5 ng/mg vs. 3.7±0.8 p <0.05). The monoamines levels in the ovaries were similar to control (1.4±0.15 ng/mg vs. 1.4±0.14 n.s). Ovulation rate was not modified by cold stress (stress 9/10 vs. control 9/9); 5-HT level in the CG was higher than in control group (7.4±1.2 ng/mg vs. 1.8±0.4 p <0.05), while the monoamine levels in the ovary were not changed (0.5±0.15 ng/mg vs. 0.4±0.1 n.s). Present results suggest that the difference in the ovulatory and monoaminergic response in the two models of experimental PCOS, results from different mechanisms triggering the development of the disease, which depends on the induction way.

Title: The anatomy of celiac ganglion related with the ovaries in female rats

Authors: *C. F. PASTELIN[1], Y. TÉLLEZ[1], M. MUÑOZ[1], N. ROSAS[2], A. HANDAL[1], Y. CRUZ[3], C. MORÁN[1];
[1]Dept. de Biología y Toxicología de la Reproducción, [2]Posgrado en Ciencias Químicas, Facultad de Ciencias Químicas-Instituto de Ciencias, Univ. Autónoma de Puebla, Puebla, Mexico; [3]Ctr. Tlaxcala de Biología de la Conducta, Univ. Autónoma de Tlaxcala, Tlaxcala, Mexico

Abstract: The main component of the autonomic innervation of abdominal organs is provided by the celiac ganglion (CG). The aim of this study was to describe in adult female rats the anatomical organization of the CG and to determine its targets. 12 urethane anesthetized adult animals were used. CG and its branches were dissected and digital photographs were taken. Using a stereoscopic microscope, the gross features of the CG and the distribution of its branches

were determined. Neurons in small plexus were determined by histological techniques. The results showed that the CG is bilateral. Right and left celiac ganglia are located between the celiac artery and the superior mesenteric artery. The right CG was found in two shapes; pear shape (67%) and banana shape (33%). Independently of the shape, seven branches emerged from this ganglion. One branch ran ventrally to the aorta and joined the suprarrenal ganglion. Three branches ran medially, between the superior mesenteric artery and the celiac artery, one of these branches innervated the liver and the stomach, the other two intestinal viscera. Another branch, the thickest one, ran above the celiac artery and connected to the left CG. Other branch ran anterior to the aortic artery and innervated the ipsilateral kidney, and another one innervated lymph nodes. No branch reached the ovary. The left CG had banana shape (100%). From a ventral view five branches were observed. The bigger one ran caudally to the inferior vena cava, behind the left renal vein, and reached a small nervous plexus attached to the inferior vena cava. From this plexus emerged the innervation of the ovaries. Our findings show that in female rats the CG is asymmetric and only the left CG innervates the ovaries. The posganglionic neurons controlling the ovarian function could be in the CG or in the plexus attached to the inferior vena cava.

Abstract: By inhibiting pituitary prolactin release, dopamine neurons in the hypothalamic arcuate nucleus play an important role in lactation. Met-enkephalin (mENK), an opioid neuropeptide synthesized both in the arcuate nucleus and other loci in the brain, activates both

mu and delta opioid receptors. Although previous studies suggested that delta opioid receptor agonists influence arcuate dopamine neurons, no direct evidence has been reported. Here, using whole-cell patch clamp recording in slices of the mouse hypothalamus, we studied the effects of mENK on the activity of arcuate dopamine neurons. First, we recorded dopamine neuron activity in current clamp and found regular burst firing with a frequency of 0.07 ± 0.01 Hz (n=9) with each burst consisting of 5-50 action potentials (mean burst frequency of 7.1± 1.3 Hz for each burst), similar to arcuate dopamine neurons in rats (Lyons et al,2010). mENK (3 μM) reduced the burst frequency to 0.003 ± 0.003 Hz (n=9; $p<0.01$) and hyperpolarized the resting membrane potential from -58 ± 2.0 mV to -71 ± 2.2 mV (n=9; $p<0.01$). In the presence of TTX in voltage clamp, mENK induced an outward current of 17.5 ± 2.3 pA (n=7) at a holding potential of -60 mV suggesting direct postsynaptic inhibition. We also studied the actions of mENK on synaptic currents. mENK (3 μM) decreased spontaneous EPSC frequency from 3.2 ± 0.7 Hz to 1.7 ± 0.5 Hz (54.0 ± 6.0 % of control, n=8; $p<0.01$) and decreased IPSC frequency from 3.4 ±1.2 Hz to 0.4 ± 0.2 Hz (28.0 ± 5.0 % of control, n=5; $p<0.01$). Taken together, our results suggest that both direct inhibition and indirect modulation of synaptic transmission are involved in mENK regulation of arcuate dopamine neuron activity.

Title: The muscarinic receptor blockade of the right suprachiasmatic nucleus decreases of the ovulatory response of the left ovary

Authors: E. VIEYRA[1], D. A. RAMIREZ[1], *S. E. CRUZ-MORALES[2], R. DOMÍNGUEZ[1]; [1]BRRU, FES Zaragoza-UNAM, Mexico City, Mexico; [2]Psychopharmacol. Div. de Investigación y Posgrado, UIICSE, FES-Iztacala UNAM México, Edo. Mexico, Mexico

Abstract: The neural mechanisms regulating ovulation are under circadian control in many species. In mammals, a master pacemaker located in the suprachiasmatic nucleus (SCN) of the hypothalamus orchestrates circadian timing coordinating reproductively relevant neuroendocrine

events necessary to maximize reproductive success. The gonadotropin-releasing hormone (GnRH) system contains the same circadian clock "machinery" necessary to generate autonomous cellular oscillations, and these subordinate clocks likely mediate daily changes in sensitivity to SCN communication. The SCN receives information from various regions of the CNS, some of which are cholinergic. The bilateral lesions of the SCN abolish estrous cyclicity, the preovulatory LH surge and ovulation. This study was designed to analyze the effects of muscarinic receptor blockade with atropine (ATR) in the Left SCN or Right SCN, at 9:00 of diestrus 1 on ovulation and serum concentrations of progesterone (P_4). Adult female rats of the CII-ZV strain at 9:00 hours at the diestrous 1 were micro-injected with 0.5 µl of saline (Vh) or 62.5 ng of ATR, into the left SCN or right SCN. The animals were sacrificed in the morning in the expected day of estrous. The micro-injection of ATR in the Right SCN resulted in high P_4 level than Vh injected ones (ATR 8.53±1.3 vs. Vh 5.05±1.0, $p<0.05$). The ATR in the Left SCN did not modify P_4 levels. The ovulation rate was not modified by ATR microinjection, but the number of ova shed by the left ovary or rats with ATR microinjection into the Right SCN was lower than Vh injected animals (ATR 3.3±0.7 vs. Vh 6.0±0.8 $p<0.05$). Present results suggest that at 09:00 of diestrous 1 day the stimulation of muscarinic receptors in the right SCN, originates a signal to a neuronal pathway modulating the multisinaptic ovulation regulation on the contralateral ovary. It is possible that such information participates in the regulation of follicular growth and differentiation.

Title: The acute steroidogenic response of the ovaries to the vasoactive intestinal peptide on proestrus day is modulated by the superior ovarian nerve

Authors: G. ROSAS[1], M. I. RAMIREZ[1], R. LINARES[1], R. CHAVIRA[2], *M. MARTINEZ-GOMEZ[3], R. DOMÍNGUEZ[1], L. MORALES[1];
[1]BRRU, FES Zaragoza-UNAM, Mexico City, Mexico; [2]Biol. of Reproduction, Inst. Nacional de

Ciencias Médicas y Nutrición “Salvador Zubirán”., Mexico City, Mexico; [3]Ctr. Tlaxcala de Biología de la Conducta, Univ. Autónoma De Tlaxcala, Tlaxcala, Mexico

Abstract: The superior ovarian nerve (SON) provides catecholaminergic and peptidergic innervation to the ovaries. *In vitro*, the vasoactive intestinal peptide (VIP) stimulates progesterone (P4), testosterone (T) and estradiol (E2) release from rat granulosa cells and whole ovaries. 24 hours after the VIP injection into the ovarian bursa (OB) of diestrus-2 rats, the E2 secretion by the left ovary was higher than by the right one. On estrus the VIPergic stimulation of the left ovary resulted in lower T levels. The aim of present study was to analyze the acute effects of OB VIP injection at proestrus on P4, T and E2 secretion in untouched rats and with uni or bilateral section of the SON. Sixty day-old female rats of the CII-ZV strain, were subjected at 10.30 h of proestrus to the unilateral or bilateral injection of 20 µl VIP (10^{-6}M) or saline solution (SS) in the OB. Other rats were submitted to the unilateral or bilateral section of the SON [left (L-SON), right (R-SON) or bilateral (B-SON)] followed by the injection of VIP into the denervated or innervated ovaries. Rats were sacrificed 60 minutes after treatment. Steroid hormones serum levels were measured by RIA. Compared to the control group, the VIPergic stimulation of the left ovary increased T (177.4±15.8 *vs.* 126.1±14.4 pg/ml; $p<0.05$) and decreased E2 levels (104.2±8.2 vs. 173.5±15.7 pg/ml, $p<0.05$). The injection of VIP into the right ovary resulted in a lower T levels (130.8±15.2 vs. 204.6±15.3 ng/ml; $p<0.05$). The injection of VIP into the ovaries of rats with L-SON resulted in lower P4 levels than animals injected with SS (VIP left ovary: 22.6±1.9 *vs.* 34.0±2.6 ng/ml; VIP right ovary: 26.1±2.1 *vs.* 35.1±2.2 ng/ml; $p<0.05$) and higher E2 levels (VIP left ovary: 288.6±21.5 *vs.* 130.5±8.8 pg/ml; VIP right ovary: 142.2±13.2 *vs.* 97.2±10.8 pg/ml; $p<0.05$). The VIPergic stimulation of the denervated ovary of rats with R-SON resulted in an increased P4 levels (33.1±2.5 *vs.* 24.9±1.7 ng/ml; $p<0.05$). The injection of VIP into the both ovaries of rats with B-SON resulted in higher P4 and T levels (30.2±2.9 *vs.* 21.0±1.8 ng/ml; 286.2±36.7 *vs.* 171.7±15.2 pg/ml; $p<0.05$, respectively) and lower E2 levels (99.9±6.9 *vs.* 174.3±17.3 pg/ml; $p<0.05$). Present results suggest that in the proestrus day the ovaries have different sensitivity to VIP which is modulated by the SON. Also, support the idea of a neural communication between the ovaries through the SON.

Title: Comparative distribution of GAD67 mRNA expression in the forebrain of prepubertal and adult female mice

Authors: *D. RATRA, C. F. ELIAS;
Mol. Integrative Physiol., Univ. of Michigan, Ann Arbor, MI

Abstract: GABA release on to GnRH presynaptic terminals within the median eminence prevents an increase in amplitude and frequency of gonadotropin pulsatile release; the latter being required for puberty. GABA, however, depolarizes GnRH cells in pre and peri pubertal female mice, and with additional evidence in the literature supporting GABA's depolarizing effects on GnRH cells, GABA assumes a more complicated regulatory role on pubertal development. The first order neuronal networks from which this GABA regulation arises is not entirely known and in an attempt to narrow down candidate neuronal populations involved, *in situ* hybridization was used to compare expression of Glutamate Decarboxylase (GAD67) before and after puberty. GAD67 is a 67kd enzyme required for the biosynthesis of GABA from Glutamate and is a marker for GABAergic neurons. This comparison would likely reveal variable expression of GAD67 unique to the developmental age of the sample; supporting findings of longitudinal differences in GABA concentrations within the stalk of the median eminence of Rhesus monkeys before and during puberty. In addition, the revealed variable expression would reside within cell populations possibly involved in regulating GnRH activity during puberty. In our study, whole-brain series from two groups of female C57BL/6J mice were used; a group of pre-pubertal females aged 20-24days with absent vaginal opening and a group of diestrous females aged approximately 60 days with observed normal cyclicity. These series were exposed to ^{35}S radiolabeled cRNA probes for GAD67. GAD67 hybridization between both groups showed considerable similarity throughout the cortex, striatum and thalamus. Within the hypothalamus however several differences were identified. The anterodorsal pre-optic area from the diestrous series contained a bright hybridization pattern absent in pre-pubertal tissue. The suprachiasmatic nuclei and the adjacent anterior hypothalamic area from the pre-pubertal series showed brighter hybridization overall compared to diestrous tissue. Lastly, the dorsomedial nucleus from the pre-pubertal series showed an increased area of hybridization compared to diestrous tissue. These results confirm variable longitudinal GAD67 expression within the hypothalamus of developing female mice and have identified GABAergic cell populations possibly involved in the regulation of GnRH activity during puberty.

Title: Gonadotropin-releasing hormone induces dentin matrix protein 1 in adult rat female pituitary glands

Authors: *I. BJELOBABA[1], M. KUCKA[1], S. J. H. CLOKIE[2], D. C. KLEIN[2], S. S. STOJILKOVIC[1];
[1]Section on Cell. Signaling, [2]Section on Neuroendocrinology, Natl. Inst. of Child Hlth. and Human Develop., Bethesda, MD

Abstract: Hypothalamic gonadotropin-releasing hormone (GnRH) is the primary regulator of reproduction in vertebrates, acting via the G protein-coupled GnRH receptor (GnRHR) expressed in pituitary gonadotrophs to control synthesis and release of gonadotropins. Using next generation sequencing, we characterized the GnRHR-regulated gene network in pituitary cells. This revealed 83 candidate genes that were up- or down-regulated by GnRH. These include genes encoding intracellular proteins involved in signaling and cytoskeleton functions, plasma membrane proteins controlling ion fluxes, and extracellular proteins acting as agonists for numerous receptors. Most notably, GnRH treatment induced a ~ 600-fold increase in mRNA expression of dentin matrix protein-1 (DMP1), one of five members of the small integrin-binding ligand N-linked glycoprotein gene family. This response was seen in cycling female pituitary cells and was 20-fold smaller in pituitary cells from males. These and related studies suggested that sex-specific DMP1 response to GnRH is established during the peripubertal period. *In vivo* studies further indicated that pituitary DMP1-mRNA is elevated during late proestrus, suggesting to us that GnRH-induced ovulation and induction of *DMP1* are synchronized and perhaps functionally related. The presence of DMP1 protein in gonadotrophs was confirmed by dual labeling immunohistochemistry. *In vitro* studies further confirmed that DMP1-mRNA expression is mediated by the GnRHR, as indicated by effects of a GnRHR antagonist and that it is not elicited by other hypothalamic releasing factors or other known gonadotroph agonists. Cell signaling studies revealed that GnRH-induction of *DMP1* is mediated by the protein kinase C pathway and reflects opposing roles of ERK1/2 and p38 MAPK. These results open a new line of research on the GnRHR-regulated network. The evidence that DMP1 production in female rat gonadotrophs is controlled by the hypothalamus through the GnRHR signaling pathway raises intriguing questions about the intrapituitary and downstream effects of DMP1 and possible roles in reproductive function.

Title: Estrogen and food state modulate leptin action on the nitrergic system

Authors: *B. BORGES, C. R. FRANCI;
Physiol., Univ. of Sao Paulo (FMRP), Ribeirão Preto, Brazil

Abstract: It is known that leptin acts on the reproductive axis, but gonadotropin-releasing hormone (GnRH) neurons do not express leptin receptor. Nitric oxide (NO) has been suggested as a possible mediator of this action of the leptin. Previous data from our laboratory showed that leptin acts directly on neurons that express neuronal nitric oxide synthase (nNOS) in some brain areas related to the control of reproductive axis. Moreover, estrogen may modulate leptin action and nitrergic system. The aim of this work was verify if estrogen and/or fasting modulate the leptin action on cells that express nNOS in the medial preoptic area (MPOA) and in hypothalamic nuclei: arcuate (ARC), ventromedial (VMH), lateral (LH), dorsomedial dorsal part (dDMH), dorsomedial ventral part (vDMH) and premammillary ventral (PMV). Methods:Wistar female rats were ovariectomized and received a cannula in the lateral ventricle. After two weeks, they were treated with estrogen (10μg) or oil (0.1ml) for three days before the experiment day. One group of animal was subjected to the fasting during 48h before experiments. In the day of experiment animals received leptin i.c.v. (3μg) or saline (control) and after 30 minutes they were perfused to remove the brain for immunohistochemistry of nNOS and phosphorylated signal transducer and activator of transcription (pSTAT3). Results: Estrogen increased the number of nNOS immunorreactive (nNOS-ir) cells in the MPOA, LH and vDMH in fed-, but not fasted-control animals. Leptin increased the nNOS-ir cells in the VMH and PMV in fed- and fasted-control animals treated with estrogen, and in the MPOA and vDMH only in fasted-animals treated with estrogen. Leptin increased pSTAT3-ir in all areas studied in both fed and fasted. Moreover, the interaction of estrogen and fasting potentiate the increase of pSTAT3-ir in the MPOA, ARC, VMH, dDMH, vDMH and PMV. Leptin increased the co-expression of nNOS and pSTAT3 in all hypothalamic regions studied in fasted-animals treated with either estrogen or oil.

However, in the MPOA this increase only occurred in fasted animals treated with estrogen. In fed animals treated with estrogen, leptin increased co-expression of nNOS and pSTAT3 only in the VMH, dDMH, vDMH and PMV. Conclusion: Our data suggest an interaction between estrogen and leptin to modulate the nitrergic system in the MPOA, vDMH, VMH and PMV in fasted animals and only in the VMH and PMV in fed animals. Morever, in fasted animals, estrogen potentiates leptin action in all studied areas, except LH. This potentiated action was co-localized in nNOS-ir cells mainly in the MPOA, DMH and PMV.

Title: Identification and selective stimulation of hypothalamic corticotropin releasing hormone containing neurons expressing light sensitive channelrhodopsin-2

Authors: *S. W. HARDEN, E. G. KRAUSE, C. J. FRAZIER;
Pharmacodynamics, Univ. of Florida, Gainesville, FL

Abstract: Corticotropin-releasing hormone (CRH)-containing neurons control activation of the hypothalamic-pituitary-adrenal axis as well as the expression of anxiety-like behavior, and consequently are heavily implicated in the onset of stress-related disorders. Despite the important role of CRH containing neurons in the stress response, little is known about their intrinsic properties or connections. In the acute slice preparation, reliable identification of CRH neurons has been complicated by the heterogeneity of neuronal phenotypes within brain nuclei expressing CRH neurons. The broad objective of this study is to validate and test a novel reporter mouse line in which the CRH gene drives expression of the red fluorescent protein, dTomato, conjugated to channelrhodopsin-2 (ChR2). Specific goals are to use of dTomato fluorescence to identify and record from CRH positive neurons, and to selectively depolarize CRH positive neurons with light to induce neurotransmitter release. CRH neurons containing ChR2 were identified in brain slices using epifluorescence microscopy. A custom built TTL controlled LED stimulator was used to activate ChR2 with a variety of light pulses and trains. Whole-cell patch

clamp recordings were employed to characterize the intrinsic properties of CRH positive and CRH negative neurons, and to quantify responses to optical stimulation. Somatic recordings of CRH neurons in current-clamp mode revealed action potentials elicited by rapid pulses of blue light. Light-induced currents in voltage-clamp mode were quantified with respect to intensity and pulse length. Light-induced presynaptic stimulation and release of neurotransmitter was assessed by bath application of glutamate receptor antagonists. CRH / ChR2 positive neurons are able to be reliably identified for physiological studies in the acute slice preparation. LED-based activation of ChR2 is appropriate and effective for depolarizing these neurons in the hypothalamus and promoting presynaptic neurotransmitter release in the amygdala. Success in these objectives indicates a new ability to reliably identify and selectively drive CRH positive neurons in brain circuits mediating stress responding. This approach may allow more detailed and mechanistic studies on the role of CRH neurons in the stress response.

Title: Remote stress-free peripheral administration of an endocannabinoid receptor antagonist suggests both central and peripheral actions regulating hypothalamic-pituitary-adrenal axis activity

Authors: *R. J. NEWSOM[1], R. J. GARCIA[1], H. E. W. DAY[2], S. CAMPEAU[2];
[1]Psychology, Univ. of Colorado Boulder, BOULDER, CO; [2]Psychology and Neurosci., Univ. of Colorado, Boulder, CO

Abstract: We recently reported that intraperitoneal (i.p) injection of a CB1 receptor antagonist, AM251, resulted in c-fos mRNA induction in the basolateral amygdala (BLA), paraventricular nucleus of the hypothalamus (PVN), and the prefrontal cortex (PFC), as well as an elevation in plasma corticosterone (CORT). This was in distinct contrast to a lack of induction in several measures such as c-fos mRNA in regions including the lateral septum (LS), bed nucleus of the stria terminalis (BST), medial preoptic area (MPOA), anterior pituitary gland, and in plasma adrenocorticotropin hormone (ACTH). This evidence suggested that the endogenous cannabinoid (eCB) system mediates tonic inhibition of activity in some central regions associated with

hypothalamic-pituitary-adrenal axis regulation, but peripheral actions at the adrenal glands were not assessed and could not be ruled out. In addition the stress of the intraperitoneal (i.p.) drug injection may have contributed to some of the c-fos mRNA induction observed. To more clearly examine the putative contribution of central vs. peripheral drug effects, and to help minimize potential injection stress effects, adult male Sprague Dawley rats were surgically implanted with i.p. catheters.After recovery from surgery, rats were placed, in their home cages, inside acoustically-attenuating chambers to acclimate overnight, and their ip catheters were connected to a length of PE tubing exteriorized. The next morning, at the circadian trough of HPA axis activity, rats were remotely injected with AM251 (1 or 2 mg/kg) or vehicle (n=7-8 per group). Rats were sacrificed 1 hour after administration, and brains, pituitary glands, and adrenal glands were quickly excised and frozen. Ongoing analyses indicate that CB1 receptor mRNA is more robustly expressed in adrenal glands compared to pituitary glands, in a pattern that might support the elevation in plasma CORT, but not ACTH, previously reported after administration of CB1 receptor antagonist. Additional brain c-fos mRNA induction analyses suggest that the prior pattern observed with ip injection of the CB1 receptor antagonist was not dependent on the stress of the injections. Overall, these results suggest both central and peripheral endocannabinoid signaling contribute to HPA axis regulation.

Title: Estrous cycle effects on hypothalamic-pituitary-adrenal (HPA) responses to single-dose nicotine, continuous nicotine by osmotic mini-pumps, and nicotine withdrawal by mecamylamine in female rats

Authors: *M. E. RHODES[1], M. UDDIN[1], T. E. KAROWSKI[2], R. K. CZAMBEL[2], R. T. RUBIN[3];
[1]St. Vincent Col., LATROBE, PA; [2]Ctr. for Neurosciences Res., Allegheny Gen. Hosp., Pittsburgh, PA; [3]Psychiatry, VA Greater Los Angeles Healthcare Syst., Los Angeles, CA

Abstract: Our laboratory is studying the sexual diergism of hypothalamic-pituitary-adrenal (HPA) axis responses to cholinergic stimulation and antagonism. We previously reported that HPA responses to nicotine (NIC) and NIC antagonists are sexually diergic: Female rats had higher HPA responses than did male rats following 1) single-dose NIC, 2) single-dose NIC following continuous NIC for two weeks (modeling NIC habituation in experienced tobacco users), and 3) single-dose mecamylamine (MEC) following continuous NIC for two weeks (modeling NIC withdrawal in experienced tobacco users). The present study extends these findings by determining the influence of estrous cycle stages on HPA responses in the females. Jugular vein-cannulated male and female rats were housed individually and administered 0.3 mg/kg free-base NIC in the three experimental conditions noted above. Estrous cycle stage was determined by light microscopy of daily vaginal smears stained with methylene blue to determine cell types and proportions. Females then were arranged into proestrous and estrous (PE) and diestrous and metestrous (DM) groups, reflecting animals with relatively higher and lower circulating gonadal hormones, respectively. Blood sampling occurred before and after drug administrations for the determination of adrenocorticotropic hormone (ACTH) and corticosterone (CORT) by highly specific immunoassays.
Following single-dose NIC, PE females had higher ACTH and CORT responses than did DM females and males. In contrast, following single-dose MEC (without continuous NIC), DM females had higher ACTH and CORT responses than did PE females and males. Males and females as a single group both had reduced ACTH and CORT responses to NIC challenge following NIC habituation; within the females, the PE group appeared to be more sensitive to the habituating effects of continuous NIC than did the DM group. NIC withdrawal by MEC increased ACTH and CORT responses in both males and females; PE females had higher ACTH and CORT responses than did DM females and males.
These results highlight the influence of the estrous cycle on HPA responses to NIC: DM females were more resistant to NIC habituation than were PE females and males, whereas PE females were more sensitive to NIC withdrawal than were DM females and males. Quitting smoking appears to be harder for women than men, and we can hypothesize from our results that the reinforcing and withdrawal effects of NIC may change across the menstrual cycle. Studying the relationships among NIC, stress, and gonadal hormone cycles may aid in developing improved smoking cessation plans for women.

Title: Neuroendocrine but not behavioral arms of the stress axis altered by gastric bypass in male rats

Authors: *B. E. GRAYSON[1], A. P. HAKALA-FINCH[2], M. KEKULAWALA[2], H. LAUB[2], A. E. EGAN[2], S. C. WOODS[2], J. P. HERMAN[2], R. J. SEELEY[2], S. C. BENOIT[2], Y. M. ULRICH-LAI[2];
[1]Dept. of Intrnl. Med., [2]Univ. of Cincinnati, Cincinnati, OH

Abstract: Although the rates of metabolic syndrome (MetS) and stress-related psychiatric disorders continue to increase in the US, it is unknown whether they are causally related. It has been suggested that weight loss may be an effective strategy to treat not only MetS, but also accompanying stress-related psychiatric disorders. Unfortunately current pharmacologic treatments result in only small transient reductions in body-weight. Several bariatric surgeries, however, produce sustained body-weight reduction in obese individuals. The present work determined whether surgically-induced weight-loss affects neuroendocrine and behavioral indices of stress-related psychiatric disorders in a rodent model. Adult Long Evans male rats were maintained on either a low-fat chow (Lean animals) or a palatable high-fat diet (Obese animals) prior to surgery. Animals received either sham surgery (Sham), vertical sleeve gastrectomy (VSG) or Roux-en-Y Gastric Bypass (RYGB). Both VSG and RYGB lost approximately 15% of their body weight following the surgeries. RYGB had an overall increased basal tone of the HPA axis as indicated by elevated morning (nadir) non-stress plasma corticosterone levels, increased adrenal weight and reduced thymus weight. During an acute stress test, RYGB exhibited a dampened HPA responsivity, possibly due to increased negative feedback from the elevated basal glucocorticoids. RYGB also exhibited attenuated cFos expression in the paraventricular nucleus and prefrontal cortex. In contrast, anxiety-related behaviors in the elevated plus maze and depressive-like behaviors in the forced-swim test were unaffected by either VSG or RYGB. Collectively, although VSG and RYGB result in similar

metabolic improvements, they differentially affect the HPA axis, with RYGB exhibiting a phenotype similar to chronic stress exposure. Increased basal HPA tone following RYGB may have significant long-term consequences to overall health, and suggests that RYGB individuals may be at increased risk for pathology following subsequent chronic stress exposure.

Title: Stress plasticity of the noradrenergic regulation of inhibitory synaptic inputs to CRH neurons of the hypothalamic paraventricular nucleus

Authors: *C. CHEN, J. G. TASKER;
Cell & Mol. Biol., Tulane Univ., New Orleans, LA

Abstract: The hypothalamic-pituitary-adrenal axis is a main regulatory system in the response to stress. Corticotropin releasing hormone (CRH) neurons of the hypothalamic paraventricular nucleus (PVN) release CRH as an initial signal in the HPA response to stress. CRH neurons in the PVN are activated by ascending projections from the noradrenergic A2 cell group located in the caudal nucleus of the solitary tract. The noradrenergic inputs have important effects on the function of neuroendocrine and autonomic systems. The PVN is under robust GABAergic regulation. Our study focused on the noradrenergic regulation of GABAergic synaptic inputs to CRH neurons under control conditions and following acute and chronic stress. Using whole-cell patch clamp recordings in CRH neurons in brain slices from mice expressing eGFP in CRH neurons, we found that norepinephrine (NE) application gave rise to two effects on GABAergic synaptic inputs, eliciting both a facilitation and a suppression of spontaneous inhibitory

postsynaptic currents (sIPSC) in separate CRH neurons. The facilitatory response was mediated by α1-adrenoceptor activation and was sensitive to blockade of spiking with Tetrodotoxin (TTX); the NE-induced suppression of sIPSCs was mediated by α2-adrenoceptor activation and was TTX-insensitive. The facilitatory response was blocked by inhibiting postsynaptic G protein activity with intracellular application of the G protein blocker GDP-β-s, but the suppressive response was not. These results suggest that norepinephrine activates 1)α1-adrenoceptors located in the postsynaptic cell membrane and elicits the release of a retrograde messenger that activates presynaptic GABA neurons, and 2) α2-adrenoceptors located at the presynaptic terminals of GABA synapses and suppresses GABA release. We found that acute restraint stress (30 min) prior to preparation of the brain slices abolished the NE-induced facilitation of sIPSCs, while the NE-induced suppression of sIPSCs was left intact. Exposure to chronic variable stress (3 weeks, alternating stressors) prior to slices preparation, on the other hand, abolished both the facilitation and the suppression of IPSC by NE. Our findings reveal the mechanism of NE regulation of GABAergic synaptic inputs to CRH neurons, which may contribute to activation of the HPA axis in response to stress, and indicate robust plasticity of the NE regulation of CRH neurons under different conditions of acute and chronic stress. Stress-induced changes in the synaptic regulation of CRH neurons could lead to dysregulationof the HPA axis, and may contribute to various stress-associated disorders, such as major depression and anxiety disorder.

Title: Interactive effects of low testosterone and obesity on the central and peripheral nervous systems

Authors: *A. JAYARAMAN, D. LENT, C. PIKE;
Univ. So California, LOS ANGELES, CA

Abstract: The normal, age-related loss of testosterone has deleterious effects on brain, adipose, and other androgen-responsive tissues throughout the body. Consequences of low testosterone include increased risk for a range of health conditions, including Alzheimer's disease (AD), obesity, and type 2 diabetes (T2D). Interestingly, obesity and T2D are independent risk factors

for AD. We hypothesize that the effects of low testosterone independently and cooperatively affect development of these disorders. Understanding the interactive effects of low testosterone with metabolic disturbances may contribute to identifying preventive and treatment strategies for T2D as well as determining the consequences of such interactions on neural health. Inflammatory pathways represent one mechanism of interaction. Pro-inflammatory pathways play a key role in the pathogenesis of several diseases, including T2D and AD, and are regulated by sex steroid hormones, obesity, and other factors. Testosterone can attenuate inflammation in part by decreasing the expression of pro-inflammatory cytokines such as TNFalpha and IL-1beta. Conversely, high-fat diet is associated with activation of pro-inflammatory pathways. High-fat diet also induces obesity, promotes T2D, and is associated with decreased testosterone levels. As one approach to investigating these relationships, we compared the effects of diet-induced obesity on nervous system endpoints under normal and low testosterone conditions. In particular, we determined the effects of low testosterone levels and high-fat diet on (i) expression of pro-inflammatory cytokines (ii) metabolic indices of T2D, (iii) levels of reactive astrocytes, activated microglia, and macrophage infiltration, and (iv) neuron survival and neurite outgrowth. Our results show that low testosterone levels and high-fat diet significantly elevate blood glucose levels, reduce insulin sensitivity, and increase expression levels of TNFalpha and IL-1beta transcripts. In addition, we find that neurons exhibit reduced survival and poorer neurite outgrowth when co-cultured with glial cultures generated from high-fat fed animals in comparison to glial cultures from animals maintained on a normal diet. We also observe changes in the inflammatory pathways in the sciatic nerve in response to low testosterone and diet-induced obesity. These results demonstrate neuroinflammatory effects of high-fat diet, a relationship that is affected by testosterone levels. Together, our findings suggest that low testosterone and obesity are interactive regulators of neuroinflammation that may increase risk of downstream disorders such as T2D and AD.

Title: Hypothalamic dysfunction in 5q14 deletion syndrome

Authors: *Y. SAKAI[1], Y. MATSUSHITA[2], K. OHKUBO[3], T. HARA[3];
[1]Dept. of Pediatrics, Dept. of Pediatrics, Kyushu Univ., Fukuoka, Japan; [3]Dept. of Pediatrics, [2]Kyushu Univ., Fukuoka, Japan

Abstract: 5q14.3 deletion syndrome is a rare chromosomal disorder characterized by moderate to severe intellectual disability, seizure and dysmorphic features. We report a 14-year-old boy with 5q14.3 deletion syndrome who carries a heterozygous deletion of myocyte-specific enhancer factor 2c (MEF2C) gene. In addition to the typical neuro-developmental features of 5q14.3 deletion syndrome, he showed recurrent hypoglycemia, appetite loss and hypothermia. Hormonal loading tests using insulin, arginine, and growth hormone releasing factor revealed that growth hormone was insufficiently released to serum in response to these stimulations, disclosing the hypothalamic dysfunction in the present case. To uncover biological roles of MEF2C in the hypothalamus, we studied its expression in the postnatal mouse brain. Notably, neuropeptide Y (NPY)-positive interneurons in the hypothalamic arcuate nuclei highly expressed MEF2C. In contrast, the Rett syndrome-associated protein, Methyl-CpG binding Protein 2 (MECP2) was barely expressed in these neurons. MEF2C knockdown or overexpression experiments using Neuro2a cells revealed that MEF2C activated the endogenous transcription of NPY. Conversely, siRNA-mediated knockdown of MECP2 led to derepression of the Npy gene. Taken together, these data support the concept that MEF2C and MECP2 share common molecular pathways for homeostatic expression of NPY in the adult hypothalamus. We herein propose that individuals with 5q14 deletion syndrome may exhibit neuroendocrine phenotypes that overlap with those in Rett syndrome through smilar molecular mechanisms.

Title: Effects ofperinatal sucrose administration in rats

Authors: *I. ZARCO DE CORONADO, S. MUUS-MENDOZA;
Fisiologia, UNAM, Mexico DF, Mexico

Abstract: This study was carried out in order to determine the effects of perinatal sugar rich diet (prenatal day 7 to postnatal day 25 in dams and offspring Wistar rats. Primigest animals were receiving Purine Chow Fodent Diet 5001 and 20% sucrose solution. Control rats received just water. Sugar solution or water and chow consumption, and body weight were registered. At the end animals were sacrifized under anesthesia. Experimental dams ingested sucrose solution /chow in the respective proportion 81.51%/17.48% and control animals 32.34%/67.65%. The body weight of control mothers increase and postweaning decrease was respectively 31.1 1.41 /58.2 and experimental mothers 49.0/58.2. Experimental dams exhibit hepatosteatosis and increased retroperitoneal fat. At birth, control offsprings weighted 5.57 g, and experimental offsprings weighted 6.08 g (p=0.014). At postnatal 25th day, female control offsprings weighted 37.98 g and experimental offsprings 45.30 (p=0.001); and male control offsprings weighted 37.01 g, and experimental offsprings 46.98 g (p=0.001). These data suggest perinatal sucrose diet modifies neuroendocrine factors of the homeostatic energy system.

Title: Ovarian hormones, but not androgens, affect neuron and glia number in the medial prefrontal cortex

Authors: *W. A. KOSS, R. M. SADOWSKI, J. M. JURASKA;
Psychology, Univ. Illinois Urbana-Champaign, CHAMPAIGN, IL

Abstract: There are sex differences in the adolescent development of the prefrontal cortex of both rats and humans (Geidd et al, 1999; Markham et al, 2007). At the cellular level, our laboratory has found that female rats show a greater loss of neurons in the medial prefrontal cortex (mPFC) than males during the adolescent period. Additionally, the loss of neurons occurs in both the outer (layers 2/3) and inner layers (layers 5/6) of the female mPFC whereas males only lose neurons in the outer layers. These changes result in an adult sex difference in the overall number of neurons in the mPFC (males>females). Sex differences also appear after

puberty in the number of glia in the rat prefrontal cortex (Markham et al, 2007). To investigate the role of pubertal hormones in organizing the cellular composition of the mPFC, the gonads were removed in the current study in both female and male rats prior to puberty (postnatal day 20-22) and same-sex littermates received sham surgeries. The total number of neurons and glia in the mPFC were stereologically quantified using software from Microbrightfield Inc. Results revealed that females without ovaries had more neurons and glia than intact females in the mPFC and this result was also significant for layers 5/6, but not layers 2/3. In contrast, males castrated prior to puberty did not have altered neuron or glia number in any layer of the mPFC. These data indicate that pubertal androgens do not affect the development of the mPFC during adolescence; however, the ovarian steroids play a significant role in the decrease in the number of neurons and glia in layers 5/6 of the female mPFC.

Title: Fetal Testosterone is associated with white matter volumetric sexual dimorphism in children

Authors: *A. N. RUIGROK[1], E. CHAPMAN[2], M.-C. LAI[1], M. V. LOMBARDO[1], B. AUYEUNG[1], J. SUCKLING[3], K. TAYLOR[4], G. HACKETT[5], E. T. BULLMORE[3], S. BARON-COHEN[1];

Institute, Univ. of Cambridge, United Kingdom, Brain Mapping Unit, Dept. of Psychiatry, Univ. of Cambridge, Cambridge, United Kingdom; [4]Dept. of Clin. Biochemistry, Addenbrooke's Hospital, Cambridge, Cambridge, United Kingdom; [5]Dept. of Fetal Medicine, Rosie Maternity Hospital, Cambridge, Cambridge, United Kingdom

Abstract: Testosterone is known to have organizational effects on brain structure and function in non-human species. Variation in fetal testosterone (fT) was recently found to predict regional

gray matter volume in pre-pubertal boys. In an extension to this line of research we investigate how variation in fT predicts regional white matter volume in the same sample of boys aged 8-11 years old. We hypothesized that volume of areas associated with fT level overlap with sexually dimorphic regions in a congruent direction (e.g. a positive correlation with fT overlaps with areas larger in males and a negative correlation overlaps with areas larger in females) in an independent group of children in the same age-range. Structural brain scans were conducted in twenty-eight boys (mean age 9.5 years) who are part of the Cambridge Child Development Project. Fetal testosterone was measured from amniotic fluid samples collected between 13 and 20 weeks of gestation (fT levels ranged from 0.25-1.70 nmol/L). Data from the NIH Pediatric Repository of children (101 boys; 116 girls) between 8-11 years old (mean age of both sexes 9.5 years) were used as an age-matched group to identify sexually dimorphic structures. SPM8 and DARTEL toolbox were used for data preprocessing. Fetal testosterone positively predicted volume of a white matter region encompassing the left internal capsule, cortico-spinal tract, cortico-ponto-cerebellar tract, and the long segment of the arcuate fasciculus. No negative correlation of fT with white matter was observed. Areas overlapping with the corpus callosum (anterior and bilateral posterior) were larger in males, whereas areas overlapping with bilateral internal capsule, cortico-spinal, cortico-ponto-cerebellar tracts and the inferior cerebellar peduncles were larger in females, as well as a bilateral area overlapping with the inferior longitudinal and inferior fronto-occipital fasciculi. These results are the opposite of what was hypothesized; the area positively correlated with fT in boys overlaps with a sexually dimorphic region larger in girls. These findings suggest that fT may act differently as an organizing mechanism in white matter than in gray matter in 8-11 year-old children. Future research will apply diffusion tensor imaging and tractography to examine the relationship between white matter microstructural properties and fT.

Title: Expression and regulation of sexually dimorphic genes in the developing mouse cortex and hippocampus

Authors: C. ARMOSKUS, D. MOREIRA, *H.-W. TSAI;
Dept. of Biol. Sci., California State University, Long Beach, Long Beach, CA

Abstract: The cortex and hippocampus are important for the control of cognitive and social behaviors, many of which are sexually dimorphic. However, the mechanisms that mediate the development of the brain structures and neural circuits underlying these functional differences between the sexes have not been discovered. Using gene expression microarrays, we have previously identified several novel sexually dimorphic genes expressed in the neonatal cortex and hippocampus, including Klk8 and Mid1 genes. Klk8 gene is highly expressed in the hippocampus and encodes a tryptic serine protease called kallikrein related-peptidase 8, involved in activity-dependent synaptic changes, such as long-term potentiation. Mid1 gene is located in the pseudoautosomal-region of the X- and Y- chromosomes and encodes a microtubule-associated protein with E3 ubiquitin ligase activity to target proteins for degradation through ubiquitination. Using mice as the model, many studies have established the essential role of perinatal surges in testosterone secreted by the testes during late embryonic development and immediately after birth in masculinization of brain structures and behaviors. Since androgen receptor is highly expressed in the cortex and hippocampus, we thus hypothesized that perinatal exposure to testosterone was required to regulate transcription of Mid1 and Klk8 genes in the male cortex and hippocampus. To test our hypothesis, we treated timed pregnant female mice daily with of vehicle (0.05 ml sesame oil, sc) or testosterone propionate (TP, 100 μg) starting on embryonic day 16. On the day of birth, the cortex and hippocampus were collected from vehicle- and TP-treated, male and female pups (n=10 per group). Total RNA was extracted from these tissues, followed by reverse transcription with real-time polychain reaction (RT-qPCR) to measure expression of Mid1 and Klk8. We found a significant effect of sex on Klk8 expression in the cortex and hippocampus. In both vehicle- and TP-treated mice, males showed higher levels of Klk8, than females. Mid1 was expressed higher in females than males, but was not affected by TP treatment. Our results have demonstrated sexually dimorphic expression of Mid1 and Klk8 genes in the neonatal mouse cortex and hippocampus. Although these genes don't seem to be regulated by testosterone, their sexually dimorphic expression along with molecular functions might implicate their important roles in the control of brain sexual differentiation, which might be involved in the development of distinct cognitive behaviors and sex-biased diseases, especially those that involve the cortex and hippocampus.

Title: Species differences in the distribution of androgen receptor and sex differences in three newly identified species-specific clusters in the preoptic and anterior hypothalamic areas of the adult rats and mice

Authors: *M. R. JAHAN, K. KOKUBU, C. MATSUO, R. FUJINAGA, A. YANAI, T. WATANABE, N. TAKEMOTO, M. N. ISLAM, K. SHINODA;
Yamaguchi Univ. Grad. Sch. of Med., Ube, Yamaguchi, Japan

Abstract: Background: The preoptic and anterior hypothalamic areas (PO/AH) are important sex-steroid responsive brain regions regulating intrinsic programs relevant to homeostatic, neuroendocrinergic and instinct behavioral functions. Some species difference in morphology and physiology, however, has been suggested in sex-hormone-induced functions of the PO/AH, whereas detailed distributions of sex-steroid receptors have never been compared between rats and mice. Nevertheless, data obtained from knockout mice have often been uncritically referred to those accumulated in rats. The purpose of this study is to clarify the differences in distribution pattern of androgen receptor (AR) in the PO/AH between rats and mice of both sexes. Material and Methods: Expression of AR in the PO/AH was immunohistochemically compared between adult rats (Wistar, SD) and mice (C57BL/6, DBA/2j, Balb/c) of both sexes, using completely serial frozen sections of paraformaldehyde-fixed tissues. Results: AR expression was much stronger in males than in female of both rodents. In general, AR-immunoreactive (AR-ir) cells were more conspicuous in mice than rats in both sexes, particularly in the medial preoptic area (MPO), posterodorsal preoptic nucleus, dorsal PO/AH junction (DPAJ) and suprachiasmatic nucleus (SCN). Exceptionally, AR-ir cells were more densely concentrated in the sexually dimorphic nucleus (SDN) of the MPO and periventricular zone of the AH in rats than mice. In addition, we discovered two distinct rat-specific small AR-ir cell clusters in both sexes as the “rostral nebular island (RNI)” in the DPAJ and “caudal nebular island (CNI)” in the caudal level of AH, while they are never observed in mice. The RNI and CNI are also identified in Nissl staining and exhibit significant male-dominant sex differences in their volume and cell numbers. We also found a distinct mouse-specific AR-ir cell cluster in the AH as the “tear drop nucleus” (TDN) in both sexes. The TDN was inconspicuous in delineation in Nissl staining, but shows significant male-dominant sex difference in its volume and AR-ir cell numbers when compared between gonadectomized male and female mice after equivalent enhancement in AR expression by excessive dihydrotestosterone. Conclusion: Prominent species difference in AR expression was clarified and the species-specific, sexually dimorphic AR-ir cell clusters were newly identified. The present results might explain different androgen induced psychotic, behavioral and endocrinergic responses between two rodents, warning that data related to androgen-

sensitive functions obtained from the two different rodents might not directly be applied each other.

Title: Microcolumnar properties show sexual dimorphism in areas 17 and 46 of monkey brain

Authors: *W. MORRISON[1], E. L. GIANNARIS[2,3], L. CRUZ[4], F. MORTAZAVI[3], B. URBANC[4], J. SANTOS[1], D. L. ROSENE[3], H. E. STANLEY[1];

Abstract: Sexual dimorphism is a general feature of mammalian neuroanatomy, from classical differences in the hypothalamus and amygdala to more recent observations of dimorphic hemispheric asymmetry of hippocampal structure (Cahill 2006). An important feature of the cortex is its organization into vertical columns referred to as micro- or mini-columns. Various aspects of microcolumnar structure, such as relative density (strength), width, spacing and regularity, can be quantified using statistical density maps (Cruz et al., 2005). We investigated whether gender differences extend to microcolumns, as suggested by Casanova and Tillquist (2008). We examined area 17 and area 46, two cortical areas that have been shown to have gender-specific functional differences in humans as well as rats (Tranel et al., 2005; Juraska 1984).
From a cohort of 7 male and 10 female M. mulatta, ages 7.4-19.7 years, area 17 tissue sections were prepared using NeuN immunohistochemistry. Neuron locations were identified with an

automated recognition algorithm and microcolumnarity assessed using the statistical density map. Columnar organization was related to gender through the use of stepwise discriminant function analysis, which shows whether or not a structural variable is useful in classifying an animal as male or female. The same analysis was performed in area 46 using Nissl stained tissue from a cohort of 14 male and 8 female monkeys, ages 4.8-19.8 years, previously analyzed (Cruz et al., 2008). Significant sexual dimorphism was observed in area 17 and the ventral portion of area 46 but not in dorsal area 46. In areas 17 and ventral 46, the microcolumns of males appear to be regularly spaced, while those of females were significantly less regular in spacing. Additionally, in ventral area 46, females were observed to have stronger columns.
Finally, when the same methods are applied to an aged cohort (9 male and 12 female monkeys aged 20.4 to 32.3 years) results suggest that gender specific structural differences diminish with age.

Title: Exposure to bisphenol A during early development alters neuron and glia number in the prefrontal cortex of adult male, but not female, rats

Authors: *R. N. SADOWSKI[1], L. M. WISE[2], S. L. SCHANTZ[1,3], J. M. JURASKA[1,2];
[1]Neurosci. Program, [2]Psychology, [3]Comparative Biosci., Univ. of Illinois at Urbana-Champaign, Champaign, IL

Abstract: Previous work has shown that exposure to bisphenol A (BPA) during early development can alter sexual differentiation of the brain in rodents, although few studies have examined effects on areas of the brain associated with cognition. The current study examined if developmental BPA exposure alters total number of neurons and glia in the medial prefrontal

cortex (mPFC) in adulthood. Long-Evans hooded rats were bred in the laboratory, and pregnant rats were orally exposed to corn oil (vehicle), 4 µg/kg, 40 µg/kg, or 400 µg/kg throughout pregnancy. After parturition, pups were given daily oral doses of oil or BPA, corresponding to those given during gestation, from days 1-9. Brains were examined in adulthood (P140), and layers 2/3 and layers 5/6 of the mPFC were parcellated separately to determine volume. The number of neurons and glia in the mPFC were then quantified stereologically with the optical disector. Results indicate that males exposed to 400 µg/kg BPA had increased numbers of neurons and glia in layers 5/6. Although there were no significant effects of BPA in layers 2/3, the pattern of increased neuron number in males exposed to 400µg/kg was similar to that seen in layers 5/6. Interestingly, increased neuron number in the PFC has also been reported in autistic male children (Courchesne et al., 2011). No effects of BPA were seen in females or in males exposed to the other doses of BPA. This evidence suggests that males are more susceptible to the long-lasting effects of BPA on the mPFC.

Title: Effects of exposure to bisphenol A during adolescence on neuron number and volume in the prefrontal cortex

Authors: *L. M. WISE[1], R. N. SADOWSKI[2], S. L. SCHANTZ[3,2], J. M. JURASKA[1,2]; [1]Dept. of Psychology, [2]Neurosci. Program, [3]Comparative Biosci., Univ. of Illinois, Champaign, IL

Abstract: Bisphenol A (BPA), an endocrine disruptor commonly used in a variety of consumer products, has been found to alter neuroanatomy in multiple brain areas. However, few studies have examined long-term effects on the prefrontal cortex, and there is a lack of studies that

address whether BPA exposure during adolescence influences prefrontal neuroanatomy into adulthood. In the current study, Long-Evans male and female rats were administered 0, 4, 40, or 400µg/kg/day BPA during adolescent development (postnatal days 27-46). All other sources of BPA exposure were eliminated for the lifespan of the subjects. In adulthood (postnatal day 150), the volume, neuron number, and glia number of the prefrontal cortex are being assessed. The volume of the frontal white matter is also being analyzed. Previous research from our laboratory has shown a sex difference in volume of the ventral medial prefrontal cortex and frontal white matter. Preliminary data in the current study finds an abolishment of the sex difference in the frontal white matter with adolescent BPA exposure (sex x treatment, p=.02). Volumes of the prefrontal cortex layers 2/3 and 5/6 also show a similar pattern towards abolishment of the sex difference. Neuron number is currently being assessed.

Title: The role of circulating androgens and the androgen receptor in sex differences in the mouse VMH

Authors: *J. L. BRUMMET[1], C. L. JORDAN[2], S. M. BREEDLOVE[2];
[1]Psychology, [2]Neurosci., Michigan State Univ., East Lansing, MI

Abstract: The ventromedial nucleus of the hypothalamus (VMH) is a sexually differentiated area of the brain that is rich in steroid receptors. We compared the VMH of males and females to an induced testicular feminization (iTFM) mouse, which is genetically male, but lacks a functional androgen receptor (AR). Mice were gonadectomized at postnatal day 60 (PN60), implanted with a Silastic capsule that was either blank (B) or contained testosterone (T), and sacrificed at PN90. Brains were frozen, sectioned, thionin stained, and analyzed using stereology to estimate regional volume of the VMH as well as soma size, and neuron number within the nucleus. Preliminary results indicate that the regional volume of the VMH in mice is independent of AR and is controlled by circulating T (mean T-treated volume=2.6 ± .05 x 10^8 um^3, mean B-treated volume =2.3 ± .05 x 10^8 um^3; *p*=.003). As our lab previously reported in rats, the

dorsomedial and ventrolateral subdivisions of the VMH in mice account for most of the sexual dimorphism in the nucleus. In addition, neuron number is greater in males and iTfms than females, suggesting a non-AR dependent sex difference in neuron number (mean neuron number for males = 20.7 ± .95 x 10^3, iTfms= 19.1 ± .65 x 10^3, females= 16.6 ± .69 x 10^3; p=.002). Neuronal soma size is regulated by circulating T, with soma size larger in T treated animals (mean for T-treated soma size= 88.80 ± 1.78 um^2, mean for B-treated = 81.74 ± 1.60 um^2; p=.001). These results suggest that volume and soma size in the VMH are dependent on circulating T, while the sex difference in neuron number is independent of both AR and adult levels of circulating T. Preliminary evidence from follow up studies suggests there is also a sex difference in astrocyte number in the mouse VMH.

Title: Immunohistochemical localization of estrogen receptors α and β, progesterone receptor, and kisspeptin in the preoptic area of SF-1 knockout mice

Authors: *Y. IKEDA[1], T. KATO[2], M. KOMADA[1];
[1]Dept. of Anat., Aichi-Gakuin Univ. Sch. of Dent., Nagoya, Japan; [2]Systems Biomedicine, Natl. Ctr. for Child Hlth. and Develop., Tokyo, Japan

Abstract: In mammals, brain sex differentiation is considered to depend upon estrogens formed via the neural aromatization of androgens secreted by testes during a critical period including several days before and after birth. The transcription factor, Steroidogenic factor 1 (SF-1, officially designated NR5A1), regulates steroidogenesis and is essential for development of adrenals and gonads. SF-1 knockout (KO) mice serve as an animal model that is not exposed to endogenous gonadal steroids during both prenatal and postnatal development, since they lack gonads from the beginning of the differentiation. We have used them for studying when and how gonadal hormones act on the formation of sex differences in the brain during early postnatal development. In this study, we rescued SF-1 KO mice by corticosteroid injection since they die shortly after birth due to adrenal agenesis, and analyzed the expression of several markers including two estrogen receptors α and β, progesterone receptor, and kisspeptin, in the two

representative sexually different neuronal nuclei in the preoptic area; the anteroventral periventricular nucleus (AvPv), which is larger in females than in males and has important roles in female-typical GnRH/LH surge, and the medial nucleus of the preoptic region (MPN), which is larger in males than in females and has important roles in male sexual behavior, in SF-1 KO mice and wild-type (WT) controls, at postnatal stages, postnatal day 0 (P0), P7, P14, and P21, using immunohistochemistry. The localization and the positive cell number for these markers of SF-1 KO male and female mice were similar to those of WT females, indicating that the two brain regions of SF-1 KO male mice are feminized. The results support the idea that perinatal gonadal hormones are required for masculinization of the brain. Title: Sexual differentiation of kisspeptin neurons still occurs in mice lacking GnRH signaling but feminization is incomplete

Authors: *K. P. TOLSON, J. KIM, S. DHAMIJA, A. S. KAUFFMAN;
Dept. of Reproductive Med., UCSD, La Jolla, CA

Abstract: Kisspeptin, encoded by *Kiss1*, regulates puberty and reproduction. In rodents, one population of kisspeptin/*Kiss1* neurons resides in the hypothalamic AVPV/PeN region. AVPV/PeN *Kiss1* neurons are sexually-dimorphic (greater in females), yet the mechanisms regulating their development and sexual differentiation remain poorly understood. Although neonatal estradiol (E2) normally masculinizes the AVPV/PeN kisspeptin system, emerging evidence suggests that developmental E2 may also be important for feminization of kisspeptin cells. However, precisely when in development E2 promotes kisspeptin feminization is

unknown. Here, we determined whether *Kiss1* expression is permanently impaired in adult *hpg* females (lacking GnRH and gonadal steroids) under different E2 replacement paradigms, and whether E2 is needed during juvenile or pubertal periods for complete feminization of *Kiss1* neurons. We demonstrate that 1) *hpg* females, who normally lack E2 exposure, have reduced AVPV/PeN *Kiss1* expression, even after various durations (acute and chronic) of adulthood E2 treatment; 2) despite reduced *Kiss1* levels in *hpg* females, significant sexual differentiation of *Kiss1* still occurs in *hpg* mice; 3) exposing *hpg* females to E2 during the pubertal period does not rescue their lower adult *Kiss1* levels; and 4) in normal mice, removal of ovarian E2 before the pubertal or juvenile periods does not prevent complete feminization of AVPV/PeN *Kiss1* expression or LH surge generation, indicating that puberty is not a "critical period" for *Kiss1* development. Thus, while sexual differentiation does occur in *hpg* mice, feminization is not maximal, and E2 is needed sometime before juvenile development for complete feminization of AVPV/PeN *Kiss1* neurons.

Title: Prenatal exposure to the antiandrogen flutamide affects mesocorticolimbic dopaminergic system in rats

Authors: M. PALLARÉS[1], E. ADROVER[1], M. IMSEN[2], C. J. BAIER[3], *M. C. ANTONELLI[1];
[1]IBCN, Facultad De Medicina, Buenos Aires, Argentina; [2]Inst. de Investigaciones Biomédicas, Buenos Aires, Argentina; [3]Inst. de Investigaciones Bioquímicas de Bahía Blanca, Bahía Blanca, Argentina

Abstract: We have previously demonstrated that prenatal stress (PS) can exerts an impairment of midbrain dopaminergic system (DA) metabolism especially after puberty, suggesting a particular sensitivity of DA system to variations in gonadal hormones peaks. We further demonstrated that the hypothalamic-pituitary-testicular axis status of male rats exposed to PS

was altered since age-dependent changes on the external genitalia, pituitary and testicular hormones profiles and spermatogenesis rate were found. PS was shown to disrupt perinatal testosterone surges and since the developing forebrain DA system was shown to be influenced by androgen exposure, the aim of this study was to evaluate if the prenatal administration of flutamide, an androgen receptor blocker, to pregnant rats during late gestation, might affect the dopaminergic system development. Pregnant rats were treated daily from gestational day 14th to 21st with either vehicle (VEH: 5% ethanol-propylene glycol) or 10 mg/kg flutamide (FLU). Our results show that FLU reduced anogenital distance of male progeny and induced a delay in the completion of testis descend in all evaluated ages in comparison to VEH rats. Moreover malformation of penis, cryptorchidisim and atrophied seminal vesicle were also observed on FLU offspring. Morphological studies in mesocorticolimbic DA areas revealed that FLU males presented a decrease in the number of MAP2 immunoreactive neurons in comparison with VEH, suggesting that prenatal FLU induce a reduction in the dendritic arborization of mesencephalic structures, impairing normal connectivity between areas. Our results demonstrate that prenatal androgen manipulation induce similar consequences to PS suggesting that one of the possible mechanisms of prenatal insults might be related to the alteration of the organizational role of androgens and the differential modulation of their activational role on brain development

Title: Neonatal exposure to estradiol valerate increases dopamine content in nigrostriatal pathway during adulthood in the rat

Authors: *R. SOTOMAYOR-ZÁRATE[1,2], R. RIQUELME[1], P. ESPINOSA[1], A. DAGNINO-SUBIABRE[1], P. JARA[3], G. M. RENARD[1,2], G. CRUZ[1];

Abstract: The specific windows of sensitivity correspond to periods in which certain stimuli can generate long-term lasting effects (Lucas A. 1991). Research in programming has been focused in the study of stimuli that affect sensitive periods of development such as prenatal and neonatal stage. We previously showed that exposure to estradiol valerate (EV) to female rats during the first 12 hours of life increased the content of dopamine (DA), serotonin (5-HT) and noradrenaline (NA) in ventromedial-arcuatus hypothalamus of the adult rat (Sotomayor-Zárate et al. 2011). Alterations in nigrostriatal pathway could be involved in brain sensitivity to drugs of abuse and may play a role in addictive process. Therefore, the purpose of this work was to determine the neurotransmitters changes induced by neonatal EV (0.1 mg/50µL s.c per rat) administration on nigrostriatal pathway of adult female rats. Sesame oil (50µL s.c. per rat) was administered in a control parallel group. For this purpose, rats were killed by decapitation at 60 days of age and substantia nigra (SN)-ventral tegmental area (VTA) and striatum were microdissected. Tissues were weighed and homogenized in perchloric acid and centrifuged at 4°C. The supernatant was cleaned through a filtration unit and injected in a HPLC coupled to electrochemical detection to determine the content of DA, NA and 5-HT.
We observed that neonatal EV administration produces a significant increase in DA content in striatum and SN-VTA. In addition, the content of NA increases in striatum but no changes were observed in SN-VTA. In contrast, the content of 5-HT decreases in striatum but no changes were observed in SN-VTA.
Altogether, our results show that neonatal exposure to EV permanently modified the content of monoamine neurotransmitters in nigrostriatal pathway of adult rats. This might imply that the estrogenized rats could have a greater susceptibility to the effects of drugs of abuse.

Title: Effects of alcohol consumption in sleep architecture of Mexican elderly patients: A retrospective study

Authors: *M. M. MELENDEZ[1], A. GALLEGOS-CARI[1], N. F. HERNÁNDEZ-LLANES[1], R. E. CAMACHO-SOLIS[1], U. JIMENEZ-CORREA[2], F. AYALA-GUERRERO[2], J. VELAZQUEZ-MOCTEZUMA[3], A. JIMÉNEZ-ANGUIANO[3];

[1]IAPA-DF, Mexico City, Mexico; [2]UNAM, Mexico City, Mexico; [3]UAM I, Mexico City, Mexico

Abstract:
Introduction:Mexico City is one of the most populated cities in the world. According with the National Institute of Statistics, Geography and Informatics, elderly population, in this city, was estimated in half million people in 2010, equals to 7% of total population, and this percentage will growth up to 28% in 2050 (almost a million elderly people). Sleep disorders are common nosological entities found in general population. Sleep disorders like insomnia are common in general population and prevalence of insomnia has been estimates between 9.0% and 17.7%, In México, Téllez-López et al. (1995) reports a prevalence of 22% in adult population. Studies made in other countries show that, in elderly population, prevalence has been estimated 28% in the USA, 32.9% in China and 37% in Iceland. Until today, there are no studies about sleep architecture in elderly patients of Mexico City. Aging process has been related with a modification in sleep pattern, including a shift in circadian phase, a decrease in slow wave sleep and difficulties in sleep maintenance. Risk factors associated with insomnia are sex, age, psychiatric comorbidities (like depression) and stress. Daytime sleepiness, a marker for insomnia, is largely observed in elderly population and is a risk factor for cognitive decline, obstructive sleep apnea, among others. Substance use also is related with sleep quality. Is reported that benzodiazepines, caffeine, alcohol and tobacco modifies sleep patterns, and this effect is more pronounced in elder population. The objective of this study was to assess the effect of alcohol consumption pattern in sleep architecture in a sample of elder population of Mexico City. Method: A retrospective cross-sectional study of files of elderly patients of the Sleep Disorders Clinic of the National Autonomous University of Mexico (UNAM) was conducted. The files include sociodemographical data, Epworth Sleepiness Scale and polysomnography records. All files were evaluated and diagnosed with insomnia according with the ICSD-2 Classification. Statical analysis was made with SPSS. Descriptive statistics was obtained over the sociodemographical data, insomnia and no-insomnia groups were compared over sleep architecture, alcohol consumption and sociodemographical data. Odds ratio was estimated for risk measurement in alcohol consumption and sociodemographical data for insomnia. Results: Differences in sleep architecture and alcohol consumption were observed between the insomnia and no-insomnia groups.

Title: The relation between alcohol consumption pattern and sleep architecture in Mexican elderly patients

Authors: *A. GALLEGOS-CARI[1], N. F. HERNANDEZ-LLANES[1], R. E. CAMACHO-SOLIS[1], U. JIMENEZ-CORREA[2], F. AYALA-GUERRERO[2], J. VELAZQUEZ-MOCTEZUMA[3], A. JIMÉNEZ-ANGUIANO[3], M. A. MENDOZA-MELÉNDEZ[1]; [1]IAPA-DF, Mexico City, Mexico; [2]UNAM, Mexico City, Mexico; [3]UAM I, Mexico City, Mexico

Abstract: Introduction: In Mexico City was estimated half million of elderly people in 2010,equals to 7% of total population, and this percentage will grow to almost a million in 2050. According to the "Survey on psychoactive Substance Use in Older Adults of Mexico City" conducted in 2012, the prevalence of alcohol consumption in the last 12 months in elderly was 32.3%, 44.2% for male and 24.9% for female. It's known that use and abuse of substances like benzodiazepines, caffeine, alcohol and tobacco affects sleep, and this effect is more pronounced in elder population. Aging process has been related with alterations in sleep pattern, including a shift in circadian phase, a decrease in slow wave and REM sleep. Some risk factors associated with insomnia are sex, age and comorbidity with depression and anxiety disorders. Daytime sleepiness, a marker for insomnia, is largely observed in elderly population. Sleep disorders like insomnia are common in general population, and in México, it is reported a prevalence of 22% in adults but studies in elderly population have shown an estimated prevalence range from 28% to 37%. The objective of this study was to measure changes in sleep architecture of Mexican elderly patients and its association with alcohol use and abuse. Method: We conducted a prospective study of 30 elderly users of the Sleep Disorders Clinic of the National Autonomous University of Mexico (UNAM). The participants signed an informed consent, authorizing their participation in the study, and completed the "Survey on psychoactive Substance Use in Older Adults of México City", an instrument designed to collect sociodemographical data, alcohol and other substances use patterns, index of quality life and sleep quality Epworth Sleepiness Scale. All participants were evaluated and diagnosed according with the ICSD-2 Classification by polysomnography. Statical analysis was made with SPSS. We analyzed descriptive statistics over sociodemographical data. Student´s t test was applied to compare insomnia and no-insomnia groups, sleep architecture and sleep quality, patterns of alcohol consumption and sociodemographical data. We also estimated odds ratio to measure risk factors associated with alcohol consumption and insomnia. Results: Alcohol use and abuse is related with changes in quality of sleep and sleep architecture among elderly patients with insomnia disturbances.

Title: Neural substrate of rapid eye movements during REM sleep in humans: Comparison of cortical activation patterns among REMs and several types of waking saccades

Authors: *S. KAN[1], T. KOIKE[2], M. MISAKI[3], S. MIYAUCHI[1];
[1]Advanced ICT Res. Inst., Natl. Inst. of Information and Communications Technol., Kobe, Japan; [2]Natl. Inst. for Physiological Sci., Okazaki, Japan; [3]Laureate Inst. for Brain Res., Tulsa, OK

Abstract: Since the discovery of the relationship between rapid eye movements (REMs) and dream content, one important issue is functional similarity between REMs and waking saccades. This relationship suggests that REMs occur to scan dream images during REM sleep. Animal studies reveal that cortical and subcortical structures, particularly the pons, play crucial roles in the generation of REMs. In contrast, there are no detailed comparisons of the activated regions related to REMs and waking saccades in humans, although the measures of these eye movements such as peak velocity have been rigorously compared. If REMs are analogous to waking saccades, REMs should be regulated by saccade-related cortical regions with visual information. To test this prediction, we compared spatial activation patterns among REMs and three types of waking saccades.
Twenty male and three female healthy volunteers participated in a sleep experiment, and 14 of them also participated in a waking saccade experiment. To identify brain activity accompanied by REMs, we simultaneously recorded fMRI and EEG in the early morning while participants slept in the MR scanner. fMRI data were analyzed in an event-related fashion. Three types of saccades were used in the waking saccade experiment: 1) visually guided saccades; 2) voluntary saccades with visual information; and 3) voluntary saccades without visual information. We calculated the correlation coefficients of spatial activation patterns in several cortical and subcortical regions among REMs and the three types of saccades and compared the correlation

coefficients.
REM-related activation was observed in the frontal eye field (FEF), supplementary eye field (SEF), medial visual cortices, putamen, thalamus, and brainstem. All these regions, except the brainstem, were also activated to some degree in the three waking saccade conditions. Furthermore, spatial correlation analysis showed that activation patterns of the medial visual cortices were similar among REMs, the visually guided saccades, and the voluntary saccades with visual information. In contrast, the activation patterns of the SEF and those of putamen were similar between REMs and the voluntary saccades without visual information. Although several saccade-related cortical regions were also activated in REMs, the lack of parietal eye field (PEF) activation accompanied by REMs and the role of PEF in saccade regulation suggest that the neural substrate of REMs are not identical to those of waking saccades with visual information.

Ctr. and Sackler Sch. of Med., Tel Aviv, Israel; [6]Dept. of Physiol. and Pharmacol., Sackler Sch. of Med. and Sagol Sch. of Neurosci., Tel Aviv, Israel

Abstract: In wakefulness, rapid eye movements (REMs) direct our fixation and attention to specific parts of the visual scene, shaping visual perception and guiding behavior. REMs are also prevalent during REM-sleep, a state associated with dreams and vivid mental imagery, but their relation to cortical neuronal activity and dreaming remains unclear.
In this study, we took advantage of the unique opportunity to examine neuronal activity associated with REMs during sleep and wake in the same participants. Thirteen presurgical epilepsy patients underwent continuous monitoring, providing written informed consent as approved by UCLA's IRB. Full-night polysomnographic sleep studies included EOG, EMG, four scalp electrodes and continuous video monitoring. Depth electrodes were implanted, according to clinical criteria, in 129 sites in medial temporal lobe, parietal and frontal cortices, recording depth EEG, LFPs, and unit activity (n=600). REMs were detected semi-automatically by a computer algorithm followed by visual inspection, to minimize false detections and precisely pinpoint REM onsets.
On average, 2.6 and 4.4 REMs/min were detected in wake and REM-sleep, respectively, and their shape was indistinguishable in wake vs. REM-sleep. Occurrence in NREM sleep was not significantly different from zero, so we considered only wake and REM-sleep for further analysis.
Neuronal activity across multiple cortical and MTL regions was robustly modulated with REMs. Accordingly, most neurons (63% in wake, 52% in REM-sleep) showed robust reduction in firing rate (33% of maximal firing rate on average, $p<0.05$) immediately before REM onsets, at times when behavioral saccadic suppression occurs. Reduction in firing was followed by increased spiking activity (60% of maximal firing rate) peaking 300-400ms after REM onsets ($p<0.05$). In wakefulness, the exact timing of such increased activity exhibited regional variability supporting a cortical-hippocampal propagation, and such variability is currently under examination in REM-sleep. In parallel with modulations in unit activities, REMs in both wake and sleep were associated with a positive peak (evoked potential) in the depth EEG occurring immediately before REM onset, akin to PGO potentials observed in animal studies. Finally, some neurons (37% in wake, 48% in REM-sleep) increased firing in the few hundred milliseconds before REM onsets, and this effect was stronger in sleep.
Overall, the results indicate that REMs are associated with shared patterns of cortical activity across vigilance states in humans, suggesting that REMs 'reset' activity patterns (and possibly visual perception) in both wakefulness and sleep.

Title: Human behavioral lapses upon sleepiness correlate with local suppression of single-unit spiking activity and regional increases in LFP low-frequency oscillations

Authors: *Y. NIR[1,3], T. ANDRILLON[4], N. SUTHANA[5], C. CIRELLI[3], I. FRIED[5,2], G. TONONI[3];
[1]Dept. of Physiol. and Pharmacol. & Sagol Sch. of Neurosci., [2]Functional Neurosurg. Unit, Tel Aviv Med. Ctr. and Sackler Sch. of Med., Tel Aviv Univ., Tel Aviv, Israel; [3]Dept. of Psychiatry, Univ. of Wisconsin-Madison, Madison, WI; [4]Lab. de Sci. Cognitives et Psycholinguistique, EHESS/CNRS/ENS-DEC, Paris, France; [5]Dept. of Neurosurgery, David Geffen Sch. of Med. and Semel Inst., UCLA, Los Angeles, CA

Abstract: Lack of sleep affects cognition, mood, and health, modulating brain activity and behavior. Recently, we showed that prolonged wakefulness in rats leads to regional neuronal inactivity, low-frequency (2-6 Hz) waves, and behavioral deficits. Here we investigated whether similar phenomena occur in humans using the well-validated Psychomotor Vigilance Task (PVT).

Ten presurgical epilepsy patients underwent continuous monitoring, providing written informed consent to participate as approved by UCLA's IRB. Participants performed a face/place categorization in a modified PVT (n=27 sessions) while images were presented infrequently (ISI=2-8s). Some session pairs (n=8) were conducted before/after full-night sleep deprivation conducted for clinical purposes, and before/after normal sleep (n=2). Depth electrodes (>100 sites) were placed according to clinical criteria and included regions in medial temporal lobe (MTL), frontal and parietal cortices, and some scalp EEG channels. Extracellular activity was recorded from 1457 units.

Subjects successfully performed the face/place task (95% correct). Reaction times included normally-distributed fast trials, and a tail of exponentially-distributed slow trials (lapses). Objective sleep pressure had a selective and robust effect on lapses. Accordingly, sleep deprivation increased lapses more than two fold ($p<0.05$) and time spent awake before each session predicted lapses ($p<0.01$). Subjective ratings of sleepiness were a more variable predictor. Controls argued against learning / motivation / circadian factors as affecting lapses.

Next, visually-evoked neuronal activity during PVT was examined. 96 neurons (18% of MTL

neurons) responded significantly to pictures. We compared neuronal activity during lapses vs. trials with identical images associated with fast correct behavioral responses. Importantly, focusing on correct trials rules out eye closure and micro-sleeps. During lapses, unit responses in multiple MTL regions exhibited a significant suppression ($p<0.01$) in firing rates 200-300ms after image onset. Such suppression was local - could not be detected in non-responsive MTL or frontal channels. Visual presentation also led to increased power in high (>40Hz) frequency LFPs and decreased power in low (<20Hz) frequencies. During lapses, low-frequency power was significantly increased, whereas high frequency power was significantly reduced - in line with suppression in spiking activity. LFP effects were likewise observed mainly locally in the MTL. These findings suggest that in humans, as in rats, "local sleep" during wakefulness may underlie the cognitive effects of sleepiness.

Title: Fading signatures of critical brain dynamics during sustained wakefulness in humans

Authors: *C. MEISEL[1], E. OLBRICH[2], O. SHRIKI[1], P. ACHERMANN[3];
[1]NIMH, Bethesda, MD; [2]Max Planck Inst. for Mathematics in the Sci., Leipzig, Germany; [3]Univ. of Zurich, Zurich, Switzerland

Abstract: Sleep encompasses roughly a third of our lifetime, yet its purpose and biological function are not well understood. Without sleep optimal brain functioning such as responsiveness to stimuli, information processing or learning may be impaired. Such observations suggest that sleep plays a crucial role in organizing or reorganizing neuronal networks of the brain towards states where information processing is optimized.
Increasing evidence suggests that normal cortical activity operates near a critical state characterized by balanced activity patterns. Theory and experiment have shown that such critical dynamics optimize information processing.
However, it remains unknown whether critical dynamics is affected in the course of wake and sleep which could account for changes in information processing capabilities.
Here, we investigate the hypothesis that wakefulness moves cortical networks away from a

critical state which is restored by sleep.
We analyze EEG from eight healthy subjects during a 40 hour period of sustained wakefulness (sleep deprivation) and after recovery sleep.
We find the precise power-laws governing the cascading activity of neuronal avalanches and the distribution of phase-lock intervals (PLIs) under normal conditions to be increasingly disarranged towards a bimodal distribution during sustained wakefulness. Accordingly, we find the branching parameter to be close to 1 initially indicating that one event on average leads to one future event and to significantly increase to a value larger than 1 with growing sleep deprivation. We conclude that the decline of balanced activity indicates a progressive distance from criticality towards states characterized by an imbalance towards excitation where larger events prevail dynamics. Conversely, sleep restores the critical state resulting in recovered power-law statistics and branching parameter. These findings support the intriguing hypothesis that sleep may be important to reorganize cortical network dynamics to a critical state thereby assuring optimal computational capabilities for the following time awake.

Title: Reproduction of whole-head MEG and EEG patterns during Human Sleep Spindles in a large scale neural model with realistic cortical anatomy

Authors: E. MUKAMEL[1], D. J. HAGLER JR.[2], G. P. KRISHNAN[3], E. PETRILLO[3], S. S. CASH[4], T. SEJNOWSKI[1], *M. V. BAZHENOV[5], E. HALGREN[2];

Abstract: Sleep spindles are prominent thalamocortical bursts of 10-15Hz oscillations lasting ~1s. They have been implicated in memory and disease, and their neurobiology at a circuit, synapse and channel level have been extensively studied in animals. Spindles measured with the electroencephalogram are largely synchronous and distributed, whereas those measured with the magnetoencephalogram are largely asynchronous and focal, leading to the hypothesis that the

former are generated by the matrix thalamocortical system, and the later by the core. Here we test this hypothesis with a computational neural model containing both matrix and core elements in the thalamus and cortex. The thalamus implements all relevant intrinsic currents. The cortex includes 25,600 patches realistically arranged on the folded cortical surface. The cortical activity during modeled spindles is propagated to the EEG and MEG sensors. Three models are examined, a 'core model' with a single focal thalamo-cortical spindle generating system, a 'matrix model' with a single diffuse system, and a 'core/matrix model' with separate but interacting focal and diffuse systems. Only the core/matrix model reproduced the empirically observed topography, strength and coherence of EEG and MEG during spindles. The core/matrix model explicitly represents the interaction of focal and diffuse thalamo-cortical systems, with readily obtained empirical predictions at multiple levels. This integration of focal with distributed information processing may be a general mechanism of thalamocortical physiology.

Title: Sleep stage transitions in the network model of the thalamocortical system

Authors: *G. P. KRISHNAN[1], E. HALGREN[2], M. BAZHENOV[1];
[1]Univ. of California, Riverside, Riverside, CA; [2]UCSD, San Diego, CA

Abstract: In the EEG, stage two of sleep is characterized by spindle activity (8-12 Hz) and the occasional K-Complex, while stage three or slow wave sleep is characterized by the slow oscillation (< 1 Hz). Activation of neuromodulatory systems controls transition between sleep states. An increase in the level of acetylcholine release associated with activation of nicotinic and muscarinic receptors depolarizes cortical pyramidal cells and thalamic relay cells both in awake states and during REM sleep. This effect is achieved mainly by blocking resting potassium conductances in these cells. Furthermore, in states of arousal when forebrain activity is high, intracortical synapses are relatively depressed via presynaptic GABA-B and muscarinic receptors. In this study, we show that a decrease in intracortical excitatory connections is sufficient for the transition from slow oscillation to stage two sleep. We demonstrate this using a

computational model of the thalamocortical network including core and matrix thalamic relay cells, reticular thalamic neurons and cortical layers. The network displayed stage two sleep activity with intermittent spindles at 8 Hz in thalamic and cortical neurons similar to experimental studies. External stimulation applied to thalamic reticular neurons led to isolated Down states - K-Complexes - in the entire thalamocortical network. Upon increase of the strength of excitatory intracortical connections, sleep slow oscillation like activity emerged in the network. The increase in excitatory connections was sufficient to induce active (Up) and silent (Down) cortical states which occurred synchronously across the network leading to the average activity around 1-1.5 Hz. The active states lasted for 500-600 msec, while silent states lasted for 100-300 msec. Increasing potassium leak conductance, an effect associated with decreased acetylcholine release during deep sleep, facilitated the transition to slow oscillations. The transition between sleep stages occurred abruptly in the model with a short period of mixed activity. Overall, this study confirms that the change in synaptic connection strength which is produced by activation of neuromodulatory systems can act as a primary mechanism for the transition between stage two sleep and slow wave sleep.

Title: Longitudinal data reveal a linear increase in the frequency of peak sigma power across ages 6-18

Authors: *N. DARCHIA[1], I. G. CAMPBELL[2], I. FEINBERG[2];
[1]Ilia State Univ., Tbilisi, Georgia; [2]Dept. of Psychiatry and Behavioral Sci., Univ. of California, Davis, CA

Abstract: Sleep and EEG change substantially across childhood-adolescence. NREM delta (1-4 Hz) power increases steeply in infancy to a maximum in mid-childhood and then begins a slow decline that accelerates sharply at age 12, falling by about 60% in the next 5 years. NREM theta power begins age decline earlier than delta but its decline also accelerates sharply between 12-16.5 years. A third key NREM frequency is sigma (12-15 Hz) whose power is largely determined by sleep spindles. It has previously been shown that the frequency of peak sigma

power shifts during adolescence. But the trajectory of this shift has not been established. Our longitudinal study now enables us to describe this age trend.
Semi-annually all night EEG was recorded in 92 children in 3 cohorts: C6 (n=25, 11 girls) started at age 6, studied for 4 years; C9 (n=30, 15 girls) started at age 9, studied for 7 years; C12 (n=37, 18 girls) started at age 12, studied for 6 years. EEG was recorded on consecutive nights at the subjects' homes on habitual school-night sleep schedule. Artifact-free epochs were analyzed with FFT (PASS PLUS, St. Louis). We calculated average power across the first 5 hours of NREM sleep for 0.2 Hz bands between 10.8 and 15.0 Hz, and determined the 0.2 Hz band in which sigma power showed a clear peak.
The maturational trend for sigma differed from the patterns seen for delta and theta. Maturational trends differed among frequencies within sigma: power decreased with age in low sigma frequencies (e.g. 12.0-12.2 Hz, $F_{1,861}$=64.3, $p<0.0001$) and increased with age in mid-sigma frequencies (e.g. 13.6-13.8 Hz, $F_{1,861}$=28.0, $p<0.0001$). This difference in maturational trajectories among frequencies was largely due to the steady linear increase in the frequency of peak sigma power ($F_{1,841}$=119, $p<0.0001$) with age. The rate of increase had not slowed by age 18 years.
The linear increase in frequency of peak sigma power across ages 6-18 yrs may be a manifestation of a general developmental trend to faster EEG frequencies perhaps reflecting maturation of thalamocortical circuits thought to generate sleep spindles. It is striking that the linear age trend in peak sigma frequency differs from the non-linear delta and theta maturational trends, trends that we have proposed reflect cortical maturation driven by synaptic pruning. It is biologically interesting that the age pattern of sigma differs from that of delta even though their occurrence is systematically related within NREM sleep. The remarkably robust and strikingly different maturational trajectories in the major NREM frequency bands further demonstrate the value of the sleep EEG as an arena to study, non-invasively, the neuroscience of sleep and brain development.

Title: Estimation of the number of internal states in the brain as an indicator for the conscious level and content: An ECoG study in monkeys

Authors: *T. YANAGAWA[1], N. OOSUGI[1,2], N. HASEGAWA[1], N. FUJII[1];
[1]Brain Sci. Inst., RIKEN, Wako Saitama, Japan; [2]Dept. of Life Sciences, Grad. Sch. of Arts and Sci., The Univ. of Tokyo, Tokyo, Japan

Abstract: One key characteristic of consciousness is segregation and integration of psychological processes (Tononi 2004), which is believed to correlate with the network complexity of underlying brain dynamics. Previous studies showed that neural activity evoked by external stimuli had more complex pattern in conscious state than in loss of consciousness (Massimini et al, 2005). However the way to quantify the network complexity from ongoing neural activity without external stimuli was not well established. Here, our goal was to use the total number of internal states in the brain as an indicator for the network complexity, and verify its link to the level and/or the content of consciousness.
We recorded electrocoticographic (ECoG) signals from most of the lateral cortex in five macaques during awake (eye-open, eye-closed), sleeping (slow-wave), and anesthetic conditions. Ketamine-medetomidine and propofol were used for the anesthetic agents. ECoG signals were binned by 200ms non-overlapped windows, and the power spectrum was calculated for each window and each channel from 5 to 100Hz. For each frequency band, the number of internal states was defined as the number of spatial patterns in the powers, which was automatically determined by a cluster analysis. We found the number of internal states in gamma frequency band was significantly greater in the awake condition than in the anesthetic and sleeping conditions. The findings suggest that non-conscious state (under anesthesia or slow-wave sleep), compared to the conscious state (awake), could be characterized by the decrease of complexity in neural dynamics. Furthermore, the number of internal states was calculated for each cortical region. We found a significant difference between the numbers of internal states in the primary visual cortex between eye-open and eye-closed states in the awake condition, which suggests that the number of internal states could also reveal the content of consciousness (visual awareness).

Title: Facial muscle contractions during REM sleep and its association to Rapid Eye Movements and emotional dreamed content

Authors: *A. P. RIVERA[1], I. RAMÍREZ SALADO[1], E. LÓPEZ RUIZ[1], O. PROSPÉRO-GARCÍA[2];
[1]Chronobiology and Sleep Department, Neurosci. Div., Inst. Nacional De Psiquiatria Ramon De La Fuente, Mexico, Mexico; [2]Lab. de Canabinoides, Dept. de Fisiología, Facultad de Medicina, Natl. Autonomous Univ. of Mexico, Mexico, Mexico

Abstract: Facial muscle contractions (FMC) are features commonly associated with emotional expression during waking, yet poorly studied during sleep. Recent studies show a pattern during sleep in both healthy subjects and patients with major depression, in which FMC have a significantly higher frequency and amplitude during Rapid Eye Movement (REM) sleep than during non-REM (NREM) sleep and show an association to the Rapid Eye Movements (REMs) proper of this sleep stage. Notably, as previous studies demonstrated, REMs are also associated with emotional dream mentation (EDM). Yet, the possible functional relationship between FMC and EDM, remains unexplored.
This study analyzed FMC of the corrugator and zygomatic major -two facial muscles typically associated with emotional expression- and explores possible temporal correlations of EDM in healthy subjects during REM sleep. Additionally, it examined the interaction between FMC and REMs with EDM.
Two 8h sleep recordings were obtained from 6 female volunteers. Facial EMG recordings were obtained from the corrugator supercilii and zygomatic major (left and right) muscles. Sleep was scored using the standard AASM criteria. On the second night, FMC were visually measured.
Experimental awakenings exploring EDM (through narration, rating of a dream scale, and Dreams Qualified Report) were performed during REM sleep stages that lasted at least three minutes. Awakenings were determined by a FMC that lasted more than 100 ms and by the amplitude of any facial muscle that exceeded by 500% the background EMG activity. Additionally, experimental awakenings were performed during NREM and REM sleep stages without FMC. Following sleep recordings, FMC and REMs were quantified and analyzed for possible correlations between them. EDM global scores were gauged by exploring their correlation coefficients.
Periods with FMC and REMs were associated to higher levels of EDM in healthy subjects as compared to periods without FMC. Moreover, EDM modality (e.g. happy vs. anxious) was linked to certain muscle activation (e.g. higher FMC of zygomatic vs. lower corrugator).
The present study shows that during REM sleep with FMC (vs. periods without FMC) the corrugator, zygomatic muscles and REMs are associated to EDM. Additionally, FMC were differentially associated to emotional modality according to the activated facial

muscle.Altogether, these findings are consistent with theoretical perspectives of higher emotional variations during REM sleep associated to dream content.

Title: Thalamocortical localization of human K-complexes using SEEG

Authors: *R. A. MAK-MCCULLY[1], B. ROSEN[1], H. BATUJI[3], R. CARRON[4], D. SCAVARDA[5], P. CHAUVEL[5], F. BARTOLOMEI[6], M. REY[7], E. HALGREN[2]; [2]Radiology, [1]UCSD MMIL, La Jolla, CA; [3]INSERM U879, Bron, France; [4]Service de Neurochirurgie Fonctionnelle et Stéréotaxique, Assistance Publique des Hôpitaux de Marseille, Marseille, France; [5]Faculté de Médecine, Aix-Marseille Univ., Marseille, France; [6]Lab. de Neurophysiologie et Neuropsychologie, INSERM, U751, Marseille, France; [7]Service de Neurophysiologie Clinique, Ctr. Hospitalier Universitaire Timone, Marseille, France

Abstract: K-complexes (KCs) occur as isolated downstates during stage 2 NREM sleep. KCs show a prominent frontal-central distribution in humans when measured with EEG, ECOG, or MEG. Bipolar SEEG recordings, however, are insensitive to volume conduction, allowing a highly local and focal measure of KC generation. We examined the cortical distribution of KCs and the correlation between the thalamus and cortex during KCs using SEEG recordings from patients undergoing evaluation for epilepsy. All patients studied (four male and two female, not analyzed by sex) had depth electrodes in both the thalamus and cortex. Cortical KCs were identified on a scalp EEG channel or relevant cortical bipolar contact when scalp EEG was unavailable. A significant drop in high gamma power at the time of the KC in cortical bipolar contacts verified that these events were isolated downstates (i.e. KCs). We found that KCs occur focally and locally across the cortex but are not seen in all leads. KCs can correlate with KCs in other cortical locations, as well as in the thalamus. The relative cortical and thalamic electrode locations influence these correlations. Along with KCs, spindles are the other hallmark of stage 2

sleep and have a known thalamocortical mechanism. The KC is also identical to the downstate of the slow oscillation (~1Hz) that emerges in stage 3 sleep. The slow oscillation has been considered a cortico-cortico process that may be synchronized by the thalamus; therefore, understanding the thalamocortical interactions underlying KCs helps elucidate its relationship to other sleep graphoelements, as well as its function.

Title: Occurrence of delta rhythm in awake human intracranial local field potential recordings

Authors: *R. N. SACHDEV[1], I. I. GONCHAROVA[2], N. GASPARD[2], L. J. HIRSCH[2], D. A. MCCORMICK[3], D. D. SPENCER[4], H. P. ZAVERI[2];
[1]Neurobio., Yale Univ. Sch. of Med., NEW HAVEN, CT; [2]Neurol., [3]Neurobio., [4]Neurosurg., Yale Univ. Sch. of Med., New Haven, CT

Abstract: The scalp EEG and the intracranial local field potential of the neocortex are widely used as a measure of the cortical state. At any one moment during sleep the entire cortex is thought to be in a single state, i.e. in slow wave or rapid eye movement sleep. Similarly, during wakefulness the entire cortex is thought to be in a persistently activated state where the EEG is dominated by frequencies in the theta to gamma range (5 Hz and upwards). Recent work in rodents has challenged these ideas about the nature of neocortical activity during wakefulness. In quietly sitting awake mice the local field potential and membrane potential of single neurons in somatosensory and auditory cortex can show oscillations in the delta (1-4 Hz) range. Whether local delta is simply a phenomenon of rodent neocortex or also occurs in the human brain is not known. Here we used chronic (up to 2 week-long) intracranial EEG recordings in patients, who were being prepared for surgical intervention, to look for evidence of local slowing during wakefulness. Two one hour-long segments of video and intracranial EEG, were taken for analysis. One epoch was 2-3 days after implant of > 100 intracranial electrode contacts that spanned a large and variable extent of the neocortex, and a second epoch obtained from the same

electrodes occurred ~ 7-8 days after the electrodes had been implanted, and anti-epileptic drugs had been tapered off or stopped. Video for each hour was inspected for whether the patients were active and awake. These recordings reveal that in all 12 patients, before and after drugs had been tapered off, there was significant (> 3 standard deviations of the mean delta power estimated over an average of 114 contacts) delta activity on approximately 10 % of the recording sites, even when other recording sites showed little evidence of delta activity. The cortical area that showed delta rhythm varied from patient to patient, and the site was distinct from the post-operatively determined site of seizure onset. During the epochs of delta, local recording sites (within a centimeter) showed significant coherence, while more distant recording sites showed no significant coherence, indicating that this state was not akin to the epochs of slow wave sleep, when the entire montage of > 100 recording sites show very similar, coherent delta rhythm. Thus, during wakefulness even in human beings, there is no obligatory, spatially broad, persistently activated state dominated by high frequency activity. Instead, when people are awake some cortical areas can be in states dominated by delta rhythm.

Title: The effect of chronotype on stress response, sustained attention, and emotional memory

Authors: C. GOBIN[1], A. I. FINS[2], J. B. BANKS[1], *J. L. TARTAR[1];
[1]Farquhar SBS, [2]Ctr. for Psychological Studies, Nova Southeastern Univ., DAVIE, FL

Abstract: Extreme morning or evening chronotypes often experience difficulties in emotion processing and report mood disturbances. For example, individuals with an extreme evening preference have a high prevalence of learning problems and poor psychological health (Dagan and Einstein, 1999; Ottoni, Antoniolli & Lara, 2012; Shirayama et al., 2003) and individuals with an extreme morning preference show higher rates of depressive disorders (Xu, et al., 2005). However, the extent to which chronotype affects psychological functioning amidst stress is unknown. In an effort to shed light on this uncertainty, we examined the relationship between chronotype and stress responsivity. We administered a placebo or experimental cold-pressor test

(CPT) stressor prior to the cognitive and emotional task in the early morning (0900-1000) or evening (2100-2200) at times that were both congruent and incongruent with participant's self-reported chronotype in an independent samples design. Following placebo or stress exposure, participants were tested on emotional memory recognition and sustained attention (SART task) performance. In addition to the chronotype scale (MEQ), participants also filled out a series of questionnaires related to psychological health (CES-D, STAI, and POMS) and a sleep quality inventory (PSQI). Cortisol levels before and after the stressors were also measured. We also tested how chronotype-associated polymorphisms in the Per3 gene are related to the ability of acute stress to affect emotional and non-emotional task performance in the morning and evening. Preliminary analyses indicate that performance for an emotional task is affected when the testing time is incongruent to an individual's chronotype. However, this is not the case for a non-emotional sustained attention task- testing time does not affect SART task performance at chronotype-incongruent times. Combined these findings illustrate how individual chronotype can affect cognition and stress responses.

Title: Computational study of sleepiness and circadian rhythms on rotating shift schedules

Authors: *S. POSTNOVA[1], D. D. POSTNOV[2], P. A. ROBINSON[1];
[1]The Univ. of Sydney, Sydney, Australia; [2]The Univ. of Copenhagen, Copenhagen, Denmark

Abstract: Desynchrony of circadian rhythms and disturbed sleep during shiftwork lead to fatigue and significantly increased risks of cancer, diabetes, and heart disease. Nevertheless, shiftwork is an integral part of our 24-h society, and an average of 20% of the population work shifts. It is, thus, essential to find conditions reducing sleepiness and circadian desynchrony in shiftworkers. However, experimental studies are highly mixed due to the enormous number of different schedules used in industries. Here we use computational approach to examine sleep and circadian dynamics on widely spread 3-shift rotating systems in order to pin down the biological mechanisms underlying experimental observations and to predict shift schedules with minimal disturbances.

We use a physiologically based mathematical model of sleep-wake cycles and circadian system which incorporates the mutual inhibition between the sleep-active ventrolateral preoptic nucleus of the hypothalamus and the wake-active monoaminergic nuclei in the brainstem and hypothalamus. The switch in the dynamics of these nuclei is controlled by the homeostatic and circadian processes, with the circadian process being regulated by the suprachiasmatic nuclei of the hypothalamus. The circadian phase is entrained by light input, which is itself changed by shift times and sleep dynamics. This combined model has been validated on a number of sleep phenomena, including normal sleep, circadian desynchrony, and permanent shiftwork.
Using this model we examined how sleep and circadian dynamics are affected by three major factors: (i) rotation speed, i.e., number of days on each of the 3 shift types; (ii) shift start time; and (iii) direction of rotation, i.e., forward versus backward. Consistent with experimental observations we find that for forward schedules very quick and very slow rotation leads to significantly lower sleepiness compared to intermediate rotation speeds. In this case shift start time does not have a significant effect on the resulting sleepiness. The situation is different for backward rotation. In this case shifts starting around 04:00 - 05:00 have low sleepiness even at intermediate rotation speeds, while quick rotation can be associated with significantly higher sleepiness depending on the duration of changeover time between the different shift types. We also find that forward rotation is generally better than backward for quick (1-2 days) and slow (>9 days) rotation, but backward is of advantage for intermediate speeds. This study helps explaining mixed experimental observations, and provides a framework for better understanding of sleep dynamics during shiftwork.

Title: Single units in the human medial temporal lobe during propofol anesthesia

Authors: *J. NIEDIEK[1], M. NAVRATIL[1], V. A. COENEN[2], C. E. ELGER[1], M. SOEHLE[3], F. MORMANN[1];

[1]Dept. of Epileptology, [2]Stereotaxy and MR based OR Techniques, Dept. of Neurosurg., [3]Dept. of Anaesthesiology and Intensive Care Med., Univ. of Bonn, Bonn, Germany

Abstract: General anesthesia induced with the anesthetic drug propofol globally reduces neuronal activity in a dose-dependent manner. However, the effect of propofol administration on single neurons in the human brain cannot be examined with classical non-invasive methods such as fMRI, PET, or EEG. We used single-unit recordings from, up to now, eight epilepsy patients to investigate the precise time-course of single neuron activity in the human medial temporal lobe (MTL) during propofol anesthesia.
We recorded the activity of single neurons in the MTL of neurosurgical patients undergoing epilepsy monitoring prior to resective surgery. These patients were implanted with, most often, eight intracerebral depth electrodes to precisely locate the epileptic focus. Each depth electrode was equipped with eight micro-wires protruding from its tip. The electrodes were explanted after the epilepsy monitoring had ended, typically one or two weeks after implantation. For the anesthesia protocol, estimated propofol effect-site concentrations were raised to a level where loss of consciousness occurred, and then further until burst suppression was observed.
We analyzed the activity of 38 single- and multi-units in the hippocampus, amygdala, entorhinal cortex, and parahippocampal cortex. All units completely ceased to fire at high propofol concentrations, and started to fire again when the propofol concentration dropped. All observed units maintained their baseline firing rate over an extended range of low propofol concentrations. Remarkably, when the propofol concentration reached a certain critical level, units stopped firing in an abrupt, rather than gradual, manner. Hippocampal neurons showed a tendency to stop firing earlier than did neurons in other MTL regions. Furthermore, the clinical loss of consciousness appeared to coincide with the cessation of neuronal activity in the MTL.
Our data reveal that during propofol anesthesia, neurons in the human MTL maintain their firing across a large range of propofol concentrations, but completely stop firing when a critical concentration is reached. Behavioral studies have shown that propofol administration reduces performance in memory tasks associated with the MTL. Whether the observed firing cessation is a neural correlate of impaired memory function remains to be tested in future studies.

Title: Do specific common sleep postures independently evoke headaches and breathing obstruction?

Authors: N. AL-TIMIMI[1], *J. GILLICK[2];
[1]NEUROSCIENCES, [2]Anesthesiol. & Med., UCSD, San Diego, CA

Abstract: Specific common twisted sleep postures are independently associated with: 1) onset, recurrence and laterality of pattern headache disorders (pHA); and, 2) the presence of sleep disorders.
Data:
A history and myofascial-exam data sheet was completed during a comprehensive general medical evaluation in 367 consenting compensation applicants. The data sheet was attached to exam-notes and a copy given to the subject. After limited data extraction, the report and notes were submitted/ filed. GpA, the first 109, selected for TMJ, bruxism or jaw tenderness, were queried in specifics of sleep posture, HA details, and work impact. GpB, 258 unselected, sequential subjects provide prevalence and parallel, less detailed data.
Current Sleep Postures: The evaluator and each subject mutually agreed on the accuracy of sleep posture recorded:
TCU: (GpB=201/258; GpA=106/109) (Twisted ± curled-up) as current 1° sleep posture ⇒ chest side-twisted down, face-neck twisted to breathe, Knee(s) bent >90°; and,
NBP: (GpB=37; GpA=0) (Neutral body posture) as current 1° sleep posture ⇒chest, neck, face are neutral, untwisted; knees bent <90°.
Pattern headaches (pHA) are similar in: onset time; duration; start area; impairment level; frequency; ± autonomic signs.
Results:
Pattern headaches (pHA)-GpB -(also reflect GpA)
pHA frequency in 201 TCU is 90% = 30-x's > 3% in 37 NBP.
Face-neck twist direction & pHA side: both ⇒right in 61%.
Face-twist direction & pHA side, both ⇒left in 38%.
Neck pain (CS) in TCUs is 90% = 8-x's > 16% in NBP.
pHAs are 83% ipsilateral with CS: right ⇒56%; left ⇒27%; mixed ⇒17%
Pterygoid (LPt) muscle spasm with Trigeminal ganglion hypersensitivity :TCU is 96% = 32-x's > 3% in NBP.
LPt, pHA, & CS =79% ipsilateral dominant: right ⇒56%; left ⇒23%; mixed ⇒21%
pHA- Functional impact details (GpA):
Affect: 86% (91) have pHA: 1/3-ignore it as background; 1/3 episodically self-treat; &, 1/3 affect ADL's enough to seek medical advice ± self-treat.
pHA- Work Loss (>6 hr/wk) occurs in 63%= 67 [46% ⇒lose focus ≥2 hr ≥3d/wk; 16% ⇒non-productive or absent ≥5 x ½d/mo; 38%⇒lose 2 to 6 full days/wk.]

Sleep Dysfunctions (SD) are common in TCU:
They include: Proven sleep apnea (OSAS); Suspected sleep apnea- history alone (sOSA); & Pain, psych and snoring (Other).
GpA: In the 106 with TCU, SD= 93%: OSAS=46%; sOSA= 25%; & Other= 27%.
GpA has no NBPs.
GpB: In the 201 with TCU: SD= 95%= 12-x's >8% in NBP; OSAS= 48%, 0 in NBP; sOSA= 33%, 0 in NBP; &, Other= 16%= 2-x's >8% in NBP
Start of TCU behavior,
TCU, ±32%, start as small children; 68% start as adults⋯including related background presence of pHAs, neck stiffness, restless nights, etc.

Title: Sleep slow oscillations modulate brain-wide information processing

Authors: *R. COX, J. VAN DRIEL, L. M. TALAMINI;
Dept. of Psychology, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: During deep sleep, slow rhythmic brain signals alternate between depolarized UP states and hyperpolarized DOWN states at a frequency around 0.7 Hz. These slow oscillations travel in a predominantly anterior-to-posterior direction across the scalp. UP states are characterized by greater sleep spindle (10-16 Hz) and gamma (50-80 Hz) power, higher neuromodulatory activity, enhanced excitability and increased spiking. Thus, most brain processing appears to occur in the UP, rather than the DOWN state. Although studies of functional connectivity across various sleep stages have been performed, the question of whether and how slow oscillations modulate functional connectivity remains unexplored.
We detected slow oscillation peaks and troughs in 128-channel EEG recordings of six napping participants, using multiple seed electrodes located at frontal, central and parietal midline sites as well as left- and right-sided sites. Resulting UP and DOWN state epochs were compared in the time-frequency domain between 3 and 100 Hz across all recording sites. We investigated power

modulations, phase synchrony and cross-frequency coupling, both within and between sites. Preliminary data reveals a strong coupling of power in the sleep spindle and gamma bands to the UP state. Spatially, this coupling was largely limited to a topographical region surrounding the seed electrode used for UP/DOWN state detection. Combined with existing evidence of slow oscillations behaving as 'traveling waves', our data suggest that as UP states move across the scalp, they carry with them an island of enhanced information processing. Ongoing analyses will provide additional insight into how measures of functional connectivity are affected by slow oscillations.

Title: Cumulative sleep restriction alters lipid metabolism - transcriptomic and metabolomic studies in humans

Authors: *V. AHO[1], H. M. OLLILA[2], T. PORKKA-HEISKANEN[3];
[1]Inst. of Biomedicine, Univ. of Helsinki, Helsinki, Finland; [2]Natl. Inst. for Hlth. and Welfare, Helsinki, Finland; [3]Inst. of Biomedicine, Helsinki, Finland

Abstract: Objectives: Short or insufficient sleep has been associated with increased risk for metabolic diseases, such as atherosclerosis and type II diabetes. To elucidate the molecular mechanisms linking sleep homeostasis and metabolism, we compared transcriptomic and metabolomic profiles of partially sleep-deprived subjects to normally sleeping controls at experimental and epidemiological levels.
Materials: For the experimental study simulating a 5-day working week with restricted sleep, subjects spent a week in laboratory conditions. After two nights' baseline sleep (8 hours sleep/night), subjects were partially sleep deprived for five successive nights (4 h/night) followed by two nights' recovery sleep (8 h/night). Control subjects spent the time in laboratory sleeping normally (8 h/night). Fasting blood samples were collected from 10 sleep-deprived and 6 control subjects after baseline, sleep restriction (SR), and recovery phases.
The epidemiological sample was a subset of a Finnish population-based sample Finrisk2007. For the DILGOM subsample, subjects (N=518) filled a questionnaire including questions on sleep sufficiency and gave fasting blood samples.

Methods: Lipid profiles including lipoprotein particle species, cholesterol, and triglycerides were measured from serum with NMR metabolomics. Total RNA was extracted from blood mononuclear leukocytes, and RNA expression was analysed using Affymetrix whole genome microarrays complemented with pathway analyses of differentially expressed genes.
Results: The most enriched pathways among genes that were down-regulated after experimental SR were involved in metabolic processes, such as cholesterol transport and homeostasis ($P<0.001$). Supporting this, in the epidemiological sample, these pathways were also enriched among genes whose expression was lower in subjects reporting insufficient sleep (SRIS) ($P<0.05$).
However, the metabolomic screening showed a different effect for the two samples. In the experimental study, the lipoprotein profile after SR seemed beneficial with less low density lipoprotein (LDL) particles ($P<0.01$), apolipoprotein B (apoB) ($P<0.005$), and LDL cholesterol ($P<0.0005$). On the contrary, in the epidemiological sample the SRIS had lower levels of high density lipoproteins (HDL) ($P<0.01$).
Conclusions: Under conditions of both short-term and long-term sleep restriction, lipid - particularly cholesterol- metabolic pathways are significantly modified at the level of transcription as well as at the level of serum lipoprotein profiles. We propose that these mechanisms may contribute to the development of cardiovascular diseases.

Title: Global brain blood-oxygenation level dependent responses to autonomic challenges in obstructive sleep apnea

Authors: *P. M. MACEY[1,2], R. KUMAR[3], J. A. OGREN[1], M. A. WOO[1], F. L. YAN-GO[4], R. M. HARPER[3];
[1]UCLA Sch. of Nursing, [2]Brain Res. Inst., [3]Dept. of Neurobio., [4]Dept. of Neurol., Univ. of California at Los Angeles, Los Angeles, CA

Abstract: Obstructive sleep apnea (OSA) is accompanied by brain injury and dysfunction in regions that regulate autonomic action, which may impair regulation of cerebral blood flow and

oxygenation and contribute to other syndrome pathologies, such as exaggerated sympathetic tone. The objective was to assess cerebral blood oxygenation responses to autonomic challenges in OSA over control subjects. We separately assessed female and male patterns, since OSA characteristics and brain injury differ between sexes. We studied 94 subjects, including newly-diagnosed, untreated moderate-severe OSA patients (6 female age mean±std: 52.1±8.1 years; 31 male 54.3±8.4 years), and healthy control subjects (20 female age 50.5±8.1 years; 37 male age 45.6±9.2 years). We measured responses every 2 s with the global blood-oxygenation level dependent (BOLD) signal using an MRI scanner while subjects performed cold pressor, hand grip, and Valsalva maneuver challenges. All challenges elicited rapid changes in BOLD signals which differed between groups to the cold and hand grip challenges (cold pressor peak at 8 s: OSA 0.14% vs. 0.31% in controls; hand grip: peak at 6 s in control, but decline in OSA), but not to the Valsalva (repeated-measures ANOVA, $p<0.05$). OSA females showed greater differences in magnitude and temporal patterns of responses relative to their healthy counterparts from the OSA males (cold pressor: female OSA peak 0.19% at 8 s vs. 0.35% at 12 s in controls, 8 s peak male OSA 0.13% vs. 0.34% in control; hand grip: no female OSA vs. control differences, 6 s peak male OSA 0.04% vs. 0.30% in controls; Valsalva: at 4 s 1% lower in female OSA vs. control, no difference in males). Obstructive sleep apnea patients show reduced and slower-to-develop brain BOLD responses to autonomic challenges, relative to healthy controls. The impaired brain and peripheral vascular responses are more pronounced in females than males. The findings emphasize the consequences of OSA to vascular processes, which have the potential to result in further neural injury, interfere with timely perfusion of brain tissue, and modify performance of those structures.

Title: Multi-voxel pattern analyses reveal similarities and differences in the semantic representations of words and objects

Authors: B. J. DEVEREUX, A. CLARKE, A. MAROUCHOS, *L. K. TYLER;
Dept. of Psychology, Univ. of Cambridge, Cambridge, United Kingdom

Abstract: Understanding the meaning of words and objects (e.g. “apple”) requires the activation of underlying conceptual representations. Such representations are assumed to be coded such that meaning can be evoked irrespective of the stimulus modality, a view which is supported by evidence of a common semantic system that is activated for both words and objects (e.g. Bright et al. 2004; Martin 2007). However, activation of a common semantic system does not necessitate that these regions represent the same information during word and object processing. A stronger test for modality-invariant semantic representations is provided by multi-voxel pattern analysis (MVPA), which, further to identifying regions involved for both words and objects, also allows us to characterize the similarity of information content in those regions across modality. We ask whether representations are similar across modalities in an fMRI study where words and pictures representing 60 concepts were presented. For both modalities, participants responded with a category-level name for each item. Activation maps for each word and object were extracted and used as input to two searchlight-based MVPA techniques. The first method was representational similarity analyses (RSA). In this model-driven approach, three representational dissimilarity matrices (RDMs) were computed, which captured low-level visual properties of the words and objects and the semantic category structure common to both. These were then correlated with searchlight activation RDMs. The second analyses was a novel data-driven method, using cluster analysis to identify regions of shared information content across modalities.
The RSA revealed strong correlations between the visual model RDMs and the dissimilarity patterns in early visual cortex for both words and objects. For the semantic RDM, there was an extensive left-lateralized network of significant correlations for the object data, including the left fusiform gyrus, lateral occipital complex, left posterior middle temporal gyrus (LpMTG) and left angular gyrus (LAngG). The word data showed significant correlations more anteriorly into left MTG, but no significant correlations in the fusiform. As with the object data, there were also significant correlations in LpMTG and LAngG, suggesting these regions may form part of a core semantic network activated during semantic processing of both words and objects. However, the data-driven cluster analysis method showed that the representations computed in these regions do not cluster together across modality, suggesting these regions may play different functional roles for the semantic processing of words and objects.

Title: Multiple time scales of auditory stimulus adaptation in human cortex

Authors: *S. ELIADES[1], N. E. CRONE[2], D. BOATMAN-REICH[2];
[1]Otolaryngology-Head and Neck Surgery, [2]Neurol., Johns Hopkins Univ., BALTIMORE, MD

Abstract: It is well established that cortical auditory evoked responses decrease with stimulus repetition in animals and humans, a phenomenon known as stimulus-specific adaptation (SSA). Little is known, however, about the effects of SSA on high-frequency cortical oscillations (> 60 Hz) which are not phase-locked and are used increasingly to investigate human cortical processing. To address this issue, we recorded electrocorticographic (ECoG) activity from six epilepsy patients with implanted subdural electrode arrays. An auditory odd-ball paradigm was used with tones (frequent: 1000 Hz; infrequent: 1200 Hz) and speech (frequent: /ba/; infrequent: /da/), as well as reversed and equal stimulus probability conditions. Time-frequency analysis was performed to measure statistically significant event-related changes in high gamma (70-150 Hz) power relative to pre-stimulus baseline. Time-domain averaging was used to derive concurrent auditory evoked responses (N100). We found strong adaptation of high gamma power at electrode sites where auditory responses were elicited. Responses to infrequent stimuli were stronger than responses to frequently repeated stimuli for both tones and speech, consistent with previous SSA studies. Multiple adaptation time scales were identified, including rapid adaptation at the onset of a stimulus block and slower adaptation across sequences of stimulus repetitions. Infrequent stimuli and equal-probability stimuli elicited similar responses, suggesting that differences in responses to high and low probability stimuli reflected adaptation of the high probability response. Although the auditory evoked N100 showed the expected pattern of adaptation, the relationship between high gamma and evoked response adaptation was variable. These results suggest a mechanism for coding high probability auditory inputs that adapts to stimulus regularities on multiple time scales.

Title: Effect of visual context on the activation of move- and use-related actions during semantic object processing

Authors: *A. D. SHAPIRO[1], S. KALÉNINE[2], A. FLUMINI[3], A. M. BORGHI[3,4], L. J. BUXBAUM[1];
[1]Moss Rehabil. Res. Inst., Elkins Park, PA; [2]Lille Nord de France Univ., Lille, France; [3]Univ. of Bologna, Bologna, Italy; [4]ISTC-CNR, Rome, Italy

Abstract: A number of lines of evidence suggest that observation of manipulable objects activates the motor system (e.g., Chao & Martin, 2000; Craighero, Bello, Fadiga, & Rizzolatti, 2002; Martin, 2007; Noppeney, 2008; Tucker & Ellis, 1998). Many manipulable objects, however, are associated with several actions. For example, a tape dispenser may be grasped with a power grip (clench) to move it, whereas the end of the tape may be grasped with a precision grip (pinch) to use it. Recent studies have shown that object processing may recruit both of these action types (Bub, Masson, & Cree, 2008), and that they may compete with each other within single objects (Jax & Buxbaum, 2010; Jax & Buxbaum, 2013). This study explored the hypothesis that evocation of move- or use-related actions is responsive to the congruence of the visual scene in which objects are presented.
Twenty-one healthy adults were asked to categorize object pictures presented in different naturalistic visual contexts that evoke either move- or use-related actions (e.g. tape dispenser in drawer vs. on desk top). Categorization judgments (natural vs. artifact) were performed by making a move- or a use-related action (clench vs. a pinch) on a response device. Categorization reaction times were analyzed as a function of Context (use or move) and Gesture (clench or pinch). Although the actions performed were irrelevant to the categorization judgment, responses were significantly faster when actions were compatible (use context-pinch, move context-clench) compared to incompatible (use context-clench, move context-pinch) with the visual context. Prior demonstrations indicate that action evocation during object processing may be modulated by action intentions (e.g, Pavese & Buxbaum, 2002), distance from the viewer (e.g., Costantini, Ambrosini, Scorolli, & Borghi, 2011), relationships to other objects (Borghi, Flumini, Natraj, & Wheaton, 2012) and verbal context (e.g., Lee, Middleton, Mirman, Kalénine, & Buxbaum, 2013). These data extend such findings by demonstrating that activation of move and use-related gestures during semantic object processing may additionally be modulated by the visual scene in which the objects are presented, with clear implications for object processing in naturalistic tasks.

Title: Contrasting CMSs activity during core-self and autobiographical-self processes

Authors: *H. F. ARAUJO[1,2], J. KAPLAN[1], H. DAMASIO[1], A. DAMASIO[1];
[1]Brain Creativity Inst. - Univ. of Southern California, Los Angeles, CA; [2]Grad. Program in Areas of Basic and Applied Biol. - Univ. of Porto, University of Porto, Portugal

Abstract: At any moment, individuals may access information that pertains to facts and events of their biographies - "the autobiographical self" (Damasio 1998) or "narrative self" (Gallagher 1999) - as well as information that pertains to their current body states - "the core self" (Damasio 1998). The neural bases of these two kinds conscious self processes remain uncertain, although a frequent account associates activity in cortical midline structures (CMSs) with self-reference (Northoff et al. 2006). Here, we investigate the involvement of CMS in domains of autobiographical self and in domains of core-self.
We conducted a block-design fMRI study, in which 19 subjects answered questions about their own traits, their general biography, their current interoceptive states and their current exteroceptive states (4 experimental conditions). In each run, each of the conditions (blocks of 24 seconds) was repeated 3 times and separated by a "one-back task" (also in blocks of 24 seconds). The one-back-task was used as a baseline in order to ensure disengagement of self-related processing. There were three runs per study.
Preliminary analysis of data shows that, compared with conditions of core-self, conditions of autobiographical self are associated with greater activity in CMSs (namely medial prefrontal, anterior cingulate and posteromedial cortices). The reverse contrast (core-self > autobiographical self) yields greater activity in the posteromedial cortex (PMC). These results suggest that the involvement of CMSs in the assessment of self-related information varies according to the kind and quality of the representations involved.

Title: Neural responses to musical consonance and dissonance in the human superior temporal gyrus

Authors: *F. FOO[1], D. KING-STEPHENS[2], P. B. WEBER[2], K. D. LAXER[2], R. T. KNIGHT[1]; [1]Univ. of California, Berkeley, CA; [2]Neurol. and Neurosurg., California Pacific Med. Ctr., San Francisco, CA

Abstract: Research on the neural basis of consonance and dissonance processing in music has depended on non-invasive electrophysiological and functional imaging techniques in humans. However, the fine-grained spatiotemporal dynamics of consonance and dissonance perception within the auditory cortex remain unknown. Using Electrocorticography (ECoG) that records electrophysiological signals directly from subdural grids located on the lateral surface of human cortex, we aimed to investigate whether subregions of the superior temporal gyrus (STG) are differentially responsive to consonant and dissonant chords. We recorded from two patients with extensive ECoG coverage in either left or right STG and additional frontal sites, as they passively listened to highly consonant and highly dissonant piano chords. We observed two cortical sites of interest within the left STG: one that had no difference in response to both consonant and dissonant chords, and another, 2 cm anterior to the former site, that showed increased responses to dissonant chords in the high-gamma frequency range (HG; 70-150Hz) ($p<0.05$, FDR corrected) within the first 100ms after stimulus onset. Event-related potentials showed a similar spatial distribution pattern for consonant and dissonant chords in the STG. Similar HG effects were observed in the right STG, where a cortical site not differing in response to consonant and dissonant chords had an adjacent site (1 cm inferior) that showed increased HG responses to dissonant chords. These data indicate that sensitivity to consonant and dissonant

chords within the STG is apparent at a resolution of 1-2 cm in both hemispheres. Additionally, we observed that a site in left inferior frontal cortex showed increased HG activity 300ms after stimulus onset only for dissonant chords that likely represents a subsequent orienting response to the musical dissonance. We propose that the increase in HG activity for dissonant chords reflects heightened synchronous neuronal firing in response to the phenomena of beats or "roughness" that characterize our perception of dissonance. In sum, the findings indicate that direct cortical recording can track perceptual aspects of musical processing with temporal and spatial precision.

Title: Relationship between brain activity and sense of self-agency during kinesthetic illusory feeling induced by tool use: a functional near-infrared spectroscopy sdtuy

Authors: *S. WAKATA[1,2], S. MORIOKA[2];
[1]Rehabil. institute, Kamigyo Clin., Kyoto, Japan; [2]Dept. of Neurorehabilitation,, Grad. Sch. of Hlth. Sciences, Kio Univ., Nara, Japan

Abstract: [Objective]
When using a tool, the tool becomes assimilated as a part of the body, it is thought that the body schema extends dynamically in real time (Iriki,1996). Self-agency is the feeling that "the body is performing this movement by itself" (Gallagher, 2000), and can be involved when we observe movement out of the body. For example, It is involved when the movement of fingers projected onto a screen lined up with the position of a hand is passively observed (Kaneko, 2004). However, it is unclear whether self-agency is involved when the movement of a tool is projected onto a screen lined up with the position of a hand; furthermore, the underlying neural networks have yet to be elucidated. This experiment aimed to clarify these questions by using functional near-infrared spectroscopy.
[Materials & Methods]
Twelve healthy, right-handed subjects were enrolled in the study. Participants were seated on chairs, and asked to look at a screen. The illusion condition was displayed on the screen as extension of a hand, and the non-illusion condition was shifted on the screen approximately 15

cm left. The tool used was a tongue. Subjective ratings of self-agency were measured using a questionnaire. To determine the difference in the subjective ratings of self-agency between the conditions, we performed a Wilcoxon signed-rank test. To determine the difference in oxygenated hemoglobin (oxyHb) levels between the conditions, we performed one-tailed sample t-tests for each region of interest. Finally, Spearman's rank correlation coefficient was used to evaluate the relationship between oxyHb levels and the subjective ratings of the illusion. The threshold for statistical significance level was set at $p < 0.05$.
[Results]
The illusion condition was scored significantly higher than the non-illusion condition in the subjective ratings of self-agency. In the right prefrontal area, the response during the illusion condition was significantly increased compared to the response during the non-illusion condition, Furthermore, there was a positive correlation between the oxyHb increase and the subjective ratings of the illusion. In the left primary sensory-motor area, the response during the non-illusion condition was significantly increased compared to the response during the illusion condition; moreover, there was a negative correlation between the oxyHb increase in this area and the subjective ratings of the illusion.
[Conclusion]
The left primary sensory-motor area and the right prefrontal area are related to self-agency during kinesthetic illusory feeling induced by tool-use.

Title: Mental imagery and multisensory integration

Authors: *C. C. BERGER, H. H. EHRSSON;
Karolinska Institutet, Stockholm, Sweden

Abstract: Multisensory interactions are the norm in perception, and an abundance of research on the interaction and integration of the senses has demonstrated the importance of combining sensory information from different modalities on our perception of the external world (Stein & Stanford, 2008). However, although research on mental imagery has revealed a great deal of functional and neuroanatomical overlap between imagery and perception (Kosslyn, Ganis, & Thompson, 2001), this line of research has primarily focused on similarities within a particular modality and has yet to address whether imagery is capable of leading to multisensory integration. In recent behavioral experiments, we found evidence in favor of multisensory integration or real and imagined stimuli in adapted versions of classic multisensory illusions. Here, we present the results of a psychophysics ventriloquism experiment (n = 18) and a functional magnetic resonance imagining experiment (fMRI) experiment (n = 22) on an adapted version of the classic ventriloquism illusion that provide convergent evidence of imagery-perception multisensory integration. In the psychophysics ventriloquism experiment, we found that the perceived location of sound became ambiguous earlier on in the spatial 'staircase' when participants imagined the appearance of a centrally located visual stimulus than when no visual stimulus was imagined [$t(17) = 2.39$, $p = 029$], an effect that can be attributed to the translocation of sound toward the imagined visual stimulus. In our fMRI experiment, we found that temporally synchronous (vs. temporally asynchronous) imagined visual stimuli lead to a significant translocation of stationary auditory stimuli towards the
imagined visual stimuli [$t(22) = 2.50$, $p = .021$] and significant activation ($t = 3.34$, $p = .032$, corrected) in the left superior temporal sulcus—a key site for the integration of audiovisual stimuli (Noesselt et al., 2007). These findings provide support for perceptually based theories of imagery and suggest that neuronal signals produced by imagined stimuli can integrate with signals generated by real stimuli of a different sensory modality to create robust multisensory percepts.

Title: The construction of a whole body multisensory gestalt by the human premotor cortex

Authors: *G. GENTILE, M. BJÖRNSDOTTER, V. I. PETKOVA, Z. ABDULKARIM, H. H. EHRSSON;
Karolinska Institutet, Stockholm, Sweden

Abstract: How does the brain construct a unified representation of one's own body that assembles all of its parts into a perceptually coherent whole? Previous research has shown that the integration of bodily signals in multisensory fronto-parietal areas underlies the perception of a limb or an entire body as part of one's physical self. In the present study, we sought to investigate the mechanisms that support the construction of a whole body perceptual gestalt from the representation of its individual parts. In a behavioral experiment on 20 healthy participants, we extended previous work on full-body ownership illusions and showed that the integration of visuo-tactile signals from one of 3 body parts (hand, torso or leg) leads to the generalization of the feeling of ownership from the stimulated body part to the whole body (questionnaire data; $p<0.001$). In an fMRI experiment involving 16 healthy participants, we induced the feeling of ownership of an entire body by applying synchronous touches to the hand, torso, or leg of the participant's unseen real body and a mannequin in direct view from the first person perspective. Asynchronous visuo-tactile stimulation was used as control. We employed multivariate classification to identify patterns of neural activity that were either specific to the representation of a single body part or that generalized significantly across all body parts to create a unified representation of a self-attributed whole body. First, we found that neuronal populations in the left ventral premotor cortex exhibited illusion-specific activity patterns that generalized across all 3 body parts ($p<0.05$ corrected), in line with the construction of a whole body perceptual gestalt. Crucially, this "spread of ownership" from one part to the whole was abolished in a control condition with synchronous visuo-tactile stimulation to a detached hand, proving the importance of viewing an entire body for the full-body illusion to arise. Second, we found that neuronal populations in the bilateral ventral premotor cortices and in the left intraparietal cortex integrated visuo-tactile signals in a body-part-specific fashion ($p<0.05$ corrected), giving rise to disjointed representations of the three body segments. We propose that, on one side, bodily signals are integrated in a body-part-specific fashion by neurons that possess visuo-tactile receptive fields restricted to a single body segment. On the other side, we put forward that the dynamic formation of a whole body gestalt is functionally tied to neuronal populations in the ventral premotor cortex

whose visuo-tactile receptive fields extend to encompass the boundaries of multiple body segments or the entire body.

Title: Stimulus-locked activation of the extrastriate body area during tactile stimulation of the viewed hand

Authors: V. OCCELLI[1], R. STILLA[1], S. LACEY[1], M. LONGO[2], P. HAGGARD[3], *K. SATHIAN[4];
[1]Neurol., Emory Univ., Atlanta, GA; [2]Birkbeck Col., London, United Kingdom; [3]Inst. of Cognitive Neurosci., Univ. Col., London, United Kingdom; [4]Dept Neurol., Emory Univ. Sch. Med., ATLANTA, GA

Abstract: In the visual enhancement of touch (VET) effect, non-informative vision of the hand enhances tactile acuity relative to viewing a non-hand object (Taylor-Clarke, Kennett, & Haggard, Curr Biol 12:233-236, 2002). Although several studies have replicated the VET effect, its neural correlates remain unclear. In the present study, event-related functional magnetic resonance imaging was used to examine neural activation patterns while participants discriminated the orientation of tactile gratings applied to the right index fingerpad. Grating spatial parameters were selected for individual participants to be close to the threshold for orientation discrimination. In separate runs, participants continuously viewed either their own hand (without vision of the stimulated site) or a non-hand object. Data from separate localizer runs were used to identify the extrastriate body area (EBA), a region known to be highly responsive to the images of human bodies or body parts (Downing et al., Science 293: 2470-2473, 2001). We found bilateral EBA activity time-locked to tactile stimulation in the hand-view condition, compared to the object-view condition. In addition to this novel finding, similar activation was also observed in the intraparietal sulcus (IPS), consistent with prior evidence implicating the IPS in the VET effect (Konen & Haggard, Cerebral Cortex, in press). Our findings suggest a possible multisensory function for the EBA in processing body-related inputs.

Title: Preferences for integrative versus schematic sensory imagery across modalities

Authors: *S. A. LACEY, H. FENG, E. CAESAR, M. BHUSHAN, T. JOHN, K. SATHIAN; Emory Univ., Atlanta, GA

Abstract: Visual imagery can be divided into object and spatial subtypes. Object imagery involves pictorial images that integrate surface properties, such as color and texture, with structural information about shape. By contrast, spatial imagery involves more schematic images that tend to ignore surface properties and instead focus on structural information and spatial transformations. Using tasks in which people had to haptically discriminate object shape across changes in texture and vice versa, we showed that these imagery preferences also exist in haptically-derived representations, with haptic performance tending to reflect self-reported visual imagery preferences (Lacey, Lin & Sathian, Exp Brain Res, 213:267-273, 2011). Here, we tested the hypothesis that there are corresponding subtypes of auditory imagery. In one task, we tested whether people could discriminate the auditory structural property of melody across changes in the auditory surface property of loudness. Poor performance would indicate that structural and surface properties are integrated in the image and reflect the auditory equivalent of object imagery. In a second task, people had to discriminate loudness patterns across changes in melody. Poor performance here would indicate that surface properties were not attended and reflect the auditory equivalent of spatial imagery. Participants also completed the Object-Spatial Imagery and Verbal Questionnaire (OSIVQ, Blazhenkova & Kozhevnikov, Appl Cognit Psychol 23:638-663, 2009) and a self-report on imagery preference. We found that, as hypothesized, auditory imagery could be divided into two subtypes: ‘integrative’ imagers incorporated the loudness pattern into their representation of the melody (equivalent to visuo-haptic ‘object’ imagery) whereas ‘schematic’ imagers focused on the melody at the expense of loudness patterns (equivalent to visuo-haptic ‘spatial’ imagery). Preliminary correlation analyses suggest that imagery preferences are stable across the visual and haptic modalities - i.e. a visual object imager

tends also to be a haptic object imager - perhaps because vision and touch can both assess multiple object properties, e.g. shape and texture. However, these preferences did not necessarily extend to the auditory modality, perhaps because auditory stimuli have less in common with visual or haptic stimuli. Whether or not surface properties are integrated into an image may be therefore be an organizing principle of mental imagery across sensory modalities. In order to encompass the three modalities, we suggest that the 'object' and 'spatial' imagery labels be replaced with 'integrative' and 'schematic'.

Title: Perceptual phase entrainment to speech rhythm in the absence of spectral energy fluctuations

Authors: B. ZOEFEL, *R. VANRULLEN;
Ctr. de Recherche Cerveau et Cognition, CNRS, Toulouse, France

Abstract: Speech can be defined by its spectral content (e.g. fundamental frequency and harmonic "formants") and its variable amplitude over time. The fluctuations in amplitude and spectral content occur rhythmically (with a dominant frequency in the theta-band, 2-6 Hz). Recent evidence suggests that neural oscillations in auditory cortex entrain to the speech rhythm, resulting in an alignment of high excitability phases with informative features. However, mechanisms of phase entrainment are still unclear, because in a standard speech sequence the phonetic information (carried by momentary deviations in spectral content), is generally confounded with overall amplitude modulations: There is no phonetic information when spectral energy is absent; and there are moments of silence or low spectral energy between successive phonemes. Therefore, it is not clear whether brain oscillations truly align to fluctuations in phonetic information (a high-level process), or merely to the rhythmic changes in input sound

amplitude (a low-level process).
Here, we disentangle these alternatives by constructing speech stimuli whose spectral energy is constant over time. Original speech snippets were recorded by a male speaker reading parts of a novel. Stimuli were constructed by merging speech with noise, with the amount of noise inversely proportional to the instantaneous energy of the speech. Critically, the noise was designed to have an average spectrum equivalent to the average spectrum of the speech (i.e. fundamental frequency and harmonics). Consequently, total energy was constant over time, and spectral content was statistically comparable at all points in time - but some points merely contained noise while others contained real phonemes. Phonetic information still fluctuated rhythmically at ~2-6Hz, providing potential means for oscillatory phase entrainment. We assessed this entrainment by presenting auditory clicks at threshold level at random moments during our speech/noise snippets. Subjects indicated detection of a click by a button press. We found that detection was best at phases corresponding to original phonetic information and decreased continuously, with worst performance at opposite phases where noise was dominant. Yet by construction, both spectral content and amplitude of the speech/noise sequence were statistically indistinguishable across the different rhythmic phases. Thus, we demonstrate that the auditory threshold can be entrained by the rhythm of speech even when phonetic information is not accompanied by concomitant changes in input sound amplitude. In other words, phase entrainment to speech rhythm entails a high-level process.

Title: Handedness and Perspective during action recognition: Towards a neurophysiological model of action simulation

Authors: *R. KELLY, C. MIZELLE, L. WHEATON;
Georgia Inst. of Technol., Atlanta, GA

Abstract: During daily behavior, the ability to comprehend skilled action is an important aspect to understanding the world around us. Event-related desynchronization (ERD) in the Mu band (8-10 Hz) can be associated with increased cortical activity and can show patterns in motor tasks in the sensory motor system. An event-related synchronization (ERS) may represent inhibited

cortical activity. The purpose of this neurobehavioral study is to evaluate the interaction of handedness and perspective and how it plays a role in our ability to recognize the goals of motor acts. Right-handed subjects were first trained directly with different tools. Electroencephalography (EEG) was being recorded while the subjects were presented with randomly organized static visual images of tools from egocentric or allocentric perspectives performed by either a left or right hand. The results showed significant left lateralized sensorimotor ERD for right hand matched action simulation conditions (Right-handed/Egocentric, Left-handed/Allocentric images). For left hand matched conditions, more bilateral sensorimotor ERD was seen (Left-handed/Egocentric, Right-handed/Allocentric images). This suggests activation of motor representations of the observer's left hand when watching a left-handed person for comprehending actions, dependent of the perspective of the action seen. Consequently, the current research will help us better understand how we encode action and recall motor simulations and may ultimately contribute to understanding of some tool-use related deficits.

Title: The impact of sensorimotor experience on affective evaluation of movement

Authors: *L. KIRSCH[1], K. A. DROMMELSCHMIDT[2], K. DAWSON[1], E. S. CROSS[1]; [1]Sch. of Psychology, Bangor Univ., Bangor, United Kingdom; [2]Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Prior research on aesthetics demonstrates that people are more likely to judge a stimulus as pleasing if they are familiar with. While general familiarity and liking appear to be related, it is less clear how motor familiarity, or embodiment, is related to a viewer's aesthetic appraisal of a stimulus. Previously, we demonstrated that people derive greater pleasure from watching movements they are not able to embody compared to those they felt they could. To more closely investigate this finding, we subsequently conducted two dance training experiment

to clarify the relationship between sensorimotor experience and affective evaluation of a movement. The first experiment used a between-subjects design wherein 62 participants were assigned to one of three groups and took part in four days of training. One group received physical training on simple dance sequences with the Xbox KinectTM system, another visual and auditory training, and a third group received auditory experience only. Participants' aesthetic preferences for different dance stimuli were measured with a rating task before and after the training sessions. Results demonstrate that participants from the physical training condition not only improved their performance of the dance sequences, but they also reported higher enjoyment and interest in the sequences after training. These results suggest that learning to embody particular movements can indeed lead to greater enjoyment while watching those movements in the future. The second experiment is an fMRI version of Experiment 1 that directly compared how learning to embody an action impacts the neural response when watching and aesthetically evaluating that action. Using a within-subjects design, 24 participants trained for four consecutive days on dance sequences set to music videos. Each day they physically rehearsed one set of dance sequences, passively watched a second set of sequences, and listened to the music of a third set. Functional MRI was obtained prior to and immediately following the four days of training, as well as affective and physical ability ratings. This approach enables us to examine the brain basis of how action embodiment is related to the pleasure a viewer derives from watching an action. Moreover this study enables a precise comparison of self-report methods of embodiment with non-biased, empirical measures (e.g., scores given by the participant vs. the Kinect system). Together, these two studies are the first to use intensive training procedures coupled with fMRI to investigate affective judgment in relation to embodiment, and will inform both affective and motor research areas.

Title: The behavioral and neural effects of language on motion perception

Authors: *J. C. FRANCKEN[1], P. KOK[1], P. HAGOORT[1,2], F. P. DE LANGE[1];
[1]Donders Inst. For Brain, Cognition and Behavior, Radboud Univ. Nijmegen, Nijmegen, Netherlands; [2]Max Planck Inst. for Psycholinguistics, Nijmegen, Netherlands

Abstract: Perception does not function as an isolated cognitive system but is actually tightly linked with other cognitive functions. Several studies have described an influence of language on motion perception, but it remains debated at which level of processing this modulation takes place. Some studies argue for an interaction in perceptual areas, by showing that language can impact on perceptual sensitivity as well as modulate neural activity in sensory cortex during a perceptual task. A second possibility would be that the interaction is mediated by 'language areas' that integrate the semantic meaning of the linguistic as well as the visual information. Here, we investigated this issue in a combined behavioral and fMRI study. Moreover, we assessed whether language-perception interactions were specific to the language-dominant left hemisphere, by presenting visual material to the right and left visual field.
Subjects (right-handed; behavior: N=22; fMRI: N=25) performed a visual motion detection task. On each trial, the visual motion stimulus was presented in either the left or in the right visual field (RVF). Crucially, subjects were shortly presented with a motion word (e.g., rise) before each trial. The motion word could be congruent, incongruent or neutral with regard to the visual motion stimulus that was presented subsequently.
When motion words were congruent with the direction of the visual motion stimulus, subjects were faster, more accurate, and had a more liberal decision threshold compared to the incongruent condition. Interestingly, the speed benefit was present only for visual stimuli that were presented in the RVF. We observed a neural counterpart to these behavioral facilitatory effects in the left middle temporal gyrus (lMTG), an area involved in semantic matching and contextual integration, but not in the visual areas that were sensitive to the motion stimulus.
In conclusion, we show that language affects behavioral performance on motion perception, with stronger effects for motion stimuli that are processed in the language-dominant left hemisphere. These interactions were neurally mediated by 'language areas' rather than perceptual areas, suggesting that these form part of the network involved in perceptual decisions about visual motion stimuli.

Title: Decoding actions across objects

Authors: *M. F. WURM[1], G. ARIANI[2], S. PETRIS[2], M. W. GREENLEE[3], A. LINGNAU[1,2]; [1]Ctr. for Mind/Brain Sci., Ctr. For Mind/Brain Sci., Mattarello, Italy; [2]Dept. of Psychology and Cognitive Sci., Univ. of Trento, Trento, Italy; [3]Dept. of Psychology, Univ. of Regensburg, Regensburg, Germany

Abstract: Action perception likely involves the neural activation of several distinct representational levels, e.g., the kinematics vs. the goals of an action. Actions, however, can also be described in terms of their conceptual content. Action concepts are generalizations of concrete actions. For example, the action concept "cutting" is a common, perceptually independent representation of the two actions "cutting an apple" and "cutting a potato". To date, however, the neural substrates of action concepts are still unclear. Here we studied how conceptual representations of observed actions are organized in the brain using multivariate pattern analysis (MVPA) of fMRI data. Fourteen participants observed two different actions (cutting, peeling) that involved two different objects (apples, potatoes). This design allowed identifying object-independent representations of the action concepts "cutting" and "peeling". This was done by training a support vector machine (SVM) classifier to discriminate the two actions in one object (apple) and testing the classifier with the two actions in the other object (potato), and vice versa. To avoid confounds on a perceptual level, we used five exemplars of each action performed by two different actors, thus enhancing the perceptual variance of the stimuli. Participants were instructed to perform a one-back task on either the actions or the objects. We found significant above-chance classification accuracies for action concepts in posterior middle temporal gyrus (pMTG). This result substantiates previous findings on the role of the pMTG in representing perceptually invariant action information and suggests that observed actions are generalized to conceptual representations of actions in occipitotemporal cortex.

Title: Temporal dynamics of human perceptual decision making: Fine discriminations are guided by the activity of the most informative sensory neurons

Authors: *E. F. ESTER[1], J. T. SERENCES[2];
[1]Psychology, Univ. of California San Diego, La Jolla, CA; [2]UCSD, La Jolla, CA, CA

Abstract: Visual perception can be characterized as a process of inference: given a set of noisy neural responses, what is the state of the external world? For coarse discriminations (e.g., when discriminating between two orthogonal orientations), a good strategy is to query the responses of neurons that are tuned to the relevant alternatives, as those neurons undergo the largest change in firing rate. However, the same strategy is suboptimal for fine discriminations (e.g., when discriminating between two very similar orientations), as neurons that are selective for feature values further away from the relevant alternatives are more sensitive to small changes in the stimulus. Here, we recorded EEG while human subjects discriminated small clockwise or anticlockwise rotations in stimulus orientation in order to determine if fine perceptual discriminations were influenced by these informative "off-channel" neurons. EEG responses were wavelet transformed, and we used a multivariate encoding model to estimate a trial-by-trial orientation selective response profile with a temporal resolution of 50-100 msec. (see Garcia et al., Cur Biol 23:515-522). Critically, in the responses of orientation channels tuned slightly away from the target were larger than those tuned to the target on correct relative to incorrect trials, particularly in the temporal interval immediately preceding the behavioral response. These findings support the hypothesis that perceptual decisions are based on the activation level of the most informative sensory neurons, and suggest that sensory neurons do more than 'vote' for their preferred feature. Instead, the activity of sensory neurons can be decoded in a more optimal manner that exploits their sensitivity to detect small changes away from their preferred feature.

Title: Quick adaptive Bayesian assessment of sensory memory decay

Authors: *J. BAEK[1], L. LESMES[2], Z.-L. LU[1];
[1]Psychology, Ohio State Univ., Columbus, OH; [2]Schepens Eye Res. Inst., Harvard Med. Sch., Boston, MA

Abstract: Sensory memory is the literal, modality-specific neural representation of sensory stimuli in the human brain (Sperling, 1960). It provides the initial copy ("buffer") of external stimulation to human sense organs that can be processed by subsequent stages of perception and cognition. Recent studies suggest that sensory memory decays much faster for observers with mild cognitive impairment and may serve as an early sign of the Alzheimer's disease (Lu et al., 2005). In the visual modality, iconic memory is best assessed with the partial report procedure. In this procedure, an array of letters appears briefly on the screen. A post-stimulus cue directs the observer to report the identity of the cued letter. Typically 6-8 cue delays or 600-800 trials are tested to measure the sensory memory decay function. The procedure takes about one hour. The long testing time has prevented wide use of the test in clinical settings and special populations. Here we develop a quick partial report or qPR procedure based on a Bayesian adaptive framework to directly estimate the parameters of the sensory memory decay function with much reduced testing time. In the qPR, parameters of the exponential decay function are characterized by probability distributions. Starting with a prior distribution of the parameters, the method selects the stimulus to maximize the expected information gain in the next test trial. It then updates the probability distribution of the parameters based on the observer's response by Bayesian inference (Kontsevich & Tyler, 1999; Lesmes et al., 2006). The procedure is iterated until either the total number of trials reaches a set value or the precision of the parameter estimates reach a certain criterion. Simulation studies suggest that only 100 trials are necessary to reach 1dB accuracy and 2dB precision. The method was validated in a psychophysical experiment. Estimates of the sensory memory decay function obtained with 100 qPR trials showed good precision (SD=0.6 dB) and excellent agreement with those obtained with 1600 trials using the conventional procedure (mean RMSE =1dB). qPR relieves the data collection burden in characterizing sensory memory and makes it possible to assess sensory memory in clinical settings and special populations.

Title: Gender differences in influence of sound environments on performance of the memorizing numerical string task and cerebral blood flow changes

Authors: *A. MASAZUMI, U. YAMAMOTO, T. HIROYASU;
Doshisha Univ., Kyotanabe, Kyoto, Japan

Abstract: [Purpose]
In the former studies, it was demonstrated that sound environments affect the results of intellectual work and cerebral blood flow changes using functional near-infrared spectroscopy (fNIRS). Furthermore, psychology studies have reported that gender-specificity exists in the influence of pleasant and unpleasant sounds on the work environment. In this study, we investigated gender difference in the influence of sound environments by scoring a memorizing numerical string task and observing cerebral blood flow changes.
[Methods]
This study examined 24 subjects, among which 12 were males and 12 females. In this study, we selected three sound environments, namely, silence; "the sonata for two pianos in D major, K.448" by Mozart; and white noise. Subjects were exposed to sounds while working. The effect on intellectual work was analyzed by measuring the number of correct answers to 30 questions. Subjects had to memorize eight numbers in 3 sec and input them in the correct order in <7 sec. We examined the influence of different sound environments on the task by measuring cerebral blood flow changes using fNIRS.
[Results]
The results revealed that males showed the best performance when exposed to silence, whereas females showed the best performance in the presence of white noise. The influence of sound environments on the score was significant at 5% level in both males and females as calculated using the two-way factorial ANOVA without replications. Simultaneously, the results of the t-test at 5% level showed significant differences between males and females only in the presence of white noise. In addition, the same significant difference was observed in the average cerebral blood flow change. Cerebral blood flow change in males decreased and that in females increased. Moreover, it was observed that cerebral blood flow change decreases under pleasant sound conditions and increases under unpleasant conditions. Also in this experiment, in the white noise, cerebral blood flow change in males was tended to decrease and that in females tended to increase. Therefore, we suggest that males may feel that the white noise is unpleasant as opposed

to females. In conclusion, females showed the best performance in the presence of white noise, under which their cerebral blood flow change increased. Based on these results, we found that there is a gender-specific difference in the performances of intellectual work and cerebral blood flow changes in the presence of white noise.

Title: Incorporating neural signals into computational models of memory search

Authors: *S. M. POLYN[1], N. W. MORTON[2], J. E. KRAGEL[3], J. D. MCCLUEY[2];
[1]Dept Psychol, [2]Psychology, [3]Neurosci., Vanderbilt Univ., Nashville, TN

Abstract: A major goal of cognitive neuroscience is to understand how neurally recorded signals map onto psychological processes within a formal modeling framework. These frameworks are interactive systems that potentially allow us to simultaneously assess the diverse functions of distinct brain regions. In the domain of memory search, activity in one region may relate to association formation, activity in another region may reflect integrative processes, and these processes may interact during both study and recall. Exploring the dynamics of these signals requires models that can incorporate both neural data and behavioral data. Because neural data inherently varies on an item-by-item basis, these models must be specified at the single-item level; summary statistics such as serial-position curves, lag-based conditional response probability analysis, and various organizational measures remove the item-by-item variability one wants to explain. In the domain of memory search, trial-level data are in the form of recall sequences: An ordered series of responses made by a participant during the recall period. I will describe a technique that allows one to calculate the likelihood that a given recall sequence is observed, from among all possible sequences that could be produced by a given computational model. The technique does not require that the computational model is stationary; the model parameters can change both during the study period and during memory search. Analysis of synthetic neural data will be presented to demonstrate how this approach allows one to compare

various hypotheses linking neural signal to behavioral data, even in the presence of multiple interacting mechanisms at study, and a non-stationary recall process. I will also demonstrate the utility of this approach in the behavioral domain, in particular, when dealing with results that reflect multiple interacting mechanisms (such as those underlying temporal, semantic, and source organization in free recall). Certain limitations of the approach will also be discussed, with an eye towards the eventual integration of this approach with modern Bayesian techniques.

Abstract: Recent neurocognitive theories of memory retrieval attribute the subjective phenomenon of recollection to the reactivation of patterns of neural activity present during the formation of an encoded memory. This distributed cortical activity is thought to reflect multiple facets of the encoded event, including item and context specific information. While the capacity of ventral temporal and primary sensory cortices to represent stimulus-specific information is well established, the neural mechanisms that support the representation of contextual information are less well characterized. Retrieved-context theories propose a slowly changing, autocorrelated temporal context signal that contributes to the episodic nature of an encoded event. While previous studies of electrophysiological recordings in humans and rodents have identified temporal-context like signals within the medial temporal lobe, autocorrelated noise in functional magnetic resonance imaging (fMRI) signal presents a challenge to identifying neural regions that may contain such a contextual signal. Using a simulation based approach, we test the ability to identify meaningful autocorrelated signal in the fMRI timeseries. Using retrieved context models as a framework, we demonstrate the capacity to detect the presence of a stimulus-driven contextual signal in the presence of autocorrelated noise. Applying these techniques to fMRI

studies of episodic memory retrieval, we test the capacity of specific cortical to regions to represent contextual and item specific information.

Title: Inter-item distraction dissociates temporal and semantic organization in free recall

Authors: *N. W. MORTON[1], S. M. POLYN[2];
[1]Psychology, [2]Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Retrieved-context models propose that information related to studied items is integrated into a representation of temporal context, which later serves as a cue to probe memory. Consistent with these models, recent scalp EEG results suggest that item-category-specific information is integrated over time. Furthermore, the rate of this integration predicts the degree to which recalls will subsequently be clustered by stimulus category. Previous findings suggest that category clustering is attenuated when a distracting task is performed between items. We hypothesized that distracting activity disrupts temporal context, causing category-specific information to accumulate less over time; as a result, recall is less influenced by category cues. To test this account, we examined recall behavior and oscillatory scalp EEG data in free recall trials with or without distracting activity during study. We found that distraction greatly attenuated category clustering. In contrast, temporal organization, the tendency to successively recall items presented near to each other, was unaffected by distraction. Using multivariate pattern analysis, we examine whether neural signatures of integrative activity differ between the two conditions, and whether differences in integrative activity during encoding predict the degree to which category clustering is attenuated.

Title: Consolidation of newly learned words: Does the presence of pictures at encoding make a difference?

Authors: *A. TAKASHIMA[1,2], I. BAKKER[1,2], J. G. VAN HELL[3,2], G. JANZEN[1,2], J. M. MCQUEEN[1,2,4];
[1]Donders Inst. For Brain, Cognition and Behaviour, [2]Behavioural Sci. Inst., Radboud Univ. Nijmegen, Nijmegen, Netherlands; [3]Psychology, Pennsylvania State Univ., Pennsylvania, PA; [4]Max Planck institute for Psycholinguistics, Nijmegen, Netherlands

Abstract: From lesion and imaging studies, we know that memory is not a unitary system. Declarative memory is considered to entail episodic memory (memory for episodes that are confined to specific spatial and temporal contexts) and semantic memory (memory for generic knowledge or concepts). Although these two types of memories are not independent and highly interactive, they seem to involve different brain structures at retrieval, with the hippocampus often regarded to be important for retrieving arbitrary associative information encoded in a specific episodic context, whereas widely distributed neocortical areas, especially higher order associative areas, seem to be important in retrieving semantic or conceptual information.
In this study, we were interested in the neural correlates of newly learned words when retrieved at different time points. We asked if there is more involvement of the episodic memory network when retrieval occurs directly after learning, and if there is a shift towards more involvement of the semantic network as the word becomes more de-contextualized with time. Furthermore, we were interested to see the effect of having extra information at encoding, namely, visual information associated with the phonological form of the novel word. Previously we have reported that picture-associated novel words retrieved immediately after encoding involve hippocampal structures more than phonological form-only words. When retrieval took place 24 hours later, the involvement of the hippocampal system was still present for the picture-associated words, but involvement of distributed neocortical areas also increased with time.
In the present study, we extended the delay from 24 hours to 1 week. Participants learned phonological novel word forms with/without corresponding pictures and their memory for the words was tested in an fMRI scanner. Retrieval success was greater for picture-associated words compared to phonological form-only words on both recent and remote test. When memory for

the associated picture of the word was tested, exactly the same pictures were recognized faster than similar pictures at both time points, but at remote test we also observed an interaction. Specifically, although recognition of the same pictures slowed down as a function of delay, this was not the case for similar pictures, indicating decay of the episodic memory trace and some de-contextualization of the word memory. On the neural level, the memory benefit of having pictures at encoding was observed as more involvement of the hippocampus during recent retrieval, and increased activity in the fusiform gyrus and the left angular gyrus during delayed retrieval.

Title: Schema effects on spatial associative memory in humans

Authors: *M. VAN BUUREN[1,2], M. KROES[3], G. FERNÁNDEZ[1,2];
[1]Donders Inst. for Brain, Cognition and Behaviour, [2]Dept. for Cognitive Neurosci., Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands; [3]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Activated neural representations of prior knowledge, or "schemas", are found to facilitate assimilation of congruent information in both humans and rats. This schema-related facilitation is thought to be mediated by interactions between the medial prefrontal cortex (mPFC) and hippocampus. In rats, the existence of a spatial schema enabled rapid learning of new flavor-location associations. Moreover, retrieval of these associations rapidly became hippocampally independent and was mediated by the mPFC (Tse et al. 2007, Science 316, 76-82; Tse et al. 2011, Science 333, 891-895). In this fMRI study, we investigate whether the existence of such a spatial schema facilitates learning and retrieval of new object-location associations in humans and whether retrieval of these associations is mediated by the mPFC.
To this aim, we developed a human analogue of the event arena used by Tse and colleagues. The task consists of two conditions in which subjects are instructed to memorize object-location associations within two different 10 x 10 grids. In the schema condition, the associations remain

consistent over sessions, whereas in the no-schema condition the objects and possible locations are fixed, but the associations are flexible across sessions. Subjects are initially trained on 50 associations per condition on three consecutive days. On day 4, 50 new object-location associations are introduced per condition in addition to the old ones. 24 hours later, recall for both old and new associations is tested while brain activity is measured using fMRI.
Up to now, data acquisition is finalized for 17 out of 24 subjects. Behavioral results show an increase in learning over sessions for schema associations and within a session for no-schema associations. On average, schema associations were well learned at the end of day 3 (94.7% correct). As expected, during the recall session on day 5, subjects showed better memory for new schema associations (63.1%) compared to new no-schema associations (53.3%) (t (16)= 4.5, p<.0005), indicating that a spatial schema was developed. Reaction times for new associations did not differ significantly between the two conditions (p=.115). Next, we will analyze brain activity during recall using univariate regression analyses to investigate the neural mechanisms underlying schema-related retrieval.
Our findings are in line with the studies of Tse and colleagues and indicate that the presence of a spatial schema facilitates learning and memory of new, related associations in which objects are linked to specific locations.

Title: Evidence for reconsolidation of emotional episodic memories in humans

Abstract: The reconsolidation hypothesis postulates that upon reactivation, memory traces return to a labile state and are once again susceptible to disruption by treatments similar to those that impair initial memory consolidation. Despite accumulating evidence for a reconsolidation process in animals, support in humans, especially for episodic memory is limited. This discrepancy is largely due to the fact that animal studies on reconsolidation have generally employed invasive techniques to disrupt reconsolidation, which cannot be easily translated to humans. Studies on human reconsolidation have therefore used either systemic application of slow-acting pharmacological compounds, or psychological manipulations such as interference learning. As a result, human studies often have had difficulty meeting critical criteria to show that reconsolidation is a time-dependent process, or are susceptible to alternative interpretations such as interference at the time of retrieval. Here we circumvent these issues by showing that a single application of electroconvulsive therapy (ECT) including short-term narcosis following memory reactivation in patients with unipolar depression disrupts reactivated, but not non-reactivated, memories for an emotional episode in a within-subjects design. This effect is not visible immediately, but only after a 24h delay. Thus, it is time-dependent satisfying a critical reconsolidation criterion. In conclusion, we provide causal evidence for reconsolidation in humans provided by direct interference with neural activity following memory reactivation. This finding provides a proof-of-principle and opens potential therapeutic avenues targeting reconsolidation to alter memories that contribute to the persistence of psychiatric disorders.

Title: Probing rule-based schematic memory representations

Authors: *I. WAGNER[1,2], M. VAN BUUREN[1,2], M. VAN DER LINDEN[1,2], M. KROES[3], G. FERNÁNDEZ[1,2];
[1]Donders Inst. for Brain, Cognition and Behaviour, Nijmegen, Netherlands; [2]Dept. for Cognitive

Neurosci., Radboud Univ. Nijmegen Med. Ctr., Nijmegen, Netherlands; [3]Donders Inst. for Brain, Cognition and Behaviour, Radboud Univ. Nijmegen, Nijmegen, Netherlands

Abstract: Neural representations of existing knowledge, skills and attitudes, so-called "schemas", can alter the manner in which information is processed, including memory encoding, consolidation and retrieval. This processing is thought to be mediated by interactions between the medial temporal lobe (MTL) and medial prefrontal cortex (mPFC). However, it is unclear whether these areas actually hold schematic representations. Here, we studied schema formation based on two distinct sets of rules and investigated whether neural signatures of these two schemas are dissociable within MTL and mPFC.

Using functional MRI, brain activity was measured while participants learned to apply two sets of rules (spatial vs. non-spatial) in a deterministic weather prediction task (Kumaran, 2009), in which simple shapes were associated with a weather outcome. The experiment consisted of two sessions on consecutive days. On Day 1, participants performed both encoding and recall trials. During encoding trials, feedback about the weather outcome was provided, whereas during interspersed recall trials no feedback was given and participants did not have the chance to improve. Across the first session, these recall trials yield a graded measure of actual schema proficiency. On Day 2, participants solely completed recall trials. Additionally, they were required to transfer their schema knowledge to new stimuli to test for their ability to apply the schemas.

On average, participants reached almost perfect performance (>90% correct) within the first four runs of Day 1 (n=23). Performance did not differ significantly between the two schema conditions (Encoding: $t_{22}=-0.989$, ns.; Recall: $t_{22}=-2.003$, ns.). To investigate general consolidation processes with a univariate analysis, we compared recall trials between the two sessions (Day 2>Day 1). Ventromedial PFC showed increased activation on Day 2 as compared to Day 1 ($p<.05$, SVC), which cannot be explained by differences in task difficulty (indicated by % correct responses) between sessions ($t_{22}=-0.642$, ns.). This finding is in line with previous findings and supports the notion that schema consolidation is mediated by the mPFC.

To closer investigate differences in neural representations between the two schemas, we will apply multivariate pattern analysis (MVPA). Here, we will test consolidated schema-patterns and their generalisability to neural representations during a transfer session. Furthermore, we will be tracing the distinct neural schema-patterns throughout their formation and assume to find differential classifier performance for schema discrimination within MTL and mPFC over time.

Title: The critical role of prefrontal cortex in strengthening of episodic memories through reconsolidation

Authors: *M. SANDRINI, N. CENSOR, J. MISHOE, L. COHEN*;
NINDS-NIH, Bethesda, MD

Abstract: Consolidation theory characterizes consolidation as a one-time event, after which memories become resistant to interference. Research into memory reconsolidation has challenged this view. Reactivation of consolidated memories opens the reconsolidation window, a time-limited period during which memories can be modified. However, it is unknown whether neuromodulation of neocortex during the reconsolidation window might strengthen human memories. Episodic memory refers to long-term declarative memory for specific events in space and time. To neuromodulate this memory during the reconsolidation window, we applied repetitive Transcranial Magnetic Stimulation (rTMS) to right prefrontal cortex (PFC), a region involved in episodic memories.

Fifty human subjects participated in this study. Subjects learned a list of 20 words on Day 1. On Day 2, memory was reactivated by a contextual reminder cue and 10 minutes later 1 Hz rTMS was applied for 15 minutes to right PFC (PFC-R), a control site (Vertex-R), or right PFC without a reminder cue (PFC-NR). Memory recall was tested on Day 3 (24h post-reactivation, Exp. 1) or on Day 2 (1h post-reactivation, Exp. 2)

We report that non-invasive stimulation of right prefrontal cortex (PFC-R) during reconsolidation strengthened episodic memories, an effect documented by improved recall 24h post-reactivation compared to control groups (i.e. PFC-NR and Vertex-R). In contrast, there was no effect of stimulation 1h post-reactivation, showing that memory strengthening is time-dependent, consistent with the reconsolidation theory. Thus, prefrontal cortex plays a critical role in strengthening of episodic memories through reconsolidation. Reconsolidation may serve as a window of opportunity to strengthen human episodic memories with non-invasive neuromodulation, an issue of relevance for clinical applications.

Title: Knowing you know: A transcranial direct current stimulation (tDCS) study of the feeling-of-knowing in episodic memory

Authors: *E. F. CHUA[1,2], S. MEYLER[1];
[1]Dept. of Psychology, Brooklyn Col., Brooklyn, NY; [2]Grad. Ctr. of the City Univ. of New York, New York, NY

Abstract: When people fail to recall information, they sometimes have a feeling-of-knowing (FOK) that the currently non-recallable item is known and/or will be later remembered. Several previous neuroimaging studies have implicated the prefrontal cortex in the subjective level of feeling-of-knowing expressed. Because fMRI is correlational, the aim of this study was to test for a causal role of the prefrontal activity in the feeling-of-knowing. Transcranial direct current stimulation (tDCS), a non-invasive form of brain stimulation, was used to stimulate the PFC during a memory task. Participants studied 180 faces and names. Following study, they either received active prefrontal stimulation (1.5 mA for 10 minutes) or sham stimulation. At test, participants were presented with a face and asked to recall the name. Following recall, they made a FOK judgment and indicated on a scale of 1-6 whether they thought they would recognize the correct response. They then complete a 3 alternative forced choice recognition test for the name associated with the face. One week later, participants returned to the lab and completed the same task using a different set of faces and names and received either active or sham stimulation, whichever one had not been received in visit 1. Preliminary analyses (n=21) showed that participants gave significantly lower FOK judgments for face-name pairs that were later correctly recognized during active compared to sham stimulation ($p<0.05$). These results demonstrate that directly manipulating prefrontal activity has a causal effect on the level of FOK expressed.

Title: Visual evoked potentials in humans are enhanced by long-term visuo-gustatory conditioning

Authors: I. VIEMOSE, C. LILJENDAHL, J. L. LAUGESEN, P. MOELLER, W. L. P. BREDIE, *G. R. CHRISTOFFERSEN;
Dept. of Food Sci., Univ. of Copenhagen, Frederiksberg, Denmark

Abstract: Long lasting memories of associations between the visual features and tastes of objects are essential for identification of food items. However, hardly any information is available on the long-term effects of image-taste conditioning on image-induced brain potentials.
Aim: The project aimed at comparing visual evoked potentials (VEPs) induced by nonsense images presented either for the first time or after having been used as conditioned stimuli paired with gustatory (unconditioned) stimuli.
Methods: A 118 electrode EEG-array was used to record VEPs before and one day after a training session containing 3 paired stimulations with one image and an appetitive juice and 3 pairs of another image and a juice with an aversive taste. The images were unfamiliar and nonsensical 2D figures. Before and after training, images were presented for 1 sec at 3 sec intervals, 60 times each in semi-random sequence. Before and during training, images were presented in the right side visual field relative to a fixation cross (activating left posterior visual cortices). After training, the original figure plus a duplicate - placed symmetrically in the left visual field - were presented. This allowed two types of comparisons between conditioned and not conditioned states: 1) comparisons of left hemisphere VEPs before and after training and 2) comparisons after training of VEPs in the left (conditioned) and the right (non-conditioned) hemispheres. Data were analyzed in the electrodes: OI1, O1, POO9, POO3, PO9, PO7, PO5, PO3, PP09 and the corresponding right side electrodes. Results are stated as mean ± sem from 9 subjects.
Results: Conditioning altered late VEP components beginning at N2 peak and covering P3. These components were dominated by waves in the delta and theta frequency bands. After training, average theta power in the left (conditioned) side was 1.30±0.42 μV2 compared to only 0.79±0.16 μV2 in the right (not conditioned) side ($p<0.0001$). Before training, left side theta power was 0.63±0.21 μV2, significantly lower than after training ($p<0.0001$). The corresponding values for delta power were: 2.71±1.04 μV2 (left, after training), 1.31±0.33 μV2 (right, after training; $p<0.0001$) and 2.02±0.97 μV2 (left, before training; $p<0.01$). Effects of appetitive and aversive taste conditioning did not differ significantly.
Conclusions: 1) N2-P3 components of posterior VEPs showed enhanced power 24 hr after image-taste conditioning. 2) Power in the conditioned visual hemisphere was higher than in the contralateral side which had not received conditioned visual stimuli during training. The results demonstrate potentiation of the VEP induced by taste-conditioning.

Title: Context memory and remembering recruit distinct neural substrates

Authors: *S. D. SLOTNICK[1], P. P. THAKRAL[2];
[1]Boston Col., Chestnut Hill, MA; [2]Ctr. for Vital Longevity and Sch. of Behavioral and Brain Sci., Univ. of Texas at Dallas, Dallas, TX

Abstract: Context memory (i.e., memory for contextual information) and remembering (i.e., memory with specific detail) are assumed to reflect the same process. However, the neural substrates of these objective and subjective memory types, respectively, have been confounded in previous studies as context memory is highly correlated with remembering. The aim of the present fMRI study was to dissociate the neural substrates associated with context memory and remembering to determine whether they are mediated by the same process or by different processes. At encoding, participants were presented with colored and gray abstract shapes and were instructed to encode each shape and its context (i.e., whether it was colored or gray). At retrieval, old and new shapes were presented in gray and participants classified each shape as "old and previously colored", "old and previously gray", or "new", followed by a "remember" or "know" response. A "remember" response corresponded to memory for specific detail, whereas a "know" response corresponded to non-detailed familiarity. Item memory and context memory corresponded to accurate shape recognition and accurate memory for color or gray, respectively, while item memory alone corresponded to accurate shape recognition and inaccurate memory for color or gray. To dissociate remembering from context memory, the contrast of remember-item memory > know-context memory was conducted. To dissociate context memory from remembering, the contrast of know-context memory > remember-item memory was conducted. Neural regions specifically associated with remembering were observed in the occipital cortex and the dorsolateral prefrontal cortex. These results support previous findings that indicate the prefrontal cortex is associated with subjective aspects of retrieval. A single neural region was specifically associated with context memory in the right posterior middle temporal gyrus, which may reflect visual categorical processing. In addition, the conjunction of remember > know and context memory > item memory produced activity in the shape processing region of the occipital

cortex. The present results indicate that context memory and remembering are largely mediated by different neural processes.

Title: Sleep-dependent consolidation preferentially benefits pattern separation over pattern completion

Authors: *J. R. JAMES, C. B. KIRWAN;
Psychology, Brigham Young Univ., Provo, UT

Abstract: Computational models posit that memory representations for similar inputs are made more dissimilar through a process of orthogonalization known as pattern separation. Furthermore, previously-stored memory representations may be retrieved when given a partial or degraded cue through a process known as pattern completion. These models also predict that, during sleep, the location of memory representations is gradually shifted from the hippocampus to the cortex. Cortically-mediated memory representations are more generalized, stable, and useful, but also less specific than the memory representations stored in the hippocampus. Thus, sleep-dependent consolidation should preferentially benefit pattern completion performance. Specifically, participants should be more likely to pattern complete following a sleeping delay than a waking delay. In the current study, participants studied several hundred pictures of common objects. After a twelve-hour delay, during which participants either slept or stayed awake, participants were asked to indicate whether lure images were exactly the same or merely similar to those they studied. Participants' ability to correctly reject lures was a quadratic function of target-lure similarity. A mixed ANOVA revealed an interaction of similarity and delay type, indicating that these functions significantly differed by delay type. Visual inspection of the trend lines suggests that participants are better at discriminating after sleeping than after a waking delay. These data contradict the predictions of current computational models and suggest that sleep may preferentially benefit pattern separation and not pattern completion.

Title: Neural correlates of primacy and recency effects in macaque memory retrieval network

Authors: *K. MIYAMOTO[1], T. OSADA[1], Y. ADACHI[1], T. MATSUI[1,2], H. M. KIMURA[1], T. WATANABE[1], R. SETSUIE[1], Y. MIYASHITA[1,2];
[1]Dept Physiol, [2]Dept Phys, Univ. Tokyo, Tokyo, Japan

Abstract: Human functional magnetic resonance imaging (fMRI) studies have revealed involvement of a brain-wide network including the posterior parietal cortex (PPC) during memory retrieval. Investigations in nonhuman primates would help elucidate the network dynamics as well-controlled experimental techniques are available. However, a homologous memory retrieval network in the macaque brain has not been established. To identify macaque retrieval-related regions, we conducted fMRI experiments of two macaque monkeys performing a serial probe recognition task in a 4.7T MRI scanner. In this task, monkeys viewed a list of serially presented picture items and, after a delay, judged whether the test item was seen or unseen in the list. Behaviorally, a typical U-shaped serial position curve for memory accuracy accompanied by primacy and recency effects was observed in both monkeys (retrieval of initial or last item *vs.* middle item; chi-square test; $P<0.05$, Ryan's correction). We first compared cortical activity during correct recognition of previously seen items and correct rejection of unseen items, and identified 47 areas including two major PPC activation sites: the posterior inferior parietal lobule (PG/PGOp) and the intraparietal sulcus (PEa/DIP) ($P<0.01$ FDR corrected). Next, we found contrasting profiles between these two PPC regions depending on the position of retrieved items serially presented in the study list: retrieval-related activity in the PG/PGOp and hippocampus correlated with the behavioral primacy effect, while that in the PEa/DIP correlated with the behavioral recency effect ($P<0.05$, multiple regression analysis). In addition, the 47 retrieval-related regions were segregated into six subnetworks by community detection analysis using modularity optimization of the functional connectivity of spontaneous BOLD activity taken

from the two monkeys. The two PPC sites were embedded in distinct subnetworks: PG/PGOp overlapped with the monkey default-mode network, while PEa/DIP overlapped with the monkey frontoparietal network. Gross activity of the two networks during retrieval was typified by the activities of the two PPC sites with differential serial probe recognition profiles. Double dissociations of psychophysiological interactions between the two PPC sites and the hippocampus or visual cortex conformed with this network-level segregation. These results converged to reveal functional differentiation of the macaque memory retrieval network related to the primacy or recency effect, respectively. Furthermore, interspecies comparisons provided evidence of common neural substrates of memory retrieval network in monkey and human.

Title: Applying the logic of ARP´s hypermnesia hypothesis to reduce the intensity of negative emotions

Authors: *V. M. SOLIS, SR;
Psychology Dept. Natl. Univ. of Mexico, Mexico City, Mexico

Abstract: Hypermnesia occurs when memory grows across repeated trials. One tenet of the ARP´s (*alternative retrieval pathways*) hypothesis (Solís-Macías, 1998, 2008a) is enhanced hypermnesia as more pathways are activated. Pathways can be, for instance, distinct sensory modalities (visual, auditory, tactile) or conceptual categories (verb, noun, natural, human-made), among others. We applied ARP´s logic to reduce the impact of negative emotions using Padua-Gabriel´s technique (2010). People rated the negative impact of an emotion on eight consecutive days and in an unexpected follow-up 60 days later. We predicted: (1) lower negative ratings for six vs. three attributes. (2) Reductions in negativity still active after two months.

Method

Participants

Thirty undergraduates, their ages ranged from 18 and 21 years. They were randomly assigned to two groups, $\mathbf{G_1}$ (six attributes) and $\mathbf{G_2}$ (three attributes).

Materials and design

The first and eighth sessions were conducted in our laboratory. Design was a mixed factorial 2 *x* 2. *Group* (6 vs. 3 attributes) varied between-participant. *Session* (1-9) varied within-participant.

Procedure

We asked participants to think of a negative episode in their lives, instructing them to imagine it had six (three) attributes: weight, sound, texture, colour, location in the body, and odour. They used a 10-point scale to rate each dimension daily, performing sessions 2-7 at home when they were relaxed in order to re-think their emotion for about five minutes and
then rated it. They sent daily ratings via internet. Two months later, we run an unexpected follow-up.

Results

Results (all p´s < .001) for $\mathbf{G_1}$ and $\mathbf{G_2}$ show: (1) Steady declines in ratings in sessions 1-8. (2) A further dip in the follow-up. (3) Lower ratings for $\mathbf{G_1}$ than $\mathbf{G_2}$ were indicated by an ANOVA and a linear regression. (4) That $\mathbf{G_1} > \mathbf{G_2}$ was even more evident when we compared them only on the same three attributes (weight, sound and texture).

Discussion

Padua-Gabriel´s (2010) technique is efficient for various reasons: (1) Experimenters do not need extensive training to conduct it; it works out after one single session. (2) Participants learn the technique just as swiftly. (3) The advantage of imagining putative physical dimensions is that they assist people to deal with emotions more effectively by providing tangible "handles" that reduce their severity more easily than when trying to manage the entire negative emotion. (4) We validated ARP´s main prediction: Using six dimensions was more efficient for reducing the arousal caused by a negative emotion than three.

Title: Activation in posterior parietal cortex correlates with subjective familiarity: Evidence from retrospective confidence ratings and false alarms

Authors: *J. L. VINCENT;
Neurobio., Harvard Univ., Boston, MA

Abstract: Successful recognition memory decisions depend on mnemonic and decision making processes that are computed by multiple, distributed brain areas. In particular, recent neuroimaging studies have consistently associated parietal cortex with episodic memory retrieval. However, little is known about what computations these areas perform or how these areas are functionally connected. Here, I collected behavioral and functional MRI data from humans (N = 32) during the performance of an old-new recognition memory task with retrospective confidence judgments. Successful recognition memory was associated with activation in multiple regions including anterior, dorsolateral, and medial prefrontal, medial and lateral temporal, retrosplenial and posterior cingulate, as well as lateral parietal cortex. Analyses of resting state functional connectivity demonstrated that these brain regions were organized into two distinct networks, and each network was associated with a distinct region in parietal cortex. The hippocampal-cortical network included the medial temporal lobe, posterior midline structures, and the ventral posterior inferior parietal lobule. The frontoparietal network included lateral prefrontal cortex and intraparietal sulcus. The parietal component of the hippocampal-cortical network was most active during old vs. new decisions, did not differentiate hits from false alarms, and was differentially active during low confidence old and new judgments. In contrast, while the parietal component of the frontoparietal network was robustly activated by hits vs. correct rejections, it was not differentially active during either false alarms vs. correct rejections or low confidence old vs. new judgments. Thus, two distinct regions in parietal cortex can be distinguished by their relative connectivity to the medial temporal lobe vs. lateral prefrontal cortex and their responses during uncertain old judgments and errors. These results demonstrate that ventral posterior inferior parietal lobule is correlated with the subjective perception of familiarity. More generally, these observations suggest a dual network model of recognition memory decision making.

Title: Dynamic changes in interregional functional connectivity strength during autobiographical memory retrieval

Authors: *C. INMAN[1], G. A. JAMES[2], C. CAMPANELLA[1], T. PATHMAN[3], P. BAUER[1], S. HAMANN[1];

Abstract: The brain is comprised of dynamic networks of functional regions that interact with one another to execute various processing demands. Autobiographical memory (AM) involves the orchestration of multiple cognitive processes that evolve over time, including memory access and subsequent elaboration. Previous neuroimaging studies have contrasted memory access and elaboration processes in terms of regional brain activation and connectivity within coordinated multi-region networks rather than between specific regions like the hippocampus and mPFC. The purpose of the present study was to determine the changes in interregional connectivity strength across AM retrieval processes to understand network level mechanisms of AM retrieval and test theoretical accounts of dynamic AM retrieval processes. We predicted that dynamic (time-varying) connections would reflect early memory-access related connectivity between hippocampal and medial PFC regions and a separate set of later, elaboration-related connections between lateral frontal working memory regions and parietal/occipital visual imagery regions. In contrast, stable, time-invariant connections would reflect local networks and frontoparietal control networks that are hypothesized to be active throughout AM retrieval. Healthy adults generated AMs from neutral cue words in a pre-scan session and were later cued to retrieve the AMs for 16 seconds while being scanned with fMRI. We used a moving-window graph theory analysis to examine dynamic changes in the strength of connectivity among regions involved in AM retrieval. Stable connections across AM retrieval included established fronto-parietal control networks and neighboring regions involved in similar functions throughout retrieval. Bilateral connectivity between the amygdala and hippocampus sustained its strength throughout memory retrieval, possibly reflecting ongoing construction and mnemonic binding processes. As predicted, connectivity strength between the hippocampus and medial prefrontal and parietal cortex increased during early access processes. Connectivity strength between precuneus, inferior parietal lobule, and primary visual areas increased later in retrieval, consistent with visual imagery and sensory reactivation processes involved in elaboration. These changes in interregional connectivity strength are consistent with models of AM retrieval that predict dynamic coordination of brain regions supporting search, access, self-reference, episodic reconstruction, and elaboration.

Title: Retrieval success effects in the nucleus accumbens are coded in early local field potentials and neural theta oscillations: Evidence from human intracranial recordings

Authors: *E. M. BAUCH[1], T. ZAEHLE[2,3], H. HINRICHS[2], F. C. SCHMITT[2], J. VOGES[2], H.-J. HEINZE[2,3], N. BUNZECK[1];

Abstract: Recent functional magnetic resonance imaging studies have highlighted the involvement of the nucleus accumbens (NAcc) in declarative memory retrieval. More specifically, the correct discrimination between studied old and unstudied new items was shown to be associated with enhanced NAcc activations and this has been labeled ‘retrieval success’ effect. Although these findings accord with different memory models, the precise temporal and oscillatory dynamics of the NAcc in memory retrieval remain unclear. Here, we addressed this issue by recording intracranial electroencephalography (iEEG) in human epilepsy patients during a simple old/new recognition test. In a first phase, patients incidentally encoded photographs of scenes in a previously established visual oddball paradigm. After a short delay, memory was tested by presenting the old scenes together with new distractor images and patients were asked to indicate their old/new status by button presses. As a main finding, we can show that differences in local field potentials between correctly classified old (i.e., studied) and new (i.e., unstudied) images emerged already at ~100 ms after stimulus onset and endured for more than 300 ms. Moreover, time-frequency analyses revealed a theta (4-8 Hz) power decrease for old relatively to new items. Together, our findings give new insights into the neural mechanisms of memory retrieval in the NAcc. They are in line with the notion that the NAcc receives memory signals from interconnected brain regions, such as the medial temporal lobe and prefrontal cortex, and that theta oscillations may serve as a mechanism to bind these distributed neural assemblies.

Title: Parahippocampal and retrosplenial cortex are more active during remembering than during episodic future thinking

Authors: *A. W. GILMORE, S. M. NELSON, K. B. MCDERMOTT;
Psychology, Washington Univ., Saint Louis, MO

Abstract: Recent neuroimaging studies have demonstrated that both remembering events from the past and imagining events in the future activate a common set of regions within the human brain's default network (Schacter et al., 2012). While researchers have often found regions exhibiting greater activity for imagined future events relative to remembered past events (e.g., Szpunar et al, 2007), the reverse pattern (i.e., Remember > Imagine) has not been consistently observed. A number of hypotheses (Addis et al., 2007; Szpunar et al., 2007) suggest that this is due to the increased processing demands present during future simulation when combining details into a novel, coherent narrative. A reasonable alternative is that studies have simply failed to isolate regions showing greater activity for remembered past events. This subfield of cognitive neuroscience is still in its relative infancy, having come to the fore a little over half a decade ago, and thus the number of studies that have been conducted so far is relatively small. In this study we used functional magnetic resonance imaging (fMRI) to attempt to locate regions that show sensitivity to remembered past events by asking participants to remember events from their past, imagine events that might occur in their future, or imagine events involving a familiar other. Across 3 separate experiments we found regions in paraphippocampal and retrosplenial cortex that show greater activity when remembering past events than in other experimental conditions. By using both standard rapid event-related and catch trial fMRI designs (Ollinger et al., 2001), we found that this sensitivity persists when examining task trials as a whole, or when controlling for possible differences in trial-by-trial task orientation signals in the BOLD response. These regions have previously been implicated in mental simulation, and sit adjacent to, but outside of, the default network. They correspond to locations that are thought to be involved in processing contextual information (Bar, 2009). We hypothesize from these results that a signature of past experience is, at least in part, based on the amount of contextual information associated with a given event during episodic simulation.

Title: Associative retrieval mediates free recall of unrelated words

Authors: M. KATKOV[1], S. ROMANI[2,3], *M. V. TSODYKS[1];
[1]Weizmann Inst. of Sci., Rehovot, Israel; [2]Ctr. for Theoretical Neurosci., Columbia Univ., New York, NY; [3]Donders Ctr. for Neurosci., Radboud Univ., Nijmegen, Netherlands

Abstract: Human subjects successfully recognize up to 10,000 items after a brief exposure. Yet retrieving information from memory can be challenging if no specific cues are provided. In the classical free-recall paradigm, where participants are prompted to recall a list of previously presented words, the number of recalled items appears to exhibit sub-linear scaling with the number of remembered items. Notably, more words can be recalled with appropriate cues, indicating that the difficulty to recall is not caused by true forgetting. Similar results were obtained for a different paradigm where words are recalled based on graphemical cues (words beginning from letter ‘a’, ‘b’, etc.).
Here we propose a new model of free recall, based on neural network model of associative retrieval. Memorized items are stored in the network by strengthening connections between specific groups of neurons, resulting in stable activity patterns (attractors) that encode different items. Retrieval of memory is mediated by the activation of the corresponding attractor with each retrieved item triggering the next item. A sequence of attractors visited by the network activity represents items retrieved in a given trial. The dynamics of the retrieval is defined by the combination of four effects: the overlap of neuronal populations encoding presented items (semantic similarity), strengthened representation of first presented item (primacy), additional similarity acquired by the newly presented item and one of the previous items (contiguity) and,

finally, short-term memory for one of the last presented items (recency). The model also predicts that items are easier or more difficult to recall, i.e. their overall recall probability is correspondingly higher/lower, depending on how large their neuronal representation is.
We found that the model can account for the observed overall distribution of number of recalled items across trials, distribution of recall probabilities across items, serial position curve (recall probability vs. position of an item in the list) and distribution of recalled chain length, where a chain is defined as a sequence of items recalled either in the presented (positive length) or reverse (negative length) order. A more subtle, counterintuitive, prediction of the model is confirmed by data analysis (data courtesy of M. Kahana). For both the model and the data, the number of recalled words decreases, on average, with their mean recall probability, while it is roughly independent of the mean recall probability of presented words. The results support our hypothesis that recall of information from long-term memory is mediated by associative transitions between memory items.

Title: Source memory performance is modulated by transcranial direct-current stimulation over the left posterior parietal cortex

Authors: *C. LO, N. CHEN, N. G. MUGGLETON, C. JUAN, S. CHENG;
Inst. of Cognitive Neurosci., Inst. of Cognitive Neuroscience, Natl. Central Univ., Jhongli, Taiwan

Abstract: In functional neuroimaging studies, it has been consistently found that the left posterior parietal cortex (LPPC) shows retrieval-related activation during memory tasks. However, the specific role of the LPPC during memory retrieval remains unclear. In particular, the correlational nature of neuroimaging studies makes it difficult to establish causal relationship between LPPC and memory retrieval. In the present study, transcranial direct-current stimulation (tDCS) was used to address this issue. Previous studies on motor cortex show that different polarities of tDCS (anodal and cathodal) can facilitate and inhibit neural excitability respectively. By manipulating the polarities of tDCS over the P3 electrode site (10-20 system), we predicted

that memory performance would be increased by anodal stimulation, whereas cathodal stimulation would decrease memory performance. Twenty-four subjects were divided into two groups (12 anodal and 12 cathodal). Each participant was asked to come to the lab three times where source memory tasks were presented during each visit. All subjects received stimulation over P3, sham, and right primary motor cortex (M1) as the control site each on different visits. On-line tDCS was delivered throughout the entire test phase. The old/new recognition performance showed no significant differences between stimulation over P3, sham, and M1 in both anodal and cathodal groups. However, compared with the sham condition, we found that source memory accuracy was decreased significantly in the cathodal group when subjects received stimulation over P3, whereas no such effect was found in the anodal group. This result shows that the effects of cathodal stimulation are specific to source memory which engages the recollection process, and not familiarity. Although it remains unclear why there was no effect during anodal stimulation, the data shows source memory accuracy was decreased by cathodal stimulation over P3, providing evidence for the causal relationship between LPPC activity and episodic memory retrieval.

Title: Brain Derived Neurotrophic Factor is correlated with memory processes in healthy women

Authors: *L. C. MORADO[1], J. RAMIREZ-EMILIANO[2], M. S. SOLIS-ORTIZ[2];
[1]Med. Sci., Univ. of Guanajuato, León, Mexico; [2]Med. Sci., Univ. of Guanajuayo, Leon, Mexico

Abstract: The Brain Derived Neurotrophic Factor (BDNF) is considered as a biomarker of cognition and plays an important role in memory and learning and neuronal plasticity. High levels of BDNF have been found in the ovulatory and luteal phases of the menstrual cycle in young women and a decrease in the postmenopause. However if the BDNF correlates with memory in women is not well known. The aim of the present study was to correlate the levels of

BDNF with memory tasks in healthy women.
The levels of BDNF in platelets were obtained in 31 premenopausal women, 11 in the ovulatory phase, 10 in the luteal phase and 10 in the menstrual phase, and were compared with 15 postmenopausal women. The scores on 4 tasks measuring working memory, spatial memory, verbal memory, visual memory were obtained for each participant. The number of correct responses, errors, reaction time, omission, and learning of number sequences forward and backward were computed and compared between premenopausal and postmenopausal women. The scores obtained were correlated with the levels of BDNF.
BDNF levels did not differ between premenopausal women and postmenopausal women. BDNF levels were negatively correlated with the number of errors in the working memory task ($r = -0.38$, $p < 0.05$) and with the number of words learned from the verbal memory task ($r = -0.36$, $p = 0.05$) in postmenopausal women.
These findings suggested an association between memory processes, particularly in working memory and verbal memory, and levels of BDNF in premenopausal women probably related to hormonal status.

Title: Relationship between physiological and clinical measures of prospective memory

Authors: *S. A. RASKIN, N. KAUR, C. PEDRO;
Trinity Col., hartford, CT

Abstract: Prospective memory (PM) requires the ability to form and later realize intentions that are delayed over time (Einstein & McDaniel, 1990). The purpose of this experiment was to examine the underlying brain activity related to PM using an event-related potential paradigm (West & Ross-Munroe, 2002) compared to a clinical measure, the Memory for Intentions Screening Test (MIST) (Raskin, Buckheit, & Sherrod, 2011) in both healthy adults (HA) and individuals with traumatic brain injury (TBI). Results revealed that individuals with TBI performed significantly worse than HA on all variables of the MIST and also showed reduced amplitude on ERPs that have been associated with intention formation and intention retrieval when compared to HA. In addition, total score on the MIST was related to variables associated

with attention retrieval. Overall, these findings suggest that individuals with TBI have deficits in PM compared to HA and that the MIST may be a valid measure of underlying brain processes in PM.

Title: Gamma bursts surf alpha waves: An ECoG study

Authors: *A. BAHRAMISHARIF[1], M. A. J. VAN GERVEN[1], E. J. AARNOUTSE[2], M. R. MERCIER[3], T. H. SCHWARTZ[4], J. J. FOXE[3], N. F. RAMSEY[2], O. JENSEN[1];

Abstract: Traveling waves reflected by consistent phase differences across spatially adjacent electrodes have been reported in both human and animal intracranial recordings. While waves in the alpha band (8-13 Hz) have been shown to travel over space in terms of consistent phase differences, it is unknown how this phenomenon relates to neuronal activity in other frequency bands. Recent work has demonstrated that gamma amplitude (30-100 Hz) is coupled to the phase of ongoing alpha oscillations. This raises the question of whether gamma activity is also linked to the phase of alpha oscillations traveling over cortex. We analyzed resting state

electrocorticography (ECoG) data recorded from four epileptic patients. Our first observation was that alpha power dominated the spectral content in most ECoG electrodes. We found examples in each subject where traveling waves were observed in lines of neighboring electrodes. The traveling velocity was in the range of 0.7 to 2.3 m/s. By calculating the coherence in different frequency bands, we found that the traveling waves were specific to the alpha band. A cross-frequency analysis taking all frequency combinations into account, revealed a strong modulation of gamma power by alpha phase. Modulations were not robust in other bands. We further showed that the gamma bursts were phase-locked to traveling alpha waves occurring at the troughs. As a result the gamma activity 'surfs' the alpha waves. Given that alpha activity has been proposed to modulate neuronal processing reflected in the gamma band, we suggest that alpha waves are involved in coordinating neuronal processing in both space and time. In future work it would be of great interest to investigate if this phenomenon reflects behavior and cognitive processing.

Title: Local entrainment of alpha oscillations by visual stimuli phasically modulates perception

Authors: *E. SPAAK, F. P. DE LANGE, O. JENSEN;
Radboud Univ. Nijmegen, Donders Inst. For Brain, Cognition, and Behaviour, Nijmegen, Netherlands

Abstract: Prestimulus oscillatory neural activity greatly influences the detection of near-threshold stimuli. In particular, the amplitude and phase of ongoing alpha oscillations has been shown to predict whether near-threshold stimuli are detected or not. To make a causal claim about the mechanistic role of oscillatory activity, one needs to be able to manipulate the oscillations directly, independently of any cognitive or attentional instruction. Recently, several authors have attempted such manipulations through transcranial magnetic or current stimulation, and noninvasively through the presentation of periodic stimuli. Here we present compelling

evidence that rhythmic visual stimulation entrains ongoing alpha oscillations in human visual cortex, in a spatially specific manner. We presented rhythmic stimuli to one visual hemifield, and arhythmic stimuli to the other. We find a periodic pattern in detection performance of a subsequent near-threshold target only for the hemifield that was rhythmically stimulated, and not for the other hemifield. This periodic pattern lasts for at least three oscillatory cycles. The magnetoencephalogram (MEG) was measured throughout the experiment. We find strongly lateralized alpha activity in the MEG, phase-locked to the rhythmic stimulation, and outlasting the stimulation by several cycles. Using a beamformer apporach, we localized the sources of the entrained alpha activity to primary visual cortex. Importantly, the degree of entrainment quantified from the MEG data predicted the behavior: subjects with a stronger alpha entrainment were also subjects with a stronger phasic modulation of detection performance in the entrained hemifield. Taken together, these findings argue for a cortically focal entrainment of ongoing alpha oscillations by visual stimulation, with concomitant consequences for perception. The findings support the notion that oscillatory brain activity in the alpha band provides a causal mechanism for temporally organizing visual perception.

Title: Computational model of exponentially decaying persistent firing for encoding stimulus history

Authors: *Z. TIGANJ, K. SHANKAR, M. HOWARD;
Ctr. For Memory and Brain, Boston Univ., Boston, MA

Abstract: Persistent firing, observed in variety of brain regions, is believed to be important for working memory. However, persistent firing with stable firing frequency does not carry any information about the timing of stimulus presentation and does not account for some well-known characteristics of memory such as scale-invariance and forgetting. It has been shown that persistent firing with exponentially decaying firing rate can be an essential building block of working memory [1]. In order to represent several minutes of the recent stimulus history the largest time constant should also be several minutes. Through a computational study we

demonstrate here that exponentially decaying persistent firing with a range of time constants up to minutes is biologically plausible.
We show that calcium controlled cation current and interplay between calcium pumps and calcium inward currents could account for theoretically arbitrarily long time constants. We first assume that the stimulus presentation results in large calcium influx. After the stimulus has ended, the calcium controlled cation current can be sufficiently large to iteratively depolarize the cell to the firing threshold. If the amount of calcium that leaves the cell during interspike intervals is greater than the amount that enters the cell during spikes the overall calcium concentration will decay. Consequently the calcium controlled cation current will also decay and the time it takes to depolarize the cell to the firing threshold will increase from spike to spike, resulting in a decay of the firing rate as well. We show that this decay can be exponential with a time constant several orders of magnitude larger than any intrinsic time constant of the cell. Moreover, we show that these time constants can be controlled externally with dendritic inhibition allowing the system to account for various temporal, ordinal, and spatial representations.

Title: Increasing functional connectivity with cognitive load

Authors: *L. AHONEN[1,2], M. HUOTILAINEN[2];
[1]Työterveyslaitos, Helsinki, Finland; [2]Cognitive Sci., Helsinki Univ., Helsinki, Finland

Abstract: Studying working memory (WM) with computerized classical cognitive tests is an efficient way to investigate functional activation patterns in brain with different cognitive load levels. The present study investigated neural activity using magnetoenchepalography (MEG) in N-back paradigm. N-back is a task that according to previous research activates large number of WM related brain areas. There are also preliminary results in functional magnetic resonance imaging (fMRI) suggesting that lateral and other inter-areal connectivity between WM associated areas increase during higher cognitive loads. N-back provides precise way to control

cognitive load and working memory related activation. We conducted connectivity analysis based on Granger causality to test functional relations between brain regions that have been identified to be task related networks. We focused on load-dependent changes in event-related activity originating from key brain areas in frontal and parietal regions and tested the connectivity in different task conditions. We found increased fronto-parietal and lateral connections with more difficult task conditions. The connectivity was increasing in the direction from frontal areas to parietal areas and between the hemispheres. These results are in line with the previous literature as the number the active brain regions goes up, the connectivity between the related areas become more prominent. These results reveal the functional networking between brain regions during updating and maintaining task dependent information. The connections from frontal regions might generalize to other cognitively demanding tasks.

Title: Oscillatory visual activity associated with preparatory attention and working memory maintenance

Authors: *B. CRITTENDEN, M. P. NOONAN, N. ADAMIAN, M. STOKES;
OHBA, Oxford, United Kingdom

Abstract: During the delay period of working memory tasks it can be difficult to disentangle working memory maintenance activity from preparatory activity in anticipation of the upcoming memory probe stimulus. This study was designed to decouple the contribution of these two processes by investigating changes in the time-frequency spectrum during the delay period by orthogonally manipulating the working memory load and need for top-down preparatory attention.
Six participants each took part in 4 one-hour EEG sessions. Participants were asked to attend to either 1, 2 or 4 simultaneously presented memory stimuli (small circular gratings) that appeared on screen for 250ms. Participants were then required to retain the orientation of these gratings over a 2.5s delay period as best they could. Following the delay, a memory probe stimulus

appeared in one of the previously to-be-remembered stimuli locations. Participants were asked to indicate whether the memory probe was rotated clockwise or anticlockwise relative to the memory item that was previously in that location. The difficulty of the task was manipulated in two ways: the contrast of the memory probe was either high or low, with contrast fixed within blocks; in addition the rotation of the probe could be either 45°, 23°, 11° or 6°, with rotation size varying on a trial-by-trial basis.
EEG was recorded over 64-scalp electrodes using a synamps amplifier. Muscle and eye movements were also recorded and used to reject trials contaminated with saccadic and other movement related artefacts. Each session was high (45Hz) and low-pass (0.05Hz) filtered and aligned with the behavioural responses and trial-type triggers.
Looking across posterior electrodes, we found a significant difference between set size 4 and set size 1 in the alpha frequency (8-12Hz) range when participants were expecting a low-contrast memory-probe stimulus. There was, however, no set size effect when participants were expecting a high-contrast memory probe stimulus.

Title: EnygmaGym: Static versus dynamic visual computer based training results in discrete morphometric changes

Authors: *K. FUJIMOTO[1], A. KATZMAN[2], S. N. NIOGI[3], B. B. ALLEN[4], M. FASO[5], U. RAJASHEKAR[5], I. TSERETOPOULOS[5], J. MARUTA[5], J. GHAJAR[5], B. E. KOSOFSKY[2,4]; [1]Neurol., [2]Pediatrics, Weil Cornell Med. Col., New York, NY; [3]Diagnos. Radiology, [4]Neurol., NewYork-Presbyterian Hosp., New York, NY; [5]Brain Trauma Fndn., New York, NY

Abstract: Background:
We utilized MR-based morphometry to identify the regional specificity of structural changes in the brains of volunteers with one of two computer-based visual exercises: a dynamic exercise which requires predictive timing, and a static exercise which involves working memory.
Methods:

22 healthy volunteers who participated in the study were randomly divided into two training groups: group 1 with 12 volunteers (mean age = 23.3 ± 2.1) and group 2 with 10 volunteers (mean age = 22.6 ± 2.1). Each volunteer played the assigned exercise for at least three ten-minute sessions each day, five days a week over eight weeks. Three T1-weighted images were acquired on each subject before (0 weeks), during (4 weeks) and after (8 weeks) the training. All images were processed with FreeSurfer for cortical parcellation and subcortical segmentation, followed by a within-subject robust analysis of longitudinal morphometric changes. To assess the significance of changes within each training group, a two-tailed paired t-test was performed on each segmented subcortical and cortical volume between the first and last scans. Investigators remained blinded to the training groups.

Results:

We observed global and region-specific cortical thinning in group 1 after the eight weeks of training. A two-tailed paired t-test showed that the whole-brain cortical grey volume of group 1 significantly decreased (total cortical grey p=0.026, left cortical grey p=0.074, and right cortical grey p=0.008). Regional reductions in cortical volume for group 1 are shown in the accompanying table. However, the cortical grey volume for group 2 remained unchanged after the eight weeks of training.

Conclusion:

In a blinded analysis of cortical morphometric changes induced by an eight-week intensive training paradigm, we observed a differential effect of static versus dynamic visual exercises. We found a decrease in cortical volume in one group but not the other. Interestingly, regional reductions in cortical volume were more driven by changes in the right hemisphere, and were localized to regions known to subserve attention and predictive timing.

Title: Interaction effects of BDNF and COMT on brain resting-state regional homogeneity

Authors: *W. CHEN, C. CHEN, B. ZHU, X. LEI, Q. DONG;
State Key Lab. of Cognitive Neurosci. and Learning, State Key Lab. of Cognitive Neurosci. and Learning, Beijing, China

Abstract: Introduction: Catechol-O- methyltransferase (COMT) and brain-derived neurotrophic factor (BDNF) genes have been proved to interactively influence working memory (WM) as well as brain activation during WM tasks. However, whether the two genes have interactive effects on resting-state activities of brain and whether these spontaneous activation influence WM are still unknown.
Methods: In this study, three hundred and sixteen healthy Han Chinese subjects were scanned during the resting state, genotyped on COMT rs4680 (169 COMT-Val/Val Val/Val, 139 COMT-Met), and BDNF Val66Met (85 BDNF-Val/Val, 231 BDNF-Met, and finished a 2-back WM task. Resting-state fMRI data were preprocessed and calculated regional homogeneity (ReHo) using DPARSF package (www.restfmri.net). Genetic effects on ReHo were investigated using SPM. For regions that showed significant COMT-BDNF interaction, mean ReHo was extracted. Correlations between mean ReHo and WM performance were tested.
Results: Significant interactive effects of BDNF and COMT were observed in Default Mode Network (DMN) and WM related brain areas, including left posterior cingulate cortex, bilateral precuneus, right middle frontal gyrus, right middle temporal gyrus and right superior parietal lobule (Fig. 1a). Further simple analyses show that COMT Val/Val have higher ReHo than COMT Met carriers in BDNF Met carriers and have opposing effect in BDNF Val homozygote only in right superior parietal lobule, which was reverse in other areas (Fig. 2b). What's more, WM performance was positively correlated with the mean ReHo of right superior parietal lobule while negatively correlated with that of right middle frontal gyrus.
Conclusions: The findings support the hypothesis that COMT and BDNF polymorphisms influences brain spontaneous ReHo, which can further predict WM performance, suggesting that resting-state ReHo can be a reliable endophenotype that bridges genetic variation to behavior.

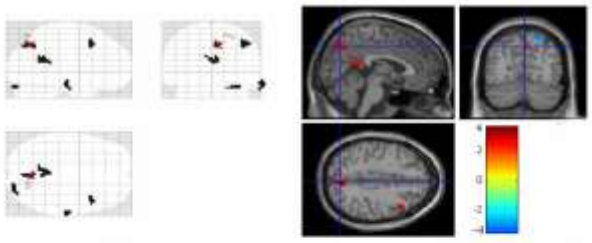

Figure 1a Interaction effects of COMT and BDNF on ReHo of the whole brain. The coordinates is [3.42, -71.40, 43.04].

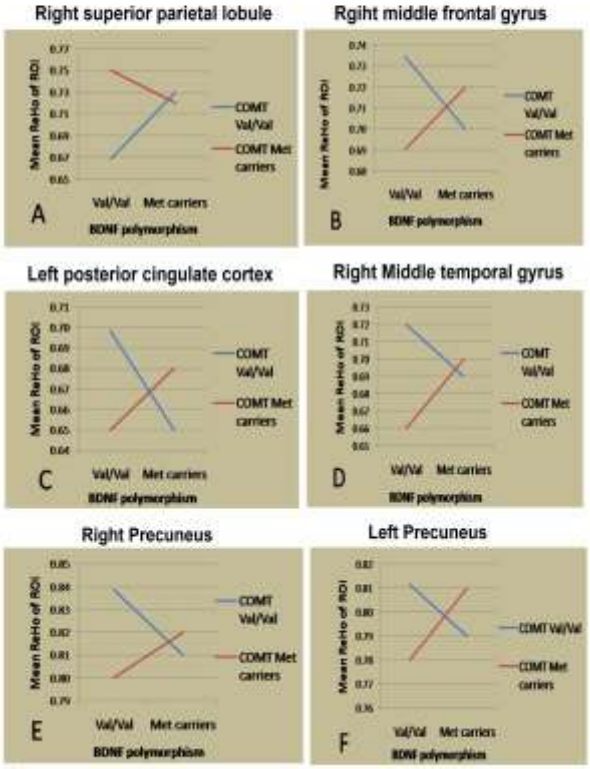

Figure 1b Simple effects of COMT and BDNF on mean ReHo in significant ROIs.

Title: Neural basis of object-based shifting of attention in working memory

Authors: *B. PETERS[1], B. RAHM[2], J. KAISER[1], C. BLEDOWSKI[1];
[1]Inst. of Med. Psychology, Goethe-University, Frankfurt Am Main, Germany; [2]Med. Psychology and Med. Sociology, Univ. Med. Ctr. Mainz, Mainz, Germany

Abstract: Working memory (WM) enables the retention of a limited number of items for a short period of time. In addition, many situations require that a subset of WM contents be transiently prioritized for processing by focusing attention on them. Current models of WM suggest that the same attentional mechanisms that are known from perception also operate in WM. In vision, shifts of attention between spatial positions within the boundaries of one object are performed faster than shifts between positions located on different objects. This within-object benefit can be explained by an automatic spread of attention within perceived object boundaries in visual cortex.
Hypothesizing the same attentional mechanisms in WM as in perception, we tested whether the within-object benefit can be observed, both on the behavioral and neural level, when subjects focus attention on spatial positions that are no longer physically present but represented in WM. 20 healthy subjects were presented two objects each containing two highlighted spatial positions. They had to memorize all four spatial positions. Attentional shifts in WM were faster for spatial positions located on the same object compared with equidistant positions on separate objects. Shifting attention in WM thus showed a within-object benefit comparable to the effect observed in a perceptual version of the same task. This behavioral benefit was associated with increased BOLD activity in posterior parietal cortex that could not be explained by differences in eye movements between conditions. Moreover, analysis of retinotopic visual cortex revealed that the automatic spread of attention within object boundaries was present also for information held in WM. Specifically, when attention was shifted to a memorized position, activity in early visual areas was enhanced at the retinotopic location corresponding to the second position co-located on the same object compared to equidistant positions located on the other object.
These results extend the previous suggestion of shared mechanisms of spatial attention in perception and WM by demonstrating that this notion also holds for object-based attention. Attentional selection of a memorized position leads to a neural co-activation of another memorized position within the same object. This suggests that when object-like representations are held in WM, attentional selection includes activation of the complete object, thus accounting for the within-object benefit.

Title: Nicotine-deprived smokers' WM capacity differences in strategy use and recruitment of brain regions linked to goal maintenance during a WM task

Authors: *A. S. WEIGARD, S. WILSON, C. HUANG-POLLOCK;
The Pennsylvania State Univ., University Park, PA

Abstract: Working Memory (WM) performance in smokers is degraded by nicotine deprivation, but how individual differences in WM capacity (WMC) affect task strategies in this condition is unclear. On a WM recognition task, individuals can use evidence of stimulus familiarity or evidence from the recollection of the stimulus representation in WM (Oberauer, 2005). While a familiarity strategy relies on simple recognition, recollection requires active maintenance of WM items and task goals, suggesting that high WMC individuals, who display increased goal maintenance (Unsworth & Engle, 2007), may primarily use a recollection strategy while low WMC individuals may rely on familiarity. The current study investigates this possibility, with predictions that 1) low WMC, but not high WMC, smokers will display a strong relationship between basic recognition speed and WM performance and 2) high WMC smokers' performance will be more strongly associated with activity in brain regions linked to goal-maintenance. A sample of 125 active smokers was split into high and low WMC groups (median split) based on scores on the OSPAN task (Turner & Engle, 1989) completed prior to the experiment. After abstaining from nicotine for 12 hours, participants completed an N-back task during fMRI data acquisition. In each block, participants were presented with 12 letters in a 0-back condition (speed), where they pressed a button with their right index finger when the letter "X" appeared, or in a 3-back condition (WM performance), where they pressed the button if the letter presented matched one presented three items prior. In both conditions, participants pressed a button with their right middle finger for non-targets. RT data from each condition was fit to the diffusion model (Ratcliff & McKoon, 2008), which indexes speed of processing on decision tasks as the parameter of drift rate (v). The low WMC group displayed a strong association between v on the 0-back and v on the 3-back, $r(63) = .44$, $p < .001$, $R^2 = .19$, while high WMC individuals did not, $r(62) = .20$, $p = .12$, $R^2 = .04$, suggesting that for low WMC individuals, but not high WMC individuals, performance on WM recognition tasks was highly related to simple recognition speed. This supports the hypothesis that low WMC smokers primarily use a familiarity strategy. To determine if high WMC individuals' WM performance is more strongly associated with recruitment of brain regions implicated in goal-directed behavior than low-WMC individuals',

regression analyses will be conducted where activity in specific regions of interest, the dorsolateral prefrontal cortex and anterior cingulate, during the 3-back is used to predict *v* on the 3-back in each group.

Title: Decoding visual short-term memory contents in occipital and parietal cortices under distraction

Authors: *K. BETTENCOURT, Y. XU;
Vision Lab., Harvard Univ., Cambridge, MA

Abstract: Visual short-term memory (VSTM) has been shown to recruit a network of brain regions, including frontal, parietal, and posterior sensory regions. However, results from different types of analyses disagree on where exactly the contents of VSTM are stored. Univariate fMRI analyses have suggested that regions in the parietal lobe, in particular superior intraparietal sulcus (IPS), play a central role in VSTM information storage. In contrast, with the exception of one study, research with fMRI multivariate pattern analysis (MVPA) has shown that the contents of VSTM can only be decoded in early visual areas, and not in areas that show sustained load related univariate delay period activity. Thus, it remains unclear where the contents of VSTM are stored. Furthermore, if information is stored within the pattern of delay period activity in early visual cortex, as suggested by MVPA, then what happens when we are faced with distracting visual information during the delay? Given the ubiquitous presence of distractors in everyday visual perception, any area involved in the storage of VSTM must retain visual information under distraction. Here, in an fMRI study using MVPA, we show that while a particular orientation held in VSTM can be successfully decoded from early visual areas in the absence of distractors, decoding performance significantly dropped when distractors are introduced during the delay period. Importantly, behavioral performance is equally good with and without distractors, showing that the decrease in decoding in early visual areas under

distraction cannot be attributed to poor task performance. In contrast, decoding performance in superior IPS is significantly above chance regardless of whether distractors are present or not. These results indicate that parietal regions likely play a central role in VSTM information storage across a variety of stimulus conditions. In the absence of distraction, early visual areas may be recruited to aid the maintenance of memory representations, likely via a visual rehearsal/mental imagery strategy. However, such contributions are unlikely to be essential for VSTM information storage in the real world where visual distraction is constant.

Title: ACC control of DLPFC interneurons tunes beta/gamma oscillation and inter-areal feedback in a laminar spiking model

Authors: *J. S. SHERFEY[1], N. KOPELL[2];
[1]Computat. Neurosci. and Neural Technol., Boston University, Sch. of Med., Boston, MA;
[2]Boston Univ., Boston, MA

Abstract: Interactions between dorsolateral prefrontal cortex (dlPFC), anterior cingulate (ACC), and sensory association cortices underlie the maintenance and manipulation of cell assemblies activated by previous sensory stimuli. This persistent “delay” activity has been implicated in working memory and cognitive control processes, but the mechanisms by which it contributes to these processes are unknown. We hypothesize that beta and gamma oscillations in interacting dlPFC & ACC control the transition between two dlPFC states: (1) one where stimulus-related activity persists after stimulus offset without modulating sensory cortices, and (2) one where persistent firing is locally coordinated by network oscillations into synchronous subassemblies that feedback and interact with activity in association cortex.
To investigate the cellular and network mechanisms that could support this behavior, we developed a computational spiking neuron model of laminar dlPFC with feedforward inputs from auditory association cortex and feedback from ACC. The dlPFC model included superficial and

deep layers with the following components: (1) a recurrent pyramidal network supporting delay activity, (2) modulatory and fast spiking interneurons, (3) beta- and gamma-generating mechanisms, (4) ACC input to superficial dlPFC and sensory inputs to middle layers. Our results indicate that (1) ACC activation of interneurons can mediate dlPFC network oscillations in the beta- and gamma-frequency ranges and (2) sensory inputs can drive stimulus-related subassemblies that fire at distributed phases of the dlPFC network oscillations. Together, these results suggest ACC may synchronize dlPFC assemblies for effective phase-coded feedback to modulate processing in association cortices. This represents a mechanism by which ACC could switch local dlPFC subassemblies from a passive maintenance to active modulatory mode. Our future studies will investigate the specific contributions of gamma and beta rhythms in different layers of dlPFC & ACC as well as the effects of coordinated feedback from prefrontal cortices on afferent sensory processing. These simulations will facilitate mechanistic theories linking working memory processes to cognitive control and attentional regulation of afferent sensory streams.

Title: The association between cognitive performance, somatic perception, and task-related brain activity in fibromyalgia patients and healthy volunteers

Authors: *B. WALITT[1], M. KHATIWADA[2], M. CEKO[3], J. VAN METER[2], R. GRACELY[4]; [1]Medstar Washington Hosp. Ctr., Washington, DC; [2]Georgetown Univ., Washington, DC; [3]NCCAM, NIH, Bethesda, MD; [4]Univ. of North Carolina, Chapel Hill, NC

Abstract: Introduction: Perceived cognitive dysfunction is a common complaint in fibromyalgia (FM). Experimental evidence suggests that FM patients activate cognitive task-related brain areas differently than healthy volunteers (Glass et al. 2011; Seo et al. 2012). This study addresses the mechanisms mediating these differences, in particular how the distressing somatic perceptions of FM (experimental pain, spontaneous pain, fatigue, functional disability, and

cognitive self-appraisal) influence cognitive task performance and task-related brain activity.
Methods: 16 FM and 13 healthy age, gender, and racially matched controls underwent a total of 69 study visits as part of an interventional trial of exercise therapy. No differences were seen in N-Back performance related to the exercise intervention, allowing us to combine all visits into the two groups. At each visit, the participants completed questionnaires measuring somatic and psychological symptoms and performed N-Back testing of working memory while undergoing BOLD fMRI scanning (block design; 0-Back alternating with 2-Back). Group differences in BOLD fMRI activity (2-Back > 0-Back) were examined using GLM flex in SPM. Voxel-wise regression analysis was performed to determine correlations between BOLD activity and 2-Back accuracy or symptom reporting. Pearson correlations were used to examine the correlation between 2-Back accuracy and symptom reporting.
Results: Healthy volunteers had greater task-related and limbic activation compared to controls (FDR $p< 0.05$) despite no statistical difference in 2-Back accuracy (56.4% v 65.8%, $p= 0.2$). Task-related activity correlated with accuracy in healthy volunteers but not in FM. In FM, task-related and limbic activity correlated with the patient's perception of their ability to attend, their verbal memory, and spontaneous pain. No correlations were found between task-related brain activity and nociceptive pain, mental fatigue, or functional disability.
Conclusion: The expected relation between task-related activation and performance is observed in healthy volunteers but is not found in FM. Our results confirm the group difference reported by Seo et al. but unexpectedly does not show any association between accuracy and brain activity in FM. Task-related brain activity does not account well for cognitive performance in FM patients.

Title: Acute sleep deprivation shows readily reversible effects on the Multi-Source Interference Task (MSIT)

Authors: *M. AULAKH, S. R. FLETCHER, C. EIERUD, J. LISINKI, B. HAMILTON, S. M. LACONTE;
VTCRI, Roanoke, VA

Abstract: Sleep loss is a common occurrence and has recently come under scrutiny as the determining cause of many catastrophic events. Previous studies (Harrison & Horne, 2000) have shown that sleep deprivation can have deleterious effects on cognitive performance and decision-making, however the neural correlates of sleep deprivation are not yet fully understood. The Multi-Source interference task (MSIT) combines elements of three different tasks (Stroop task, Eriksen flanker task, and Simon effect) to induce cognitive interference and robust activation of the dorsal anterior cingulate cortex (dACC) and dorso-lateral prefrontal cortex (DLPFC) (Bush et al., 2003). Previous studies have shown inconsistent findings when testing the effects of acute sleep loss on executive function (Drummond et al., 2006; Kilgore et al., 2006; Cain et al., 2011). The aim of this study was two-fold: (1) to determine how sleep deprivation affects executive function using the MSIT and (2) to use functional MRI (fMRI) to identify the neural regions that are preferentially effected during sleep deprivation, using the general linear model (GLM) and multivoxel pattern analysis (MVPA) analyses.

Study volunteers performed the MSIT while undergoing three fMRI sessions. Each session consisted of three MSIT runs. In the 1st session, subjects achieved three nights of normal sleep (greater than 7 hours of sleep per night). During the 2nd session, subjects achieved complete sleep deprivation for at least 24 hours. In the final session, subjects returned after 2 nights of recovery sleep.

Subjects showed delayed reaction times in the neutral condition during sleep deprivation compared to their initial scan ($p < 0.05$). The recovery session eliminated the sleep deprivation delay ($p < 0.05$).

MSIT performance slowed significantly during acute sleep loss conditions and readily reversed with recovery sleep, indicating that sleep deprivation does have acute yet transient effects on executive function. These results support the notion that total sleep deprivation affects both sustained attention and response inhibition. The improvement from baseline reaction times after sleep recovery may indicate a practice effect not previously described using the MSIT. These readily reversible effects should be explored further in comparison to pathological conditions characterized by irreversible executive functioning deficits, such as stroke and traumatic brain injury.

Title: Neural representation of rules at different hierarchical levels

Authors: *D. PISCHEDDA[1,2], K. GÖRGEN[1], J.-D. HAYNES[1,3,4,5,6], C. F. REVERBERI[2];
[1]Bernstein Ctr. For Computat. Neuroscience, Charité Universitätsmedizin, Berlin, Germany; [2]Dept. of Psychology, Univ. of Milano-Bicocca, Milan, Italy; [3]Berlin Ctr. for Advanced Neuroimaging, Charité Universitätsmedizin, Berlin, Germany; [4]Berlin Sch. of Mind and Brain, Humboldt Univ., Berlin, Germany; [5]Cluster of Excellence NeuroCure, Charité Universitätsmedizin, Berlin, Germany; [6]Dept. of Psychology, Humboldt Univ. zu Berlin, Berlin, Germany

Abstract: In everyday life, humans use rules to organize their thoughts and actions in order to achieve specific goals (Bunge & Wallis, 2007). For simple situations, single rules can be used to link a sensory stimulus (the traffic light is green) to its appropriate response (cross the road). More complex situations, however, require the application of multiple rules organized in hierarchies, where high level rules influence the selection or application of lower level rules. Previous studies have demonstrated that Prefrontal Cortex (PFC) is one of the key areas underlying rule processing and control of action. However, it is still unclear whether distinct brain regions within PFC systematically encode qualitatively different task features.
In the present study we investigated whether different features defining a complex rule set are represented in different brain areas depending on the level of control they enforce. To this purpose, we devised an experiment in which participants (N = 20) learnt complex rule sets composed by rules at two different levels of control: low (e.g., "if you see a banana, then press left") and high (e.g., "If you see a star, then only consider red targets"). The task required participants to retrieve, maintain, and apply two rule sets (one low and one high level) to target stimuli. At the beginning of each trial two cues associated with low (or high) level rules were displayed, followed by a delay (delay 1). Then a second pair of cues standing for high (or low) level rules were presented followed by a second delay (delay 2), after which the target was shown. Participants had to apply all the rules to the target stimuli and respond accordingly. The paradigm allowed us to: (i) independently assess the encoding of high and low level rules, (ii) evaluate the difference between the encoding of the two types of rules (comparing high vs. low level rule representations during delay 1, when only one type of rule was maintained), and (iii) decode rule integration (by comparing rule representations during delay 1 vs. delay 2, in which the two levels of rules had to be integrated in order to respond).
We applied multivariate decoding analysis (e.g., Haynes et al., 2007) to functional magnetic resonance imaging data to perform the above-described comparisons. Behavioral as well as

preliminary decoding results suggest that rules at different levels of abstraction are indeed processed differently in distinct brain regions within a large-scale brain network comprising parietal and prefrontal areas.

Title: The brain's response to cognitive demand under drug-induced Impairment: A topiramate study

Authors: *S. E. MARINO[1], C. WANG[2], S.-M. HAN[2], I. SAMUEL[2], J. CIBULA[2], M. DING[2]; [1]Ctr. for Clin. & Cognitive Neuropharm., Univ. of Minnesota, Minneapolis, MN; [2]Univ. of Florida, Gainesville, FL

Abstract: Many CNS drugs negatively impact cognition. How the brain copes with drug-induced impairments is not clear. Understanding this problem is important to explain inter-individual variability in patients' response to these drugs and to optimize therapeutic strategies. We examined this problem with respect to the antiepileptic drug topiramate (TPM) which has also been indicated in a number of other conditions. Healthy volunteers were administered a single, 100-mg oral dose of topiramate in a double-blind, randomized, placebo-controlled, crossover design. High-density scalp EEG was recorded while the volunteers performed a modified Sternberg working memory task with three levels of memory load (1, 3, and 5). Memory retrieval-related ERPs were analyzed across the whole brain. During baseline and placebo conditions, the central-frontal region showed strong memory load modulation; no memory load modulation was observed in bilateral frontal regions. In contrast, during the TPM condition, the memory load modulation in the central-frontal region was significantly reduced but additional brain regions showed sensitivity to memory load, including the bilateral frontal regions. By comparing the ERPs between baseline, placebo and TPM conditions for a given memory load, we further found that during the TPM condition, the ERPs from the central-frontal region were enhanced for low memory load but not for high memory load, whereas the ERPs from the bilateral frontal regions were enhanced for high memory load but not for low memory load. These findings suggest that the brain employed a compensation mechanism by recruiting

more neural resources to cope with the TPM-induced impairment under increasing cognitive demand. For the easy task (memory load=1), the compensation happened within the original task-relevant brain regions (central-frontal). For the difficult task (memory load=5), the neural resources within the original task-relevant brain regions were exhausted due to drug-induced impairment, and additional brain regions were recruited to compensate. Our correlation analysis, which identified a significant correlation across subjects between the compensatory ERP enhancement and the TPM-induced decline in behavioral performance, suggests that the level of compensation under cognitive demand reflects the level of cognitive impairment induced by drug individually.

Title: Testing the biased competition model of attention in the selection of abstract task rules

Authors: *Y.-S. SHEU[1], S. COURTNEY[1,2,3];
[1]Dept. of Psychological and Brain Sci., [2]Dept. of Neurosci., Johns Hopkins Univ., Baltimore, MD; [3]F.M. Kirby Res. Ctr., Kennedy Krieger Inst., Baltimore, MD

Abstract: Biased competition model was originally proposed as a theory for attentional selection of perceptual information, positing that stimuli within a cell's receptive field compete for cortical representation via mutually inhibitory interactions, and selection results from salience and top-down signals biasing that competition. Although a few studies have shown these principles can also apply to selection of task-relevant perceptual information maintained in working memory (WM), it has not yet been determined whether such mechanisms can also apply to the selection of more abstract types of information in WM. Here we used functional magnetic resonance imaging to investigate whether the selection of abstract, non-sensory information, such as selecting relevant over irrelevant task rules, would result in similar neural patterns predicted by the biased competition model. Participants switched between two different task rules instructed by either the shape or the color dimension of the cues, subsequent to extensive learning of cue-rule mappings. Competition was manipulated by having the color and shape dimensions of the

cue associated either with the same task rule (congruent trials) or different ones (incongruent trials). Phonological and semantic tasks were used as they preferentially activate distinct brain areas, allowing us to measure the magnitude of competition between rules. By comparing incongruent to congruent trials, increased activity was found in a network of brain regions involved in cognitive control, including inferior frontal gyrus (IFG) and parietal cortex. Greater activity in IFG during incongruent relative to congruent trials was associated with a smaller activity difference between incongruent and congruent trials in areas selective for either phonological or semantic task. This finding indicates IFG sends modulatory signals to bias neural activity in areas relevant for the current task rule. When there is competition between task rules, as in the case for incongruent cues, increased activity in IFG is needed to enhance the relevant rule information to what it is when there is no competition for task rule representation, as is the case for congruent cues. In addition, greater activity in IFG for incongruent versus congruent trials predicted the difference in reaction time between incongruent and congruent trials. Overall, these results suggest that "biased competition" may serve as a mechanism to guide the selection of abstract task rule information, biasing the competing rule representations toward the task-relevant over the task-irrelevant ones.

Title: Increased human hippocampal theta oscillations are associated with the maintenance of temporal order information in working memory

Authors: *L.-T. HSIEH[1,2], A. D. EKSTROM[2,1], K. SHAHLAIE[3], S. T. FARIAS[4], M. SEYAL[4], C. RANGANATH[1,2];
[1]Ctr. for Neurosci., [2]Psychology, [3]Neurolog. Surgery, [4]Dept. of Neurol., UC Davis, Davis, CA

Abstract: Several electroencephalography (EEG) studies have suggested that neural oscillations might play a role in working memory (WM) processes. In particular, scalp EEG studies suggest that oscillatory activity in the theta band (4-8 Hz) increases during tasks that require the active maintenance of temporal order information, relative to equally difficult tasks that require maintenance of item features. Little is known about the brain regions that are critical for scalp-

recorded theta oscillations, although there is reason to believe that regions in the hippocampus or prefrontal cortex might contribute. Here, we used invasive intracranial EEG recordings from epilepsy patients undergoing presurgical evaluation in order to identify brain regions where oscillatory activity was related to maintenance of temporal order information in WM. Intracranial EEG was recorded while patients completed two types of WM trials: ITEM trials and ORDER trials. On each trial, an instruction word (either "ITEM" or "ORDER") was shown, followed by four sequentially presented visual objects, and then after a 4 sec retention interval, a test display was shown. On ORDER trials, the test display consisted of two visual objects from the previous sequence, and patients were asked to identify which visual object came earlier in the sequence. On ITEM trials, the test display consisted of one previously presented visual object along with another foil object that was not in the sequence. Patients had to identify which of the two objects was presented in the sequence. Preliminary results from three patients show that hippocampal theta was modulated by maintenance of item and order information. Specifically, two out of the three patients showed that the successful maintenance of temporal order information was associated with enhanced hippocampal theta oscillations as compared to the successful maintenance of item information in WM. These results provide preliminary evidence for the importance of hippocampal theta in maintaining the order of recent events. Further analyses will be performed in order to characterize activity in other regions, including the prefrontal cortex.

Title: Short-term retention of visual information is supported by mechanisms of feature-based attention

Authors: *M. H. SNEVE[1], K. K. SREENIVASAN[2], S. MAGNUSSEN[3];
[1]Dept. of Psychology, Res. Group For Lifespan Changes In Brain and Cognition, Univ. of Oslo, Oslo, Norway; [2]Helen Wills Neurosci. Institute, Univ. of California, Berkeley, Berkeley, CA; [3]Dept. of Psychology, Ctr. for the Study of Human Cognition, Univ. of Oslo, Oslo, Norway

Abstract: Retention of features in visual short-term memory (VSTM) involves maintenance of sensory traces in early visual cortex. However, the mechanism through which this is accomplished is not known. Here, we formulate specific hypotheses derived from studies on feature-based attention to test the prediction that visual cortex is recruited by attentional mechanisms during VSTM of low-level features.
Feature-based attention is characterized by the selective enhancement of responses from sensory neurons preferring an attended feature. Another central characteristic of feature-based attention is the relative suppression of irrelevant (i.e., non-attended) information along the same feature spectrum. If sustained feature-based attention is the mechanism underlying VSTM maintenance of non-spatial information, we should thus observe decreased activity in the feature spectrum surrounding a maintained feature. Here, we tested this prediction using fMRI of early visual cortex. We instructed participants to remember the spatial frequency (SF) of a sample grating to perform a memory discrimination task after a delay interval. During the retention period, a distractor stimulus was presented, and its SF could be identical to the sample, or varied with respect to the sample frequency.
Our results reveal that the blood-oxygen level-dependent (BOLD) responses produced by distractors with SFs in the feature spectrum surrounding the maintained SF are reduced, indicating that neural populations coding for task-irrelevant feature information are suppressed during visual feature memory. The narrow spectral extent of this suppression agrees well with known effects of feature-based attention. Additionally, analyses of effective connectivity during maintenance show that the observed feature highlighting in visual cortex originates in V4, a visual area strongly connected with, and directly modulated by, higher-level attentional control areas such as the frontal eye fields. Furthermore, we show that attentional modulations of earlier visual areas (V1-V3) during maintenance have behavioral consequences, and that these modulations are a result of influences from V4. Again, this corresponds well with the known directions of influence in early visual cortex during attention.
In sum, the present findings fit well with observations from the attention literature, and provide compelling evidence that feature-based attention is the mechanism supporting VSTM maintenance for low-level features in visual cortex.

Title: Causal network dynamics of fluid reasoning components

Authors: *E. SHOKRI-KOJORI[1], C. MCADAMS[2], D. KRAWCZYK[1,2];
[1]The Univ. of Texas at Dallas, Ctr. for BrainHealth, Dallas, TX; [2]The Univ. of Texas Southwestern Med. Ctr., Dallas, TX

Abstract: Reasoning as a multistage cognitive process is involved in identifying rules, patterns, and associations to provide predictable representations of the environment. Several intelligence tests, such as Raven's Progressive Matrices (RPM), indicate considerable variability in reasoning performance among individuals. In characterizing sources of individual differences in reasoning performance, the capacity to process larger sets of problem features or rules has been emphasized. Less attention has been paid to how basic abilities such as change detection (CD), rule verification (RV), and rule generation (RG) affect reasoning performance and the underlying patterns of brain connectivity. We tested this hypothesis using three experimental conditions that additively recruited CD, RV, and RG processing components. Problems consisted of three panels, each containing four geometrical shapes. In CD, participants searched for a shape-change across the panels. In RV, participants verified whether a shape-change followed one of four learned rules, with minimized RG demand. In RG condition, participants inferred whether a shape-change followed a to-be-discovered rule. Hierarchical multiple linear regression analysis of performance measures (accuracy and response time) supported the position that CD, RV, and RG abilities each uniquely account for a portion of variance in RPM performance. Furthermore, functional regions of interest (ROIs) were identified by contrasting the parameter estimates for RV vs. CD, and RG vs. RV conditions. To examine modulation of causal networks in response to the added processing components, multivariate Granger causality analysis was applied to the time series data extracted from the identified ROIs, for each of CD, RV, and RG conditions. Results revealed similar connectivity patterns across task conditions, wherein ROIs such as left-Medial Frontal, left-Inferior Frontal and left-Middle Frontal gyri, as well as bilateral Posterior Cingulate, had central involvement in the causal connectivity networks. Consistent with the additive structure of the task, the number or strength of significant connections increased between CD, RV, and RG conditions, respectively. When the connectivity networks were contrasted between RV and CD conditions, predominately bottom-up connections were identified from posterior brain areas to the frontal cortex. The connectivity contrast between RG and RV revealed top-down influences from frontal ROIs on Middle Temporal and Posterior Cingulate cortices. Finally, our findings provide new insights into the nature of network dynamics essential to fluid reasoning performance.

Title: Quantitative anatomical evidence for separable dorsolateral and ventrolateral prefrontal networks

Authors: *R. S. BLUMENFELD, M. D'ESPOSITO;
#3190, UC Berkeley, Berkeley, CA

Abstract: Cognitive Neuroscientific theories drawing on results from the macaque neuroanatomical literature, posit a functional segregation along the dorsal-ventral axis of prefrontal cortex (PFC). However, human functional neuroimaging studies have not provided strong evidence for this segregation, and it is unclear whether the dorsolateral and ventrolateral sub-regions should be considered as part of separate PFC sub-networks. Here we used graph-theoretical community detection analyses on a macaque neuroanatomical dataset to quantitatively test this possibility. These analyses search for partitions of a graph that maximize within community connections and minimize between community connections. The graph we used (Modha and Singh, 2011) was synthesized from the vast amount of macaque neuroanatomical data stored on the CoCoMac database. Examining the graph of connections between frontal nodes, our community detection analyses uncovered a module of lateral PFC nodes. We then submitted this module to the same community detection procedure to look for lateral PFC sub-networks. This analysis revealed distinct partitions that roughly corresponded to dorsolateral and ventrolateral prefrontal with a few exceptions. In addition, a third partition was found that was composed of frontopolar and rostromedial nodes. Subsequently we examined the pattern of connections that the dorsolateral and ventrolateral modules maintain with posterior cortex. Qualitatively these patterns were quite different with very little overlap. Taken together, these results provide evidence that dorsolateral and ventrolateral PFC subregions are separable subnetworks, distinguished both in terms of intra-frontal cortical connections and fronto-posterior cortical connections.

Title: Human prefrontal cortex independently encodes future task-sequences and their order

Authors: *I. MOMENNEJAD[1], C. REVERBERI[2], J.-D. HAYNES[3];
[1]Princeton Univ., Princeton, NJ; [2]Psychology, Univ. Milano-Bicocca, Milan, Italy; [3]Bernstein Ctr. for Computat. Neurosci., Berlin, Germany

Abstract: Every day we need to plan and coordinate multiple future tasks. Previous studies have shown that rostral prefrontal cortex encodes individual future tasks across delays. However, so far it remains unclear how the brain encodes an ordered sequence of upcoming tasks across delays. Here, participants were scanned as they remembered to execute a single future task (single-task trials) or sequences of two tasks (sequence trials). A multivariate classifier was trained on patterns of BOLD activity that encode the single tasks, and was used to decode the identity of the same tasks when they were either first or second in a remembered sequence. The sequential order of tasks (e.g. AB vs. BA) was separately decoded. We found the following. (1) Both the first and the second upcoming tasks could be decoded from rostrolateral prefrontal and parietal cortices. (2) Sequence order was encoded in dorsomedial and dorsolateral PFC. (3) ROI analysis revealed that regions encoding the future tasks and regions encoding sequence order did not overlap. Our findings suggest that (a) the brain encodes future task sequences in a compositional fashion, and (b) there may be a segregation of task and order information in the PFC. Namely, while rostrolateral PFC encoded the identity of multiple future tasks, dorsomedial and dorsolateral PFC encoded information required for the orderly execution of abstract tasks.

Title: The neural basis of hypothesis formation and evaluation

Authors: *N. MARINSEK, B. O. TURNER, M. B. MILLER;
Psychological and Brain Sci., Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Research on split-brain, delusional, and stroke patients suggests that the left hemisphere may concoct stories, or hypotheses, to explain contradictory or ambiguous events, while the right hemisphere may evaluate the likelihood and validity of the left hemisphere's hypotheses. The goal of the present study was to localize the neural substrates of hypothesis formation and evaluation in healthy participicants. Based on studies of inference making and deductive reasoning, we predicted that the left dorsal medial prefrontal cortex (dmPFC) supports hypothesis generation, and that either the right dmPFC or right inferior PFC supports hypothesis evaluation, as these areas are associated with conclusion validation and belief-logic contradiction. In this study, we recorded subjects' brain activity with fMRI as they attempted to generate appropriate category labels for a series of word sets. We used novel word sets that were designed to either elicit hypothesis formation and evaluation ("ad hoc" word sets) or automatic processing ("automatic" word sets). We found that the ad hoc word sets were associated with longer response times - that is, subjects needed more word evidence to generate appropriate category labels - and lower accuracy ratings than the automatic word sets. Based on our assumption that subjects create and verify hypotheses to a greater extent 1) during the period before generating a possible label and 2) during ad hoc trials, we looked for differential brain activity in ad hoc trials vs. automatic trials and TRs before vs. after label generation. Consistent with our predictions, both contrasts revealed increased activity in the left dmPFC, right dmPFC, and left vlPFC, which we attribute to hypothesis formation, hypothesis evaluation, and memory retrieval, respectively. The results of this study provide a focally-specific neural explanation for the behaviors associated with split-brain and delusional patients.

Title: Attentional saliency modulates non-Bayesian updating and sequencing behaviors in a large-scale neurocognitive model

Authors: *M. PHILLIPS[1], R. UHLENBROCK[1], M. ZIEGLER[1], Y. SUN[2], H. WANG[2], R. THOMSON[3], C. LEBIERE[3], R. BHATTACHARYYA[1];
[1]HRL Labs., Malibu, CA; [2]Sch. of Biomed. Informatics, Univ. of Texas Hlth. Sci. Ctr. at Houston, Houston, TX; [3]Sch. of Computer Sci., Human-Computer Interaction Institute, Carnegie Mellon Univ., Pittsburgh, PA

Abstract: Several discrete and complementary behaviors are thought to arise when humans sequence, process and update their beliefs across a set of competing hypotheses. For instance, it has been suggested that preparation and the amount of processing required determine the processing order of stimuli (Leonhard 2011; Fortin and Masse 1999). Attentional modulation has also been shown to play a central role in the processing order of stimuli in a verbal short-term memory task (Majerus et al. 2006). However, a comprehensive and neurobiologically-detailed description of these behaviors has thus far been lacking. Here, individual and phenotypic differences in updating strategy, sequencing, and processing order were investigated in a variant of the n-arm bandit task. Human subjects typically adopted one of two updating strategies for probability estimation (normalized reporting - probabilities sum to 100%, and non-normalized reporting). Non-normalizers utilized a non-Bayesian, attentional-based saliency measure in processing order for sequential hypothesis updating. To explore the biological basis of these behaviors, a neural model which sequences, processes, and updates the beliefs of competing hypotheses was created within a large-scale neurocognitive model. Saliency-based ordering and attentional sequencing was modeled in the inferior parietal and medial frontal cortical regions (including the supplementary motor area) consistent with current theories of non-motor sequencing (Tracy et al. 2011). The model reliably reproduced the discrete human behavioral phenotypes observed in sequential hypothesis updating. These results highlight the importance of attentional saliency in sequencing and updating behaviors and provide a simulation framework for future studies to investigate attentional saliency in other high-level cognitive behaviors.

Title: Effect of sound pressure level on brain function during memory task using fNIRS

Authors: *F. INOUE, U. YAMAMOTO, T. HIROYASU;
Doshisha Univ., Kyotanabe, Kyoto, Japan

Abstract: [Purpose]
In this study, brain functions were examined during a numerical memory task within a sound environment, including the effect of sound pressure level.
[Experimental Methods]
In this study, a numerical memory task was chosen as the working task. The task shows eight random digits that subjects have to memorize. Subjects performed the task in two types of sound environments, namely, white noise and "sonata for two pianos in D major (Mozart)" composed by Mozart. Task scores and oxyhemoglobin concentration
caused by changes in cerebral blood flow were analyzed in both sound environments. The sound environment levels were 65 dB (white noise) and 75 dB (Mozart). Cerebral blood flow changes were measured using functional near infrared spectroscopy.
[Results]
There were significant differences between the two types of sound pressure levels in terms of task score and cerebral blood flow change. The difference was shown when Mozart was presented and the difference was not shown when white noise was presented. In addition, an increase in the oxyhemoglobin concentration was found in both the sound environments.
Therefore, the sound types can be classified into two classes, namely, sounds that do not easily affect subjects and sounds that do. In conclusion, while studying task performance and cerebral blood, the sound environment must be carefully chosen.

Title: Longer reaction time is associated with increased task-specific cognitive control and decreased default mode activity

Authors: *A. D. BARBER[1,2], B. S. CAFFO[3], J. J. PEKAR[1,2], S. H. MOSTOFSKY[1,2];
[1]Kennedy Krieger Inst., Baltimore, MD; [2]Johns Hopkins Sch. of Med., Baltimore, MD; [3]Johns Hopkins Sch. of Publ. Hlth., Baltimore, MD

Abstract: Within-subject, trial-to-trial fluctuations in reaction time (RT) may reflect fluctuations in attention, integration of information across regions that implement different aspects of the task, or state changes in global network efficiency. Previous studies have found that specific regions are influenced by RT independent of task demands, which may reflect the particular function of the region (e.g. response selection demand). The current study examined RT effects on brain activity in two Go/No-go tasks: a Simple task with an intuitive stimulus-response mapping (green=go, red=no-go) and a Repeat task, with an inconsistent stimulus-response mapping (color change=go, color repeat=no-go), which required working memory for task performance.

22 healthy adults were scanned for two blocks on each task. Image preprocessing and analysis occurred in SPM5. First-level general linear models included up to seven condition trial onset regressors (Post-Rest Go, Go, Go RT, No-go, Commission Error, Omission Error, and Anticipatory trials on which the RT<200 msec), which were convolved with the canonical HRF, temporal and dispersion derivatives. In addition, nuisance regressors (six motion parameters, mean white matter, mean cerebrospinal fluid, and mean whole brain time-courses) and a block regressor for each functional run were included. First-level contrasts of Go RT revealed those regions that increased or decreased activity linearly with RT for the Simple and Repeat Tasks separately. Second-level group effects were examined across subjects.

In the Simple Task, slower RT was associated with increased activation in visual (BA 19), inferior and superior temporal (BA 37/39/22), inferior and superior parietal (BA 7/40), and postcentral gyrus (BA 5/2). In the Repeat Task, activation increases with RT occurred within a right frontal region spanning dorso- and ventrolateral cortices (BA 9/44/45/46), anterior insula (BA 13), pre-supplementary motor area and anterior cingulate (BA 6/8/32) and bilateral parietal regions mainly confined to inferior and superior parietal cortex (BA 7/40) with greater extent into supramarginal and angular gyri on the right side. Examination of regions that showed decreased activity with slower RT revealed the medial prefrontal cortex (MPFC: BA 9/10/32) for both tasks.

RT modulated activity in a unique set of regions for the two tasks, reflecting task-specific cognitive/attention control. Increased recruitment of these regions may reflect greater deliberate control in slow RT trials. Decreased MPFC activation in slow RT trials may reflect default mode network suppression when control increased.

Title: Multi-task functional connectivity reveals the human brain's dynamic network architecture and stable functional backbone

Authors: *M. W. COLE[1], D. S. BASSETT[2], J. D. POWER[1], S. E. PETERSEN[1];
[1]Washington Univ., ST LOUIS, MO; [2]Univ. of California, Santa Barbara, Santa Barbara, CA

Abstract: Functional connectivity - the statistical dependence among brain activity time series - has been investigated extensively during task performance. However, task-state functional connectivity has not revealed general network architectural properties of human brain function outside of specific task contexts. This is in contrast to network properties identified in the resting-state, which researchers assume will generalize across many contexts, making them broadly functionally relevant. To identify general network architectural properties during task performance, we measured brain activity during a task paradigm involving 64 distinct task states with functional MRI. Using community detection algorithms developed for such multiplex network scenarios, we found that brain regions were assigned to different putative functional modules across task states, highlighting the human brain's flexibility in adaptively altering functional connectivity patterns to meet external task demands. Moreover, these assignments differed significantly from those identified in resting-state functional connectivity, suggesting that the human brain's dynamic repertoire cannot be fully characterized using static resting-state functional connectivity estimates. To identify consistent patterns of functional connectivity across task states, we utilized a tuning function in the multiplex community detection algorithm and found that consensus assignments showed statistically significant similarity to the resting-state assignments as measured by the z-score of partition similarity. These results suggest that while resting-state functional connectivity estimates cannot fully account for the human brain's dynamic network architecture, it nonetheless provides important information regarding the central tendency of that architecture across many task states. Resting-state functional connectivity might therefore reflect a stable functional backbone from which the wide range of task-related reconfigurations stem.

Title: Focal lesions lead to functional plasticity in the roles of individual brain regions within large-scale networks

Authors: *C. GRATTON, M. D'ESPOSITO;
Univ. of California, Berkeley, Berkeley, CA

Abstract: Focal lesions can change functional brain interactions, even in sites remote from the structural damage. Graph theoretical tools can be used to quantify network reorganization after damage. Global metrics such as Newman's modularity measure the degree to which the brain can be decomposed into separable large-scale networks. Nodal metrics, such as participation coefficient (PC) and within module degree (WD), examine the roles of individual regions play within this structure. Regions with many between-module connections (measured by PC) are connectors and regions with many within-module connections (measured by WD) are hubs.
In past work, we demonstrated that lesions impact the brain's network structure, decreasing modularity in patients compared with healthy controls and in the lesioned compared with the non-lesioned hemisphere. Furthermore, these effects are related to the properties of the damaged region, with stronger decreases seen with more connector damage. Here, we extend these findings by testing if these global changes are accompanied by local changes in the roles of individual regions. Functional plasticity in lesion patients may occur at multiple levels: in regions proximal to, homologous to, or within the same network as the sites of structural damage. We recorded a period of resting state fMRI data from a group of patients with focal lesions (N = 35) and healthy controls (N = 24). Time-series correlations were measured between each of ~90 anatomical regions. This served as the basis for creating unweighted undirected graphs. Graphs were partitioned into their optimal modules. Within this structure, we quantified the PC and WD properties of each brain region.
Results showed that widespread changes were present in the PC and WD properties of the lesioned brain. Changes were systemically related to the healthy roles of each region: the most connector and hub like regions were those most likely to decrease connector and hub properties

in patients. Furthermore, the change in the roles of regions differed between hemispheres. On average, the non-lesioned, compared with the lesioned, hemisphere shifted towards regions having more connector and less hub like properties. These changes were particularly strong in the nodes homologous to the lesion, which significantly increased in both their connector and hub properties.
These results suggest that global changes in the large-scale network organization of the brain are accompanied by local changes in the roles that regions play within these modules. This provides support for the idea that focal brain damage can cause systematic functional plasticity in the roles of non-damaged locations.

Title: Global brain organization is disrupted in children with ADHD

Authors: *J. R. COHEN[1], A. D. BARBER[2], M. B. NEBEL[2], M. D'ESPOSITO[1], S. H. MOSTOFSKY[2];
[1]Helen Wills Neurosci. Inst., UC Berkeley, Berkeley, CA; [2]Kennedy Krieger Inst., Baltimore, MD

Abstract: Attention deficit hyperactivity disorder (ADHD) is the most commonly diagnosed developmental disorder of childhood, affecting approximately 5% of children worldwide. ADHD is hypothesized to result from dysfunctional connectivity patterns within and between brain networks. Most existing research focuses on specific networks or pairs of brain regions, despite strong evidence that ADHD is associated with a distributed pattern of abnormality across much of the brain. Therefore, the goal of this study was to compare global measures of network organization across the entire brain in children with ADHD and typically developing (TD) children to determine how dysfunctional brain organization in an intrinsic (resting) state, unrelated to specific cognitive processes, may be associated with ADHD.
We collected five minutes of resting state data in children with ADHD and TD children undergoing fMRI. For analyses, groups were matched on the basis of number of participants, age, gender, and average motion during the scan. We applied graph theoretical tools to calculate

global measures of network organization across the entire brain. We focused on three measures: modularity, clustering, and global efficiency. Modularity is a measure of the brain's organization into separate, densely-connected networks (or modules) with only sparse connections across networks. Clustering is a measure of how inter-connected neighboring nodes are. Global efficiency is a measure of how few steps it takes to link any pair of nodes together (higher global efficiency indicates more long-range connections).
Modularity was significantly increased in children with ADHD as compared to TD children. When separately examining within-network connections (clustering) and long-range connections (global efficiency), children with ADHD displayed increased clustering and decreased global efficiency as compared to TD children. Taken together, these findings indicate that children with ADHD, as compared to TD children, show increased within-network connectivity and decreased connectivity across networks.
These findings imply that children with ADHD have decreased integration across distinct intrinsic networks, even in the absence of specific cognitive demands. Such integration is critical for complex cognitive processes, such as response control and working memory, processes that are impaired in ADHD.

Title: Assessing serial order processing using a novel P3 oddball paradigm: A proof of concept investigation

Authors: *W. C. HOCHBERGER[1], J. AXELROD[2], T. CARRATHERS[2], S. HILL[2];
[1]Dept. of Clin. Psychology, [2]Rosalind Franklin Univ. of Med. and Sci., North Chicago, IL

Abstract: Serial order recall is a critical component for establishing temporal order of stimuli and interacting appropriately and effectively in the environment. Recent findings have demonstrated that deficits in serial order processing go beyond the pervasive general cognitive deficits seen in schizophrenia. A traditional oddball task was implemented to assess a key component of serial order processing. The novelty of this task lies in the utilization of electroencephalography (EEG) as an indicator of maintenance of working memory serial order

information and potentially for differential degradation of working memory stores during specific processing conditions. As hypothesized, the amplitude of the P3 was greater in oddball trials compared to nonoddball trials across both processing conditions. In addition there was an interaction effect in which the amplitude of the P3 was larger when visual presentation was not externally paced, suggesting that externally pacing target recognition increases cognitive demand and results in a more rapid "exhaustion" of the P3 system. Taken together these findings suggest that the novel task is both an effective means of eliciting the P3 and represent a new way of assessing serial order processing at a physiological level.

Title: Primate prefrontal activity during simultaneous performance of spatial attention and spatial working memory tasks

Authors: *K. WATANABE[1,2,3], S. FUNAHASHI[3];
[1]The Japan Society for the Promotion of Sci. (JSPS), Tokyo, Japan; [2]Japan Society for the Promotion of Sci., Tokyo, Japan; [3]Kokoro Res. Ctr., Kyoto Univ., Kyoto, Japan

Abstract: Despite its remarkable flexibility, human cognitive information processing is severely capacity-limited. When conflicting and interfering streams of information have to be processed concurrently in dual-tasks, there are evident behavioral signs of capacity overload, such as a decrease in percent correct rates and prolonged response times relative to those in individual tasks performed separately. Since this effect, known as dual-task interference, is thought to be a direct proof of cognitive capacity limitation, dual-task performance has been extensively investigated in cognitive psychology and functional neuroimaging studies. Although earlier studies consistently proposed that the lateral prefrontal cortex (LPFC) played a key role in dual-task performance and interference, the underlying neuronal mechanisms remain almost completely unknown due to a lack of direct neurophysiological investigations. In this study, we recorded and analyzed single-neuron activities in LPFC while monkeys performed dual-tasks that required the simultaneous performance of a spatial attention task and a spatial memory task. We found that the performance of the monkeys exhibited dual-task interference, and prefrontal neuron activities showed a decreased ability to represent task-relevant content (i.e., spatial location) to a degree proportional to the increased demand of the concurrent counterpart task even in correct trials. The neural locus of the interference was identified to reside in the simultaneous, overloaded recruitment of the same LPFC neural population by the two tasks. These results indicate that information processing capacity of LPFC single-neuron activity is (1) limited to a fixed level, below that fully accommodates information of two concurrent tasks, (2) adaptively allocated between tasks in graded quantity, (3) enhancing behavioral performance as its allocation to one task increases. The present study provides direct neurophysiological evidence for, and constraints to, psychological models of dual-task interference and capacity limitation.

Title: Exploring numerosity representation in the prefrontal and parietal cortices of numerically naïve monkeys

Authors: *P. VISWANATHAN, A. NIEDER;
Animal Physiol., Univ. of Tübingen, Tübingen, Germany

Abstract: While recent years brought significant advances in our understanding of the neural substrates and mechanisms that represent numerical quantities, little is known about the development of numerosity selectivity in the brain. Work from our group has shown that single neurons in the parietal and frontal association cortices encode visual set sizes. So far, these investigations have been done exclusively in animals able to discriminate magnitude, consequently raising the possibility that aspects of neuronal numerosity selectivity might be shaped by learning and experience. Whether numerosity detectors similar in number and response characteristics also exist in naïve animals remains untested.
Here, we investigate neuronal numerosity selectivity in numerically naïve rhesus monkeys i.e. monkeys that never learned to discriminate numerosity. The monkeys performed a delayed match-to-sample-color task where they matched the color of a sample array to that of test arrays presented sequentially after a delay period. To address spontaneous selectivity to numerical quantity, the stimulus displays consisted of visual arrays of colored dots with varying numbers of items from one to five. The monkeys received no numerosity training and no relevance was associated with the numerosity information in the stimuli. We recorded multi-channel single-unit activity from the dorsolateral prefrontal cortex (PFC) and the ventral intraparietal area (VIP) of the posterior parietal cortex while the monkeys performed the color discrimination task. Based on average discharge rates during sample period, a three-factorial analysis of variance (ANOVA, $p < 0.01$) was calculated for every neuron with numerosity (one to five), color (five different colors) and stimulus protocol (standard vs. size and density control) as factors
Neurons recorded from PFC and VIP showed significant modulation of discharges to numerosity. This suggests visual numerosity is a natural perceptual category extracted by an intuitive “visual sense of number”. Numerosity-selective neurons were spontaneously tuned to preferred numerosities. This finding argues for the labeled-line code to be a default mechanism

of numerosity encoding rather than an artifact of discrimination training. Finally, we found that numerosity is encoded earlier in the VIP, suggesting that numerical information is automatically extracted in the parietal cortex, and then conveyed to the frontal lobe.

Title: Dopamine modulates numerical rule coding in the primate prefrontal cortex

Authors: T. OTT, S. N. JACOB, *A. NIEDER;
Univ. Tuebingen, Tuebingen, Germany

Abstract: Numerical competence, the capability to use quantities and numbers, is based on highly abstract principles, or rules, of how to structure, process and evaluate quantitative information. Numerical competence thus inherently requires executive control functions. We have shown previously that single neurons in the primate prefrontal cortex (PFC) encode abstract numerical rules. The cellular mechanisms giving rise to the rule-related neuronal activity are, however, poorly understood. Since the PFC receives strong projections from the dopaminergic midbrain modulating executive functions such as working memory, we hypothesized that dopamine receptors in the PFC are involved in regulating abstract rule coding.
We trained two rhesus monkeys (Macaca mulatta) to compare numerosities and to switch flexibly between two abstract numerical rules based on a rule cue. The “greater than” rule required the monkeys to release a lever if the first test display showed more dots than the sample display, whereas the “less than” rule required a lever release if the number of items in the test display was smaller compared to the first test display. We recorded single neurons in the lateral PFC while simultaneously applying the dopamine D1 receptor (D1R) agonist SKF81297 or the D1R antagonist SCH23390 to the vicinity of the cells using microiontophoresis.
Our data show that after application of the D1R agonist, neuronal activity related to the neurons’ preferred numerical rules was enhanced. Importantly, the quality of rule coding was significantly improved by stimulating the D1R compared to control conditions. Furthermore, recordings using

the D1R antagonist showed that blocking D1Rs in the PFC impairs numerical rule coding by reducing neuronal activity to the neurons' preferred rules. Together, these results show that abstract rule coding in the PFC relies on D1R stimulation. Thus, dopamine might be involved in modulating the neuronal underpinnings of executive functioning in the PFC to guide behaviour.

Title: Protected storage of working memory in the primate parietal, not prefrontal cortex

Authors: *S. N. JACOB[1,2], A. NIEDER[1];
[1]Tuebingen Univ., Tuebingen, Germany; [2]Dept. of Psychiatry, Charité, Berlin, Germany

Abstract: The primate lateral prefrontal cortex (PFC) and posterior parietal cortex (PPC) are major nodes in a brain network that supports short-term memory. While PFC has been shown to protect important memory content from distracting stimuli, PPC is driven more strongly by sensory inputs, irrespective of their relevance to the current task. We compared extracellular single-unit activity from the PFC and the ventral intraparietal area (VIP) of two rhesus monkeys trained to memorize and discriminate visually presented set sizes (numerosities). While performing the task, the animals had to suppress a salient distractor numerosity that appeared during the memory delay. Surprisingly, we found that target memories encoded in PFC ensemble activity were not maintained throughout the trial, but that distractors replaced target information as soon as they were presented. In contrast, only few VIP neurons represented the distractor stimuli: the majority of VIP neurons carried target, but not distractor information at various time points in the trial. Importantly, accumulation of target memory information in VIP, not PFC, correlated with behavior and predicted whether the animal would successfully complete a trial or commit an error. Our results challenge the commonly held view that resistance to inference in PFC is the key mechanism for selection and maintenance of task-relevant stimuli in working memory. Instead, our findings suggest that parietal association cortex can also function as a protective storage for complex abstract memories and thus guide behavior.

Title: The function of the medial prefrontal cortex during a working memory task in sexually motivated male rats

Authors: *M. L. ALMANZA[1], M. HERNANDEZ-GONZALEZ[1], M. E. OLVERA-CORTES[2], B. E. GUTIERREZ-GUZMAN[2], M. A. GUEVARA[1];

Abstract: The medial prefrontal cortex (mPFC) is involved in organizing delayed responses and, consequently, in working memory function; i.e., the type of memory that allows relevant information to be stored for a short time in order to carry out a certain task that requires immediacy and entails decision-making, but can be erased once the task is completed. Most of the studies that have evaluated working memory in rats have used food or drink as rewards; however, sexual behaviour has also proven to be a highly-rewarding motivated behaviour that has been used efficiently as both an incentive and as a reward in classical operant tasks, such as mazes and Skinner boxes. This work investigated if functional activity of the medial prefrontal cortex (mPFC) changes in relationship to working memory processes involved in the performance of a sexually motivated task in male rats. Male Wistar rats that were bilaterally implanted in the mPFC were submitted to a non-matching sample task in a T-maze using as reinforcer sexual interaction with a receptive female during 4 training days. Based on their performance throughout the training days in the task, the rats were classified in two groups, good-learners and bad-learners. Only the good-learning rats showed an increase in the absolute power of the 8-13 Hz band during the sample-run and test-run, which could be related with the learning of the working memory elements of the task. The good-learner rats showed also, only during the maintenance phase (when the rule was learned), an increased correlation of the 8-13 Hz band during the sample run, indicating that a high coupling between prefrontal cortices is necessary to the adequate processing that allows the rats make the correct decision in the maintainence phase. Together, these data show that mPFC activity changes in relationship to the working memory processes involved in a sexually motivated task of male rats.

Title: Memory coding properties of central thalamic neurons: relationship to prefrontal neuronal coding

Authors: R. L. A. MILLER, C. J. BATES, K. D. ONOS, B. A. WORMWOOD, M. J. FRANCOEUR, B. M. GIBSON, *R. G. MAIR;
Univ. New Hampshire, Durham, NH

Abstract: Central thalamus influences prefrontal cortex (PFC) through specific projections of the mediodorsal nucleus (MDn) to middle cortical layers and nonspecific projections of the rostral intralaminar nuclei (ILn) to deep and superficial layers. The MDn is reciprocally connected to widespread areas of PFC and is an important target of pallidal areas driven by prefrontal projections. The ILn are also reciprocally connected to PFC and additionally innervate areas of the basal ganglia that receive projections form PFC. Earlier studies in our lab and other labs have demonstrated that lesions damaging MDn and ILn interfere with aspects of spatial memory that depend on PFC. Here we extend this research by comparing memory-coding properties of MDn and ILn neurons with results for PFC neurons using common behavioral measures and recording procedures. Here we used moveable tetrode arrays to compare the memory-coding properties of neurons in MDn and ILn. Rats were trained to perform a right/left delayed non-matching to position (DNMTP) task in octagonal chambers with retractable levers located on the N, E, S, and W sides. The location of the lever used to initiate each trial was varied at random to distinguish between egocentric and allocentric navigation. Recording arrays consisted of four tetrodes two each in separate cannulae, one aimed more medially at the MD and central medial nuclei and one aimed more laterally at the centrolateral and paracentral nuclei. Recording implants consisted of four tetrodes mounted in an acrylic base attached to machine screws that allowed them to be lowered gradually in approximately 60 steps through thalamus. TTL pulses were generated to mark specific behavioral events within the task in order to correlate activity from identified discrete neurons. Data analyses entailed the use of Klustakwik spike sorting software and examination of raster plots and peri-event time histograms based on behavioral events. Behavioral analyses have also been conducted using time-stamped video recordings made throughout all recording sessions. Our results allow direct comparison

between MDn and ILn neurons with results from a parallel study of memory coding properties of PFC neurons.

Title: Memory-coding properties of prefrontal cortical neurons in the rat

Authors: *K. D. ONOS, B. A. WORMWOOD, R. L. A. MILLER, M. J. FRANCOEUR, E. F. HEBERT, A. W. BLAKE, B. M. GIBSON, R. G. MAIR;
Psychology, Univ. of New Hampshire, Durham, NH

Abstract: Prefrontal cortex (PFC) supports a number of aspects of executive function, including working memory. PFC, as defined by the projection areas of the mediodorsal thalamic nucleus (MDn), consists of a diverse series of cortical fields that line the medial and ventral surfaces of frontal cortex in the rat. Here we used moveable tetrode arrays to compare the memory-coding properties of neurons in MDn projection areas along the medial wall of rat PFC. Rats were trained to perform a right/left delayed non-matching to position (DNMTP) task in octagonal chambers with retractable levers located on the N, E, S, and W sides. By randomly varying the location of the lever pressed to start trials, we are able to distinguish between egocentric and allocentric coding. Recording arrays consisted of four tetrodes oriented vertically down the medial wall, 3 mm anterior to Bregma in the left and right hemispheres. The tetrodes were mounted in plastic bases with a tripod of machine screws that allowed them to be lowered gradually in approximately 80 steps through cingulate, prelimbic, and infralimbic areas of PFC. Signals originating from single neurons were identified with Klustakwik spike sorting software and analyzed as raster plots and peri-event time histograms based on TTL pulses marking significant behavioral events. Behavioral analyses have also been conducted using time-stamped video recordings made throughout all recording sessions. Our results have mapped several populations of neurons on to the cortical fields studied. These include: responses occurring just before the start of DNMTP trials, increased activity during periods of movement between

locations of levers, delay period activity related to the direction of turning during correct choice responses, and activity associated with lever pressing and positive reinforcement (water).

Title: Inactivation of medial prefrontal cortex or acute stress impairs performance of an odor span task in rats

Authors: D. A. DAVIES[1], J. J. MOLDER[1], Q. GREBA[1], *J. G. HOWLAND[2];
[1]Physiol., Univ. of Saskatchewan, Saskatoon, SK, Canada; [2]Physiol., Univ. Saskatchewan, Saskatoon, SK, Canada

Abstract: Working memory is a type of short-term memory for storage and manipulation of information necessary for higher order cognition. The capacity of working memory is often assessed by measuring the "span" or number of stimuli that can be retained in working memory. The present experiments examined whether either reversible inactivation of medial prefrontal cortex (mPFC) or acute stress impaired working memory performance using an odor span task (OST) in rats. The OST requires rats to remember an increasing span of different odors to receive food reward. Briefly, a within subjects design was used with two separate batches of male Long Evans rats (experiment one: mPFC inactivation, n=13; experiment two: acute stress, n=7). Rats were food restricted for all experiments. The rats used for the mPFC experiment had cannulae implanted into mPFC using conventional techniques. After shaping the rats to dig in unscented sand for a food reward, the rats were trained in a delayed non-match to sample procedure. The rats were permitted to dig in a scented cup of sand on a platform for a food reward. After retrieving the food, the rat was removed from the platform and placed behind a curtain to block its view of the platform. The experimenter then moved the cup to a random position on the platform and added a second cup with a novel odor. The rat's task was to choose the cup with the novel odor. After rats reliably performed the delayed non-match to sample procedure, subsequent test days involved adding additional cups with novel scents one at a time

until an error was made. The number of cups that the rat correctly chose before it made an error (not counting the first cup) was recorded as the span for that trial. Experiment one used microinfusions (0.50 μl; 30 min before testing) of the GABA agonists muscimol and baclofen to reversibly inactivate the mPFC. In experiment two, 30 min of restraint stress was administered 30 min before testing. Medial PFC inactivation impaired performance of the OST. The mean spans observed following sham, vehicle, or GABA agonist infusions were 8.23 odors, 6.49 odors, and 0.50 odors, respectively. In experiment 2, the unstressed rats displayed a mean span of 7.07 odors while the stressed rats had a mean span of 4.55 odors. The present results demonstrate a critical role for the mPFC in the odor span task. Future studies using the OST would shed light on the molecular mechanisms in mPFC underlying working memory and its disruption by acute stress. Such studies may result in novel therapeutic options for individuals with impaired working memory.

Title: Prefrontal and striatal interactions during habit learning and strategy switching

Authors: *K. S. CASTEN[1], M. SHAPIRO[2];
[1]Neurosci., Icahn Sch. of Med. At Mount Sinai, New York, NY; [2]Neurosci., Icahn Sch. of Med. at Mount Sinai, New York, NY

Abstract: Human behavior can be guided by previous experience to form either procedural or episodic memory, based on different types of information learned in distinct conditions, and processed by dissociable brain systems. Patients with medial temporal lobe (MTL) damage cannot learn new facts, but learn and retain motor skills. The opposite pattern is seen in patients with basal ganglia dysfunction, e.g. in Parkinson's or Huntington's disease. Similarly, homologous dissociations exist in other primates and rats, such that the striatum is central to procedural learning whereas the hippocampus governs episodic learning. The neural mechanisms that allow normal subjects to switch seamlessly between these two sources of information are

unknown. Damage to specific regions of the prefrontal cortex impairs different aspects of behavioral flexibility in people and in animals. Damage to the dorsolateral prefrontal cortex in primates or the analogous medial prefrontal cortex (mPFC) in rats does not impair either procedural or episodic learning, but does impair switching between the two strategies. The dorsal striatum supports multiple memory systems beyond the procedural learning system. The cortex and striatum are connected through distinct parallel loops: sensorimotor, limbic, and cognitive (Alexander, Crutcher, & DeLong, 1990; Retailleau, Etienne, Guthrie, & Boraud, 2011). While the dorsolateral striatum (DLS) is required for incremental, procedural memory developed by stimulus-response associations, the dorsomedial striatum is required for spatial memory. Executive tasks such as set-shifting are impaired in early PD, as seen in the Wisconsin Card Sort Task (Grahn, Parkinson, & Owen, 2009; Roca et al., 2012). This leads to the inevitable question—is the PFC dysfunctional in a basal ganglia disorder, or is the striatum necessary for executive function? The role of the DLS in learning to switch between memory strategies is unknown. Using a plus maze, we have shown that DLS lesions, as expected, impair the ability to learn a stimulus-response association. However, the DLS was not required for strategy switches. Future work can use multi-site electrophysiological recordings to understand how the PFC and DLS interact upon use and switching of the procedural or habit strategy.

Title: Neural activity of abstract quantitative rules applied to spatial and numerical magnitudes: Comparison of prefrontal, premotor and cingulate motor cortex

Authors: *A.-K. EISELT, A. NIEDER;
Animal Physiol., Inst. of Neurobio., Tuebingen, Germany

Abstract: Processing quantity information based on abstract principles is central to intelligent behavior and a hallmark of executive control. We have previously shown that such quantitative rules are encoded in the lateral prefrontal cortex (PFC). However, the PFC might not process

rule-related information in isolation. Other cortical areas might as well contribute to such higher order strategic behavior. Recent studies suggested that e.g. premotor areas might encode rule information already earlier and stronger than PFC neurons.
To better understand the cortical network involved in encoding quantitative rules applied to multiple magnitudes, we recorded single-cell activity simultaneously from PFC, dorsal premotor cortex (PMC) and cingulate motor cortex (CMA). Monkeys were trained to switch between 'greater than/less than' rules applied to either spatial or discrete magnitudes (line length or numerosity). In contrast to previous findings, but in accordance with the view that prefrontal cortex is involved in most abstract tasks, we found the most and strongest abstract rule activity in PFC as compared to PMC and CMA. Neurons that generalized the magnitude principle and thus responded abstractly to the overarching concept "magnitude rules" were exclusively present in PFC. In PMC and CMA, however, the rare rule-selective neurons were specialized to a specific magnitude type. This indicates that especially the PFC is an important structure to implement abstract rules related to quantity information.

Title: Neuronal activity in prelimbic and orbitofrontal cortex during operant set shifting in rats

Authors: *A. DEL ARCO[1,2], Y. KIM[1], J. WOOD[1], J. PARK[1], B. MOGHADDAM[1];
[1]Neurosci., Univ. of Pittsburgh, Pittsburgh, PA; [2]Physiol., Univ. Complutense, Madrid, Spain

Abstract: Prefrontal cortex plays a critical role in learning and maintaining the rules that guide behavior. Both prelimbic prefrontal cortex (PLPFC) and orbitofrontal cortex (OFC) contribute to flexible behavior, in part, through the assessment of previous behavioral outcomes and choices. To better understand how neuronal activity in PLPFC and OFC contribute to flexible, rule-based behavior across multiple trials, we recorded single unit activity and local field potentials (LFP) in both regions during an operant set shifting task during which animals perform several extra-dimentional shifts between two rules (Darrah et al. Behavioural Pharmacology 19: 225-234, 2008). This task is sensitive to the functional integrity of PLPFC and involves shifting between (1) illumination of a nose poke port, regardless of location, and (2) location of the port (right,

center or left), regardless of illumination. Animals had to adopt the current rule by trial and error, based on the delivery or omission of reward after each trial. Each recording session was completed when the animal successfully performed 3 shifts between 4 sets. Set shifting performance was stable during the recording sessions. Animals required 143 ±10 trials to complete the task, making 38 ±3 total errors. Single unit analysis showed that different proportions of cells in the PLPFC and OFC were activated and inhibited during different events of the set shifting task. The firing rate of a subpopulation of PLPFC and OFC units was significantly modulated by feedback from both the previous trial and the current trial. However, more PLPFC units compared to OFC were associated with the outcome of the previous trial which suggests that PLPFC has a major role in tracking the recent history of rewards. Both prefrontal regions showed an increase in low gamma band LFP power (approximately 40 Hz) spanning the delay from the instrumental poke to the outcome. This increase in gamma power may be critical for local circuit processing of the selected action and involved in linking the choice to the outcome of that choice.

Title: Enhanced functional connectivity between prefrontal cortex and striatum during associative learning of a categorization task

Authors: *E. G. ANTZOULATOS, R. LOONIS, E. K. MILLER;
Picower Inst. for Learning & Memory, MIT, CAMBRIDGE, MA

Abstract: The ability to extract the "essence" of diverse experiences is called categorization. It is compromised in autism and schizophrenia and involves a broad network of brain areas, including

the prefrontal cortex (PFC) and striatum. To study the interactions between PFC and striatum, we trained monkeys on a task in which they progressed from simple stimulus-response (S-R) learning through category learning to category performance (Antzoulatos and Miller, 2011). We recorded spiking activity and local field potentials (LFP) from the PFC and striatum simultaneously.

We evaluated changes in the functional connectivity between PFC and striatum across the 3 sequential learning stages described above. Connectivity was assessed as bias-corrected phase synchronization of frequency-transformed LFPs. After the transition from S-R learning to category learning there was an increase in synchronization of PFC and striatal LFPs at the delta (~3 Hz) and beta (~20Hz) bands. This enhancement was primarily observed late in the trial, just before emission of the chosen saccade, consistent with a role in motor preparation. By contrast, changes in early trial PFC-striatal synchronization were observed after the transition from category learning to category performance. These changes were two-fold: First, there was a general decrease in delta-band synchronization. Second, there was an increase in category-specific beta band synchronization, that is, different sets of pairs of PFC-striatal recording sites showed increased beta synchrony for the two different categories. This latter effect was observed for synchronization of prefrontal spikes to striatal LFPs, but not the reverse, i.e. striatal spikes to prefrontal LFPs, suggesting communication from the PFC to striatum. This suggests the emergence of beta-band defined category-specific functional circuits between PFC and striatum. Finally, in contrast to changes in synchronization *between* these 2 areas, there were no comparable changes in synchrony *within* either area and no changes in the spectral power of individual sites. These results give insight into the formation of functional circuits between the PFC and striatum during category learning.

Title: Orbitofrontal neurons encode reward certainty

Authors: *D. E. MOORMAN, G. ASTON-JONES;
Neurosciences, Med. Univ. of SC, Charleston, SC

Abstract: Accurate execution of complex behaviors is guided by the activity of neural populations across multiple frontal cortical areas. The rodent medial prefrontal cortex (mPFC) has been well-studied with respect to complex behaviors; recent results indicate that neurons in the mPFC encode hierarchical rules that drive task-appropriate responses irrespective of whether that response involves behavioral execution or inhibition. Other frontal regions, in particular the orbitofrontal cortex (OFC), also play an important role in goal-directed behaviors, but the relationship between OFC neuronal activity and response execution or inhibition has been less-well characterized; this is particularly true for extinction learning, an important example of context-appropriate response inhibition. Here, we recorded the activity of OFC neurons while animals performed a discriminative-stimulus (DS)-driven sucrose-seeking task followed by multiple days of extinction of the DS. In contrast to mPFC neurons, OFC neuronal activity was maximally modulated immediately following reward-predicting stimuli (RS) that were followed by a lever press and consumption of sucrose. RSs in the DS-sucrose task that did not produce a lever press, or RSs during extinction, produced comparatively weaker OFC activation, as did non-rewarded stimuli (NS) irrespective of response (press vs. withhold) or session (DS-Sucrose vs. Extinction). OFC neurons were also strongly excited before rewarded well-entry, and were strongly inhibited during reward consumption. Thus, although cue-evoked activity occurred in OFC neurons for all salient stimulus presentations, it preferentially encodes the conjunction of correct reward-prediction (i.e., RS presentation in DS-Sucrose) and behavioral response (i.e., RS-evoked lever press in DS-Sucrose). Although previous work has shown a role for OFC in representing confidence in reward selection, our results extend these findings to demonstrate that outcome confidence appears to be limited to outcomes producing rewards.

Title: Confidence judgments and prefrontal neuronal activity in monkeys performing a spatial working memory task

Authors: *A. TANAKA[1], S. FUNAHASHI[1,2];
[1]Kokoro Res. Ctr., [2]Grad. Sch. of Human and Envrn. Studies, Kyoto Univ., Kyoto, Japan

Abstract: Over the past years, we have investigated the role of the prefrontal cortex in confidence judgments by macaque monkeys that are engaged in a modified oculomotor delayed-response (ODR) task. In this task, the monkeys are required to remember the location of a visual cue during a several-second delay period, after which they are sometimes forced to take a recognition (matching-to-location) test (forced-test trials) and sometimes allowed to choose to either take or escape from the test (chosen-test or chosen-escape trials, respectively). We previously showed that the monkeys' memory performance was higher in chosen-test trials than in forced-test trials, which suggests that they tended to escape from the memory test when they were likely to make an error. We also reported that spatial selectivity of persistent delay-period activity in prefrontal neurons tended to be lower when the monkeys chose to escape from the memory test than when they made a correct response in the chosen-test or forced-test trials. These results suggest that the spatially selective delay-period activity of prefrontal neurons contributes to the monkeys' confidence judgments about the memory of the cued location. Here we provide additional evidence for this interpretation. Specifically, we examined a small fraction of spatially selective neurons, for which we could collect a sufficient number of error trials (i.e., forced-test and chosen-test trials in which the subject made an incorrect response). For the present analysis, trials were divided into four types: (1) correct forced-test, (2) correct chosen-test, (3) chosen-escape, and (4) error trials. For each trial type, we obtained trial-by-trial firing rates for each neuron's preferred and non-preferred directions, and used them to calculate the area under the receiver operating characteristic curve (AUC) as an index of spatial selectivity. In both cue and delay periods, the AUC values for the correct forced-test and correct chosen-test trials were significantly higher than those in the chosen-escape and error trials, while there was no significant difference between the former two and between the latter two. This trend was particularly pronounced in the late part of the delay period (i.e., immediately before the subject's decision to take or escape from the test). These results support the idea that the monkeys are inclined to escape from the memory test when the risk of error is high and that spatially selective neuronal activity in the prefrontal cortex is a source of confidence judgments in the context of ODR performance.

Title: The role of ventral prefrontal cortex in auditory, visual and audiovisual working memory

Authors: *B. PLAKKE[1], J. HWANG[2], M. D. DILTZ[1], L. M. ROMANSKI[1];
[1]Dept. of Neurobio. & Anat., Univ. of Rochester Sch. of Med., Rochester, NY; [2]Neurosci., Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: The ventral frontal lobe is well known for its role in language processing and social communication. Previous work has demonstrated that individual neurons within ventrolateral prefrontal cortex (VLPFC) process and integrate face and vocal information (Romanski et al., 2005; Sugihara et al., 2006). We have also recently shown that VLPFC neurons are active during audiovisual working memory (Hwang and Romanski, 2010). The effect of VLPFC lesions on tasks which assess learning or memory has been equivocal, with some studies demonstrating impairment on visual learning and memory, auditory discrimination, rule learning, and decision making, while other studies have failed to demonstrate any deficits during working memory tasks. In the current study we asked whether VLPFC was essential in an audiovisual non-match-to-sample (NMTS) task designed to assess auditory and visual working memory. During the task, rhesus macaques attended an audiovisual movie as the Sample and were required to press a button when a non-matching stimulus, i.e. one whose auditory or visual track differed from the Sample, occurred. Our subjects detected the Non-Match (NM) with a button press in order to receive a juice reward. We inactivated VLPFC while subjects performed the task by cooling the cortical surface of VLPFC below 20° C. During each testing session, 100 baseline trials were completed (WARM trials) and then the cortex was cooled below 20° C, and another 100 trials were completed (COLD trials). We assessed performance accuracy and reaction time in the auditory and visual non-match trials of the audiovisual NMTS task during WARM and COLD trials. Performance accuracy was significantly decreased during COLD trials compared to performance during WARM trials. Subjects also completed trial blocks where only auditory or visual stimulus changes occurred. There was no decrease in accuracy during visual-only Non-Match trials. In contrast, cooling of VLPFC during auditory-only trials resulted in a decrease in performance accuracy. The combined effects across all trial blocks suggests that VLPFC is necessary for crossmodal attention/ switching and auditory working memory but not for visual working memory.

Title: The effect of inactivation of dorsolateral prefrontal cortex (DLPFC) in categorical and non-categorical reversal by transcranial magnetic stimulation (TMS) in monkeys

Authors: *T. HOSOKAWA, Y. MATSUI, M. YAMADA, T. IIJIMA, K.-I. TSUTSUI; Tohoku Univ., Sendai, Miyagi, Japan

Abstract: We trained two Japanese monkeys (Macaca fuscata) to perform stimulus-outcome reversal with multiple stimuli. One of eight abstract visual stimuli, half of which were associated with juice and the rest with saline, was chosen to serve as a cue to predict which type of liquid was to be given at the end of the trial. After experiencing each stimulus for 2 or 3 times, monkeys learned the stimulus-outcome relation for all of them, showing anticipatory licking after the presentation of a juice-predicting stimulus, and no licking after the presentation of a saline-predicting stimulus. We occasionally reversed the stimulus-outcome relations without giving any explicit cue. There were two conditions in the reversal. One was the whole reversal condition, in which the stimulus-outcome relation reversed in all stimuli, and the other was the partial reversal condition, in which the stimulus-outcome relation reversed in only 4 stimuli and was preserved in the rest. The monkeys showed quick adaptation to the whole reversal, but they were slower to adapt to the partial reversal. The result suggests that the monkeys used different strategies to perform whole/partial reversals. They formed functional categories of stimuli based on the commonality of outcomes during the new learning, and performed category-outcome reversal to quickly adapt to the whole reversal, whereas in the partial reversal, in which the functional categories were unpreserved, they had to relearn the stimulus-reward associations for each stimulus taking much longer time.
We investigated the role of dorsolateral prefrontal cortex (DLPFC) in this task by using repetitive transcranial magnetic stimulation (rTMS) for reversible brain inactivation. The position for rTMS was determined as 20 mm anterior to the primary motor cortex where TMS elicited hand/finger movements. We applied low-frequency rTMS bilaterally before the monkeys performed the task (twice for each hemisphere at 1 Hz for 5 minutes). When DLPFC was inactivated by the low-frequency rTMS, the monkeys needed significantly more trials to adapt their behavior in the whole (or categorical) reversal, but no change of performance was observed

either in the new learning or partial (or non-categorical) reversal. This result suggests that DLPFC plays a critical role in the top-down behavioral control utilizing category and rule information, but not in bottom-up association learning.

Title: Logical reasoning in primates: Monkeys' prefrontal cortex neurons are modulated during manipulation but not during learning of new information

Authors: *F. DI BELLO, V. MIONE, A. GENOVESIO, E. BRUNAMONTI, S. FERRAINA; Dept Human Physiol. & Pharm, Sapienza Univ. of Rome, Rome, Italy

Abstract: One of the most remarkable traits of highly encephalized animals is their ability to flexibly manipulate knowledge in order to infer logical relations. The corresponding cognitive process can be operationally named reasoning. Transitive inference (TI), i.e., the capacity to conclude that A < C, by knowing that A < B and B < C has been used, in different forms, to study logical reasoning and knowledge manipulation in humans and other animals.
We studied the properties of a sample of neurons recorded from the Prefrontal cortex (PFc) of two monkeys trained in a TI task to investigate the underlying neural correlates. Animals were trained to learn, in a single session, the relationship between six adjacent items of an arbitrarily rank-ordered sequence (i.e. A>B; B>C; C>D; D>E; E>F; learning phase) and then to deduct the relationship between novel (non-adjacent, e.g., B>D or C>E) pairs never experienced during the learning phase and presented intermingled to learned pairs (test phase).
Behaviorally, subjects tested in TI tasks display both the symbolic distance and the serial position effects. The symbolic distance effect predicts that the performance improves with the difference between the rank of the items to be compared, e.g. comparing B and E should be easier than comparing B and C, while the serial position effect predicts that at a given symbolic distance, the performance in comparing the items with intermediate ranks is worse than comparing items with extreme ranks.
We found that the activity of about one third of the PFc neurons tested reflected the behavioral effects identified: they were tuned for the serial position effect, the symbolic distance or for both.

Interestingly, the great majority of the neurons displayed a modulation for adjacent pairs comparisons only during the test phase but not during the learning. The present results provide a first evidence of the importance of PFc in reasoning in primates within the information manipulation phase of the logical process involved in TI tasks.

Title: Pair selectivity of primate prefrontal neurons in visual paired association performances

Authors: *S. FUNAHASHI[1,2], J. M. ANDREAU[2];
[1]Kokoro Res. Ctr., Kyoto Univ. Kokoro Res. Ctr., Kyoto, Japan; [2]Grad. Sch. Hunan and Envrn. Studies, Kyoto Univ., Kyoto, Japan

Abstract: The prefrontal cortex (PFC) has been known as an important brain structure for executive control. To accomplish executive control, the PFC requires monitoring the operations in other brain structures and controlling them by sending control signals named “top-down signals.” It has been shown that top-down signals provided from the PFC play important roles to retrieve specific information stored in the posterior cortices as long-term memory. Sakai and Miyashita (1991) showed that top-down signals play a role to produce “pair-recall” activity in inferotemporal (IT) neurons, which reflects retrieval of a paired associate of the sample stimulus while monkeys performed a pair-association task. Although studies indicate that the PFC sends top-down signals to perform executive control, neural correlate of the top-down signal is not yet known. In the present study, we used a paired association task with 12 pairs of visual stimuli to examine neural correlates of top-down signals in the PFC. PFC neurons with visual response exhibited stimulus selectivity and stimulus-pair selectivity. Comparison of these selectivity with IT neurons revealed that PFC neurons had broader stimulus selectivity but had similar values of pair selectivity. Further, PFC neurons with delay-period activity also exhibited stimulus selectivity and stimulus-pair selectivity. Indices showing the strength of stimulus selectivity and

stimulus-pair selectivity were similar between visual activities and delay-period activities. However, the strength of stimulus-pair selectivity of delay-period activity was increased with a progress of the delay period. These results indicate that pair-selective activity observed in PFC neurons could be neural correlates of top-down signals that the PFC provides to the IT cortex during pair association performances.

Title: The contribution of the amygdala to stimulus-reward related neural activity within the orbital and medial prefrontal cortex of rhesus macaques during learning

Authors: J. A. RIPPLE, *P. H. RUDEBECK, A. R. MITZ, E. A. MURRAY;
Section on the Neurobio. of Learning and Memory, Lab. of Neuropsychogy, Natl. Inst. of Mental Hlth., BETHESDA, MD

Abstract: The orbital (OFC) and medial (MFC) prefrontal cortex both play critical roles in reward learning. Although it is well established from recording studies in macaques that neurons in OFC and MFC signal changes in reward contingency during learning, the origin of these signals is unclear. The amygdala (AMG), which is reciprocally interconnected with both OFC and MFC, is one of the possible sources of this reward-related activity during learning. Consistent with this idea, AMG neurons, like neurons in the OFC and MFC, signal the contingency between stimuli and rewards during learning. We have previously shown that lesions of the AMG disrupt the ability of monkeys to learn stimulus-reward contingencies (Rudebeck et al., SFN abstract, 2012). To determine whether AMG is critical for the development of stimulus-reward association signals within the OFC and MFC during learning, we recorded neural activity within these areas in three monkeys performing a stimulus-reward learning task both before and after bilateral lesions of the AMG. Within each session, monkeys were given the opportunity to learn about three novel visual stimuli and their associated amounts of fluid reward. On each trial, monkeys were shown a pair of stimuli; choice of a given stimulus led the delivery of fluid in the amount assigned to that stimulus. Through trial and error, monkeys learned to choose the stimulus that led to the greater amount of reward. While monkeys

were engaged in the task, single neuron responses in OFC and MFC were recorded. Task-responsive neurons were classified based on changes in activity in response to a number of task-related variables. These included the amount of reward associated with the two stimuli presented, the order in which the stimuli were presented, position of the stimuli on the screen on each trial and whether the best stimulus was chosen on each trial. For task-responsive neurons, stepwise and best-subsets model-fitting procedures were used to identify variables that best explained neural activity during the task. Best-fitting models were used to compare activity across areas both before and after lesions of AMG. Relative to before the lesion, neurons in OFC showed altered encoding of the choice of stimulus associated with the greater amount of reward. By contrast, relative to before AMG lesions, neurons in MFC displayed an increase in modulation of activity related to the position and value of the chosen stimulus. In combination with the decrement in behavioral learning rate observed following AMG lesions, these changes in neuronal activity suggest a role for AMG in the incorporation of feedback with stimulus-reward value in OFC during learning.

Title: The anterior claustrum and flexible behavior in the rat: A comparison of NMDA and dynorphin-saporin lesions

Authors: *A. C. TALK[1], D. BERNASCONI[1], Z. STEVENS[1], K. GRASBY[1], L. EDELSTEIN[2], J. SMYTHIES[3], B. RUSSELL[4];
[1]Univ. of New England, Armidale, Australia; [2]Medimark Corp., San Diego, CA; [3]Univ. of California, San Diego, CA; [4]Advanced Targeting Systems, San Diego, CA

Abstract: The claustrum is a small structure of poorly understood function situated subcortically in the basal forebrain. The fact that it is extensively and reciprocally connected with the cerebral cortex has led to suggestions that it is involved in coordination of cortical activity. Here we created lesions to the anterior claustrum of rats and tested performance on tasks that involve neural processing in one or more frontal or limbic cortical structures. The excitotoxin NMDA

was used to create partial lesions to the anterior claustrum. Lesions were constrained to the claustrum except in a minority of subjects. Taking into account the fact that some of the highest densities of kappa-opioid receptors in the mammalian brain are in the claustrum, in a separate study we used a custom dynorphin-saporin conjugate supplied by Advanced Targeting Systems to create lesions. We found that the claustral lesions using the targeted immunotoxin could be more complete than those provided by NMDA. In our first study, after excitotoxic lesions created by infusions of NMDA, we tested spatial reversal learning in a water maze. Lesioned rats were not impaired at acquiring the initial location of a goal platform in the maze, but were impaired at acquiring a switched location in the reversal phase. The lesioned rats also exhibited more perseverance errors compared to control rats during reversal. These same rats were not impaired at latent inhibition or working memory tasks, suggesting the effect of anterior claustral lesions may be related to behavioral flexibility. This finding is consistent with theories of claustral function that suggest it may help coordinate information necessary for cortical-dependent tasks. We are currently assessing the role of the anterior claustrum on other measures of behavioral flexibility using a cohort of rats that have been subjected to immunotoxic lesions.

Title: A Bayesian model for neural coding

Authors: *S. BEHSETA[1], B. ZHOU[2], D. MOORMAN[4], B. SHAHBABA[3], H. OMBAO[3]; [1]California State Univ., Fullerton, CA; [2]Statistics, [3]Deaprtment of Statistics, Univ. of California at Irvine, Irvine, CA; [4]Dept. of Neurosciences, Med. Univ. of South Carolina, Charleston, SC

Abstract: We propose a flexible nonparametric Bayesian model for identifying dependencies between multiple neurons. More specifically, our model can be used to detect exact and lagged synchrony of a pair of spike trains. Utilizing Gaussian Processes, we propose a flexible framework (i.e., it covers a wide range of functional forms) to model the underlying firing rates. Using simulated data, we show that our approach provides a flexible framework for firing rates, identifies dependent neurons, and estimates lag times correctly. We showcase our model by applying it on data obtained from an experiment whose main objective was to investigate the role

of different prefrontal cortical areas in guiding reward-seeking behavior and inhibition of reward-seeking in the absence of a rewarded outcome.

Title: Pramipexole disrupts synaptic plasticity the ca1 area of the hippocampus of rats that develop contrafreeloading for water, an animal model of compulsive behavior

Authors: *C. SCHEPISI[1], S. PICCININ[2], S. S. D'ORONZIO[1], A. PIGNATARO[3], M. AMMASSARI-TEULE[3], R. NISTICÒ[2], P. NENCINI[1];
[1]Dept. of Physiol. and Pharmacology, Sapienza Univ., Rome, Italy; [2]European Ctr. for Brain Res., Rome, Italy; [3]IRCSS Santa Lucia Fndn., Rome, Italy

Abstract: >**INTRODUCTION**
Chronic treatment with the preferring D3 agonist pramipexole (PPX) elicits contrafreeloading (CFL), consisting in a compulsive selection of a suboptimal choice. Functional correlates of this behavior have never been investigated so far. Ventral hippocampus has been implicated in behavioral flexibility and decision-making. Synaptic dysfunctions in this area may be involved in the development of abnormal CFL.
OBJECTIVES
We tested whether the development of PPX-induced CFL is associated with an impairment of functional and structural synaptic plasticity in the CA1 region of the hippocampus.
MATHERIALS AND METHODS
Rats were trained under a fixed ratio 3 (FR3) schedule of reinforcement for water. On days 1-6, water was only available through lever pressing while from day 7 to 20 choice between contingent and non-contingent access to water was allowed. PPX 0.5 mg/kg was administered intraperitoneally just before the beginning of the session. Hippocampal slices from the same animals were used to study bidirectional synaptic plasticity using extracellular recordings. Dendritic spine density was also measured.
RESULTS
PPX-treated rats exhibited a rigid behavior as they continued to work for water even though it

was also non-contingently available, thus enhancing spontaneous CFL. Moreover responding for water was not goal-directed since only a fraction of water gained was actually consumed by PPX treated rats. LTP elicited by a single high-frequency stimulation train (100 Hz, 1 s) was significantly reduced in PPX-treated rats with respect to controls. Moreover, PPX treatment modified dendritic spine density in the CA1 region of the hippocampus.

DISCUSSION

We demonstrated that the enhancement of CFL was associated with impairment of hippocampal synaptic plasticity in PPX-treated rats. As CFL results from a loss of behavioral flexibility and goal orientation, which represent the hallmarks of compulsive behaviors, we may speculate that synaptic dysfunction in this area is relevant for the pathogenesis of compulsive symptoms caused by D3-preferring dopaminergic agents.

Title: The early cognitive, neurophysiological, and neuropharmacological effects of a slow MPTP-induced dopaminergic lesion in macaque monkeys prior to motor symptoms

Authors: *C. R. WILSON[1,2], F. M. STOLL[1,2], M. C. M. FARAUT[1,2], J. VEZOLI[1,3], V. LEVIEL[1,2], E. PROCYK[1,2];

[1]Stem Cell and Brain Res. Inst., Inserm U846, Stem Cell & Brain Res. Inst., Bron, France;

[2]Univ. de Lyon, UCBL, Lyon, France; [3]Ernst Strüngmann Inst. (ESI) for Neurosci. in Cooperation with Max Planck Society, Frankfurt, Germany

Abstract: We investigated the 'pre-symptomatic' phase and non-motor symptoms of Parkinson's disease (PD) in a rhesus macaque model, using a low-dose protocol of the neurotoxin MPTP.
Two monkeys learned the Problem Solving Task (PST) by searching amongst several targets for one that was associated with juice reward (the search phase, SEA), and then repeating this correct response a number of times (the repetition phase, REP). A change signal then instructed them to begin a new problem by searching again. The contrast between SEA and REP phases provides an index of cognitive control (Procyk & Goldman-Rakic 2006). Monkeys were chronically implanted with at least 22 electrodes resting on the dura mater to provide electroencephalographic (ECoG) recordings.
During a stable control period, we characterized electrophysiological markers in 20-30Hz beta oscillations over frontal cortex during the delay period prior to each trial. Beta power was modulated both by cognitive control demands in the SEA and REP phases of the task, and also by within-session progression towards a final large bonus reward, demonstrating ongoing behavioural adaptation related to time-on-task.
After this control period, monkeys received a slow low-dose MPTP treatment (0.2 mg/kg, max frequency 1 injection/week). After each injection, monkeys received 2 days of rest followed by 5 days of testing with ECoG recordings. Daily analysis included cognitive performance and ECoG activity. Progression of the treatment was also monitored using PET-imaging with the ligand [11C]PE2I in order to follow levels of the dopamine transporter DAT, and scoring of motor symptoms on the Parkinsonian Monkey Rating Scale (PMRS).
Throughout the MPTP phase monkeys remained below the threshold for clinically significant motor symptoms on the PMRS, and so were in the 'pre-symptomatic' phase of the PD model. We observed a general maintenance of beta oscillatory power with ongoing treatment, and this power continued to reflect differences between SEA and REP phases of the task. We did, however, note changes in power between acute periods after an injection of MPTP, and 'recovery' periods without injections, hinting at a possible signal of recuperation. Time-on-task effects remained robust in the face of treatment as well. The maintenance of oscillatory patterns can be seen in the context of a recorded increase in DAT binding potential in the early stage of the lesion measured by the PET-imaging. This ongoing project will provide characterization of early neurophysiological and cognitive alterations induced by a dopaminergic lesion.

Title: Locus coeruleus neuronal activity during stop task performance in rats

Authors: *A. BARI, M. D. RIEDY, G. ASTON-JONES;
Neurosciences, MUSC, Charleston, SC

Abstract: Locus coeruleus-norepinephrine (LC-NE) neurons are involved in attention, decision-making and executive control. Impulsivity and attentional deficits are characteristic of pathological conditions such as Parkinson's disease, schizophrenia and attention deficit/hyperactivity disorder (ADHD), all associated with NE dysfunctions. Deficits in attention and response control can be assessed in the laboratory with the stop-signal task (SST), and are ameliorated by drugs that increase brain NE signaling. For example, drugs currently used for the treatment of ADHD (like methylphenidate and atomoxetine) have strong effects on the LC-NE system, and improve executive functions in affected as well as unaffected subjects. Here, we used a modified version of the rodent SST that tracks and adjusts with the animal's performance and is similar to the task version used in human subjects. A double-tracking algorithm adjusts stop signal delays based on the animal's stop accuracy according to a staircase procedure, while also taking into account the speed of the behavioral responses. This procedure yields stable and reliable estimates of the stop-signal reaction time (SSRT), which represents the speed of the underlying inhibitory process. We recorded single and multi unit activity of LC-NE neurons in rats performing the double-tracking SST procedure using microwire electrode assemblies (tetrodes) mounted on a drivable implant. Preliminary results indicate that LC neurons are phasically activated by stop signals that are presented on a subset of trials and instruct the animal to inhibit the ongoing behavior. Phasic activation of LC-NE neurons is larger for successful stop trials (response inhibition) compared with stop errors. During go trials (when no stop signal is presented), LC phasic activity precedes the behavioral response, but only on correct trials. Altogether these results indicate that LC phasic activity differentially signals whether the animal will inhibit or perform a certain action based on task rules and decision processes. These preliminary results confirm the proposed role of the LC-NE system in response inhibition, attention and decision making, and are highly relevant for modern theories of attention and executive control of behavior. Title: Effects of acute yohimbine on rat inhibitory control tested with the countermanding paradigm

Authors: *J. BEUK, R. J. BENINGER, E. M. MECHEFSKE, M. PARÉ;
Dept. of Biomed. and Mol. Sci., Queen's Univ., Kingston, ON, Canada

Abstract: The countermanding paradigm assesses inhibitory control by measuring a subject's ability to withhold a response to a go stimulus when a stop signal is presented occasionally (Logan & Cowan, 1984). In rats, administration of yohimbine, an antagonist of alpha-2-adrenoceptors, has been suggested to increase impulsive behaviour in the form of premature responding in the 5-choice serial reaction time test (Sun et al., 2009; Torregrossa et al., 2012). Here, we studied the exact contribution of noradrenergic receptor activation to inhibitory control by examining the effect of acute yohimbine treatment on rat performance in a countermanding task. Increased impulsivity can be demonstrated in the countermanding task by faster responding and slower stopping. Male Wistar rats (N = 21) were trained to respond to a visual stimulus (go signal) by pressing a lever below an illuminated light for food reward, but to countermand the lever press (25% of trials) subsequent to an auditory tone (stop signal) presented after a variable delay. Rats were randomly administered yohimbine (0, 1.25, 2.5 mg/kg; i.p.) immediately prior to 60-min test sessions. Yohimbine treatment significantly increased the number of trials rats performed in a session, and it decreased both response time and the proportion of go trial errors. Stopping ability was affected by yohimbine dependent on baseline performance; faster stopping rats were more impaired (slower) following yohimbine administration while slower stopping rats demonstrated improved (faster) stopping. These results suggest that yohimbine may increase impulsive behaviour by both speeding 'go' processes and impairing 'stop' processes in usually fast-stopping animals. (Funded by NSERC)

Title: Behavioral and neurochemical characterization of mutant mice lacking Lphn3, a gene implicated in ADHD and addiction

Authors: *C. A. ORSINI[1], D. WALLIS[2], B. SETLOW[1];
[1]UNIVERSITY OF FLORIDA, GAINESVILLE, FL; [2]TEXAS A&M UNIVERSITY, COLLEGE STATION, TX

Abstract: The latrophilin 3 (*Lphn3*) gene has been linked to susceptibility to attention deficit hyperactivity disorder (ADHD) and vulnerability to development of addiction. Specifically, several groups have used gene linkage and association studies to demonstrate that ADHD and substance abuse are both linked to chromosome 4 in the area of the *Lphn3* gene. This suggests that this gene may be a genetic biomarker of these disorders and may lead to more selective therapeutic targets for treating them. However, little is known about the function of this gene and its protein product. To characterize the function of the *Lphn3* gene, we generated mutant mice for the *Lphn3* gene using a gene-trap embryonic stem cell line. We then performed neurochemical, pharmacological, and behavioral assays to assess *Lphn3* function. In one cohort of mice, we harvested tissue from 4 to 6 week old male mice to quantify levels of dopamine and serotonin in the dorsal striatum. Intriguingly, we observed that *Lphn3* mutant mice had significantly higher dopamine and serotonin levels than their wild type (WT) counterparts. Given that elevated striatal dopamine is associated with locomotor hyperactivity in other mouse mutant lines, another cohort of male and female mice were evaluated in an open field arena to determine if there were differences in locomotor activity. As expected, *Lphn3* mutant mice displayed significantly more horizontal activity than both WT and heterozygous mice. Additionally, when *Lphn3* mutant mice were administered acute i.p. injections of cocaine (20 mg/kg), they showed a significant elevation in locomotor activity relative to WT mice. Finally, in a separate cohort of male and female mice, we explored the contribution of the *Lphn3* gene to reward-seeking behavior by assessing instrumental responding (lever pressing) for food pellet rewards under various fixed ratio (FR) schedules of reinforcement. Mice were first trained on a FR1 schedule for five 30 min sessions, after which they were tested on FR3, FR10, FR20 and FR40 schedules (one schedule/session). *Lphn3* mutant mice displayed significantly greater instrumental responding for food than WT mice, particularly under high response ratios. Together, these findings are consistent with a role for *Lphn3* in regulating motivated behavior, and show that a loss of gene function results in increased reward-seeking, possibly via enhanced striatal monoamine signaling. Current work is focused on characterizing *Lphn3* mutant mice in behaviors more closely linked to ADHD, such as impulsivity, and investigating the

neurobiological consequences of the *Lphn3* mutation.

Title: Population coding of decision contexts by ensembles of striatal neurons

Authors: *M. LAUBACH[1,2], J. COCKBURN[3], E. Y. KIMCHI[4], M. J. FRANK[3];
[1]Yale Univ., New Haven, CT; [2]John B. Pierce Lab., New Haven, CT; [3]Cognitive, Linguistic & Psychological Sci., Brown Univ., Providence, RI; [4]Neurol., Brigham and Women's Hosp., Boston, MA

Abstract: Decisions are not made in isolation but in specific contexts and as part of sequences. The neuronal basis of integrating information about previous behavioral decisions into the current decision context has not been resolved. The striatum is a key structure for decision making and has been shown by several groups to contain neurons that encode prior actions and outcomes. Here, we studied the potential role of the striatum in context-based decision making using a task (Kimchi and Laubach, 2009) in which the reward value of a stimulus depends on the stimulus set. A computational analysis of the task found that changes in action selection in this task can be resolved by a one-back memory of the stimulus and action from the previous trial. Reinforcement learning models were developed for the task and were fit to rats' behavioral performance. Learning models that operated on a state space (defined by the conjunctions of the current and previous stimuli and the previous action) learned to rapidly adjust behavior in line with changes in the stimulus set, as was observed in animal behavior. Most recently, we used a predictive modeling approach (aka decoding, MVPA) to validate these models in terms of trial-to-trial fluctuations in spike activity in the striatum. We found that (1) contextual states and state-action values from the conjunctive state-space model can be decoded significantly better than expected by chance by using the collective activity of ensembles of neurons, but not by using the activity of single neurons, (2) decoding was based on sparse distributed patterns of ensemble activity, with cells “tuned” to specific conjunctions of events from the previous trial, and (3) single neurons only partially predicted the model states, weakly predicted changes in the state-

action values, and contributed redundant information to the population code. Our findings suggest that decision contexts are defined by precise patterns of spike activity that are distributed over groups of striatal neurons and that action values are updated through coordinated changes in these activity patterns.

Title: Hierarchical population coding of trial phases by the striatal neurons during a choice task

Authors: *M. ITO, K. DOYA;
Okinawa Inst. of Sci. and Technol., Okinawa, Japan

Abstract: The striatum is a major input site of the basal ganglia that takes an essential role in decision making. Recent imaging and lesion studies have suggested that the subareas of the striatum have distinct roles.
We recorded neuronal activities from the dorsolateral striatum (DLS, n=190), the dorsomedial striatum (DMS, n=105), and the ventral striatum (VS, n=119) of rats performing a choice task. In this task, when a rat poked into the center hole, one of three cue tones was presented. The rat was required to keep nose-poking during the tone presentation and then to poke either the left or right hole after the offset of the tone. A food pellet was delivered probabilistically depending on the presented tone and the selected poking.
Our previous analysis found that each striatal neuron had a distinct activity pattern (multiple activity peaks through a trial), and that the firing rates at those peaks were modulated by the state (cue tones), the chosen action, the acquired reward, and the reward probability. Here we consider a hypothesis that the variety of activity patterns of a population of striatal neurons encode which phase of what trial a rat is currently in, which can be used for reward prediction, action selection, and learning.
The recorded neuronal spikes in all trials were piece-wise linearly mapped to a standard trial duration of 8.0s so that the times of key task events (the onsets and offsets of the nose pokings and the cue tones) match those of the standard trial. Seven trial epochs were defined as the periods between neighboring task events. Each trial epoch was divided into 4 to 20 trial phases of 100ms time period. One trial consists of 80 trial phases.

We randomly sampled 100 neurons from each subarea and estimated the trial phases from their population activities by a non-parametric Bayesian method. The prediction accuracy was evaluated for a new data set which was not used to make a prediction model (cross validation). In all subareas, the predictions of all 80 trial phases were significantly higher than the chance level (1/80 = 0.0125). While the average of the prediction accuracy of trial phases was the highest in DLS (DLS: 0.19, DMS: 0.16, VS: 0.10), the average of the prediction accuracy of the trial epochs was the highest in DMS (DLS: 0.71, DMS: 0.76, VS: 0.66). In VS, only the prediction of the reward epoch, after the left- or right- nose poking, is the best in the subareas. These results support our hypothesis that activity patterns of striatal neurons encode the trial epochs with population coding. Increasingly more accurate coding of finer trial phases in VS, DMS, and DLS suggests a hierarchical representation of the progress of a trial in the striatum.

Title: Varying levels of craniotopy and retinotopy in SEF during a sequential saccade task

Authors: *M. R. SILVER, E. K. MILLER;
Picower Inst. for Learning and Memory, MIT, Cambridge, MA

Abstract: The frontal cortices have long been thought to utilize topographic maps to support visuospatial behavior. Retinotopic maps are relative to the eye and thus are gaze-dependent. Craniotopic or head-centered maps are stable during eye movements and may be more ideal for storing and executing oculomotor sequences (Silver et al., 2012). Craniotopic information has been reported in the parietal cortex in the form of gain fields, but the picture in the frontal cortex is less clear because in most animal studies of sequential eye movements the two topographies are confounded. We designed an experiment that eliminates this confound and examined the supplementary eye fields (SEF), a region critical for planning sequential saccades in which both retinotopy and craniotopy have been claimed.
In a variant of the double-saccade task, we trained rhesus macaque monkeys to fixate through the presentation of two spatial cues and a one second delay, and to saccade in order to the two cued locations upon fixation offset. Importantly, the fixation cue could appear at the center of the

screen or at any one of the six other locations. This allows us to differentiate between the variance in neural activity explained by retinotopy and craniotopy.
Both retinotopic and craniotopic information contributed to patterns of neural activity in an intermingled and dynamic fashion. The strength of these factors varied between neurons and also within individual neurons during different phases of the trial. Overall, retinotopic information predominated through the cue and delay intervals, but craniotopy became more prominent during saccade execution. Our results suggest that attempts to characterize activity in frontal cortices according to a single, static topographic mapping may obscure the important role of small-timescale variations in neural representation.

Title: Contrastive roles of the two visual thalamic regions in perceptual choices

Authors: *A. NIKKUNI[1,2], A. MIYAMOTO[1], K. NUMATA[2], Y. KOMURA[1];
[1]AIST, Tsukuba, Ibaraki, Japan; [2]Ibaraki Prefectural Univ. of Hlth. Sci., Ibaraki, Japan

Abstract: It has been often suggested that the thalamo-cortical complex underlies much of our perceptual experience. However, it remains elusive how the thalamus works for perceptual experience. The primate visual thalamus has two regions: the lateral geniculate nucleus (LGN) and the pulvinar (Pul), the largest thalamic area, which has interconnections with the multiple visual cortices. To explore the functional role of visual thalamus in subjective visual experience, we recorded the single-unit activities in the visual thalamus while the monkeys performed a perceptual categorization task and an opt-out task. In addition, we inactivated the unilateral visual thalamus by injecting the GABA receptor agonist (muscimol) to examine causal roles of Pul and LGN in the two tasks.

In the perceptual categorization task, the responses of many Pul neurons showed no specificity to any perceptual contents, but their magnitude decreased in a graded manner as the stimulus ambiguity increased. In the opt-out task, the Pul responses to the identical stimuli decreased when the monkeys chose the safe option, indicating less confidence of the animals in their own perceptual categorization. The LGN neurons did not show response modulations in the two tasks. Pharmacological inactivation of Pul increased the monkeys' safe choices in the opt-out task without affecting accuracy in the perceptual categorization task. We observed the effects of pulvinar inactivation (the right side) when the target stimulus was presented in the monkey in the contralateral (left side) visual field but not when the stimulus was presented in the ipsilateral visual field. In contrast, inactivation of the LGN impaired performance on the categorization task and increased the frequency of the safe choice in the opt-out task. These results accord with the view that the LGN (first-order visual thalamus) acts upstream of perceptual categorization whereas the pulvinar (higher-order visual thalamus) acts downstream of visual categorization and plays an essential role in confidence levels of visual categorization.

Title: Activity in the mouse pedunculopontine tegmental nucleus reflects trial history

Authors: J. D. COSTABILE[1], J. A. THOMPSON[1], *G. FELSEN[2];
[1]Physiol. and Biophysics, U. of Colorado, Sch. of Med., AURORA, CO; [2]Dept. of Physiol. and Biophysics, U. of Colorado Sch. of Med., AURORA, CO

Abstract: Recent studies across several mammalian species have revealed a distributed network of cortical and subcortical brain regions responsible for sensorimotor decision making. However, most studies have examined relatively simple sensorimotor transformations, whereas real-world decisions incorporate current sensory information and previously acquired knowledge. Few

studies have examined how the brain integrates these two inputs in order to select an action. One area hypothesized to contribute to the representation of actions and their outcomes (i.e., rewarded or non-rewarded) is the pedunculopontine tegmental nucleus (PPTg), in the brainstem. Intriguingly, our recordings in the PPTg of mice engaged in an odor-cued forced-choice spatial task show a subset of neurons that exhibit selectivity for the selected action, or its outcome, on the previous trial. This result is surprising given that the rewarded action on any given trial is independent of trial history, and raises questions about the mouse's strategy on even such a simple task.
We therefore used linear filtering and logistic regression techniques to explore the influence of previous trial factors on the mouse's strategy, and found that choices were indeed influenced by trial history. Notably, on trials in which the odor stimulus was strongly associated with a rewarded action (i.e., "easy" trials),, mice based their choices exclusively on the odor. However, on trials in which the odor stimulus provided little evidence about the correct action (i.e., "hard" trials), mice based their choices more strongly on the actions and outcomes of previous trials. These results suggest that the representations of previous trial history in PPTg, among other regions, may be used to guide action selection.

Title: From learning-set to task-set in macaque monkeys

Authors: *M. C. FARAUT[1,2], E. PROCYK[1,2], C. R. E. WILSON[1,2];
[1]INSERM U846, Stem Cell and Brain Res. Inst., Bron, France; [2]Univ. de Lyon, UCBL, Lyon, France

Abstract: Our open-ended and volatile environment requires us to behave in a flexible manner to adapt optimally when contingencies change. Primates can adapt behaviour flexibly in this

way, but questions remain about how this flexibility is implemented, and what the neural correlates of such processes are.
Here we present a project to investigate behavioural flexibility in macaque monkeys, using a test of their ability to adapt to changing task information in an environment that doesn't always give the right answer.
We trained 3 monkeys on a task of Task-Set Manipulation, a monkey equivalent of the task of Collins & Koechlin (2012). In the training phases of the task, monkeys learned by trial and error the association between 2 stimuli and 3 targets using feedback to adapt their responses. Once they reached a behavioural criterion, 2 new stimuli were presented and monkeys entered a new exploration phase. Monkeys thus moved between phases of exploration and exploitation of the stimulus-reward environment. A stochastic reward environment was created by giving invalid feedback to monkeys in 10% of trials. This means that transitions between exploration and exploitation can only be triggered by a continuous checking of environmental information, and not solely by a single feedback, promoting flexibility of behaviour.
We show that monkeys used different learning strategies and adapted their responses to the stochastic environment. Monkeys demonstrated the formation of a stable learning set, a strategy that allows efficient learning of problems, acquired over a number of sessions. For example, over 400 problems, monkey P's performance showed a reduction of mean errors to criterion of 93% between the first 50 and the last 50 problems. This task contrasts with traditional learning-set paradigms which use deterministic 2-choices tasks.
In the final task, for a given session the stimuli no longer changed when the monkey reached criterion, but rather the association between stimuli and targets changed. Thus, the monkey had to switch between these different mappings. We show that monkeys exhibited a level of transfer of their learning-set to the final task. Two types of sessions alternated, some with the same mappings repeated during the session and others with mappings presented only once. The formation of a task-set would be shown by monkeys learning mappings they had already encountered more efficiently than new ones, so with better performance on 'repeated' sessions. We show the effect of the presentation of 'repeated' versus 'one-time' sessions in order to test the ability of monkeys to acquire and use task-sets.

Title: Information and value influences on foraging decisions

Authors: *D. L. BARACK[1], J.-F. GARIEPY[2], M. L. PLATT[2];
[1]Ctr. for Cog Neurosci, Duke Univ., DURHAM, NC; [2]Duke Univ., Durham, NC

Abstract: While most research into the neural mechanisms of decision making focuses on learning reward contingencies for maximizing expected value, animals often already know the expected size and usual location of rewards. Nonetheless, when foraging, animals have to choose which location to visit and learn the spatial distribution of rewards. Rewards harvested while foraging carry information, defined as a reduction in entropy, about the state of the environment, useful for guiding future actions. In a well-learned environment, even after few rewards, the animal may anticipate the information to be gleaned from future actions, which we call expected information. We hypothesize that animals foraging in a well-learned environment maximize their expected information, and, as a corollary, that animals will encode value and information separately. To begin to test this hypothesis, we investigated the neural encoding of information independently of received reward. In our experiment, fixed rewards were randomly assigned to locations in the environment, though not every location was rewarding on every trial. The subject had to select all locations regardless of received reward in order to advance to the next trial. On every trial, the amount of information, operationalized as the reduction in the number of possible spatial allocations of rewards to targets, about the animal's particular environment on that trial decreased over the course of the trial, while the expected value of upcoming actions could decrease or increase, depending on the rewards received so far in the trial.
Response times within a trial are significantly influenced (3,491 trials, 20,946 choices, multilinear regression, all $p < 0.001$) by the amount of information gained from the current choice, by the expected value of the current choice, and by the interaction of the choice number in the sequence with the information gained, choice number with the expected value, and the interaction of expected value and information. Cells in the posterior cingulate cortex (CGp), an area known to be involved in strategic choice, policy selection and adaptive behavior at longer time constants, track the amount of information gained from the current choice (GLM, log-linear link function, $p < 0.05$: 10/11 cells), the expected value of the current choice (5/11 cells), and the interaction of information and expected value (4/11 cells). Our data suggest that information and value both affect an animal's choices when exploring an environment with an unknown spatial distribution of rewards, and that CGp cells encode both value and information, possibly serving as a substrate for the influence of both on decision behavior.

Title: An oculomotor task for testing metacognitive monitoring of rule selection in monkeys

Authors: *Z. ABZUG, M. A. SOMMER;
Duke Univ., Durham, NC

Abstract: Using rules to guide decisions is an integral part of human cognition. These rules may be instructed or self-selected. The latter case is metacognitive in that a subject must monitor its selection of a rule in order to use it to control future decisions. Prior work showed that monkeys can apply instructed rules to decision-making tasks, and the neuronal basis of that process has been studied. Here we asked, can monkeys select their own rules to apply to future decisions? We designed a two-stage task to probe this question. Both stages involved a two-alternative forced choice. In the first, "rule selection" stage of each trial, the monkey foveated a central spot and two peripheral targets appeared. The monkey was required to saccade to one of the targets. During training, the monkeys learned to associate different colored targets with different abstract rules. The peripheral targets might be of different colors, so that the monkey had to select one of two potential rules; this was the Self-Selected (SS) task condition. Or, the targets might be the same color, so that the monkey had no choice of rule; this was the Instructed (INS) condition. After the monkey made a saccade to one target, the second, "rule implementation" stage of the trial began. The monkey re-fixated the central spot and two complex visual objects appeared in the periphery. They differed from each other in multiple ways (e.g. contrast) corresponding to the rules learnt during training (e.g. "choose the target with lower contrast"). If the monkey applied the rule that was in effect by making a saccade to the rule-appropriate target, it received reward. In one monkey, we found that for both SS and INS trials, and across all rules, performance was significantly greater than chance (t-test, Bonferroni-Holm corrected, $p < 0.05$). The monkey was better at using one rule than the other (ANOVA, $p < 0.003$), with a significant correlation between the likelihood of selecting the preferred rule during SS trials and performance using that rule (Pearson's $r = 0.80$, $p = 0.033$). Our results demonstrate that monkeys can select a rule and implement it for decision-making, an example of metacognitive monitoring and control. We are now using this task to examine neuronal activity in frontal cortical areas during the inter-stage period of SS trials in which the self-selected rule must be remembered for application to behavior later.

Title: Social isolation during adolescence but not adulthood modifies outcome-based decision-making

Authors: *E. A. HINTON[1,2], S. L. GOURLEY[3,2];
[1]Georgia State Univ., Atlanta, GA; [2]Yerkes Natl. Primate Res. Ctr., Atlanta, GA; [3]Pediatrics, Emory Univ., Atlanta, GA

Abstract: Background: Adolescence is a vulnerability period for the development of treatment-resistant depression, which includes symptoms such as diminished goal-directed decision-making and anhedonia. Adolescence is also a period of marked structural maturation and refinement in the prefrontal cortex. While contemporary models argue that adolescent-onset psychiatric vulnerabilities emerge in part due to the impact of pathological stimuli on prefrontal cortical development, empirical support remains limited.
Methods: We developed an ethologically-based animal model of adolescent adversity in which female mice are isolated for the majority of the adolescent period and then re-housed in large social groups in adulthood. Decision-making strategies were then classified using response-outcome contingency degradation. In order to examine dendritic spine morphology, we isolated or socially-housed adolescent transgenic mice expressing thy1-derived Green Fluorescent Protein and imaged deep-layer prefrontal cortical dendritic spines.
Results: Adult mice with a history of adolescent-, but not late-adolescent- or adult-, onset social isolation develop stimulus-response habits at the expense of engaging in response-outcome goal-directed decision-making. In addition, mice isolated in adolescence exhibit anhedonic-like insensitivity to sucrose despite being socially re-integrated in adulthood. Our initial evidence also indicates that adolescent isolation fundamentally redirects the developmental trajectory of dendritic spine maturation in deep-layer prefrontal cortex. Adult-emergent behavioral deficits

can be reversed by application of a Rho-kinase (ROCKII) inhibitor during adolescence. Discussion: Given that ROCKII inhibition facilitates activity-dependent cytoskeletal reorganization, our findings provide direct evidence that structural plasticity during adolescence determines long-term behavioral outcomes. Ultimately, improved treatment approaches initiated during the structurally labile adolescent period may have long-term beneficial consequences.

Title: Changes in behavior and lateral intraparietal neuron activity reveal diverse adjustments in decision-making processes after errors

Authors: *B. PURCELL, R. KIANI;
New York Univ., New York, NY

Abstract: Humans and non-human primates adjust their behavior following errors. These adjustments are thought to reflect strategic changes in decision-making processes to prevent the occurrence of future errors and maximize the rate of reward. Different models propose different mechanisms for post-error performance changes, but these alternative accounts have been difficult to distinguish using behavioral data alone. We investigated the behavioral and neural mechanisms of post-error performance changes in humans and monkeys during a perceptual decision-making task. Subjects viewed a patch of stochastic moving dots and made decisions about the net direction of motion. They reported their choices when ready by making a saccadic eye movement to one of two possible targets. Task difficulty was manipulated by varying the percentage of coherently moving dots. Humans and monkeys exhibited a diversity of behavioral adjustments following errors, with the most common being increased reaction times (i.e., post-error slowing). We fit the subject's behavior with a drift-diffusion model. The model assumes that noisy evidence about motion direction is integrated over time until a response threshold is reached. We found that different subjects employed different mechanisms of post-error adjustments that included delayed integration of evidence, changes in integration rate, and changes of response threshold. We analyzed single-unit responses recorded from the lateral intraparietal area (LIP) of four monkeys to investigate the neural mechanisms underlying these adjustments. The changes in LIP neuron firing rates support our model-based inference about the

differences in the monkeys' decision-making strategies following errors. These results suggest that there is no single mechanism of post-error slowing; rather, different subjects react differently to errors with varying effects on the speed and accuracy of consecutive decisions.

Title: Spatial working memory impairment following selective lesions of the thalamic reuniens

Authors: *J. A. PRASAD, Y. CHUDASAMA;
McGill Univ., Montreal, QC, Canada

Abstract: On account of it's efferent projections to the hippocampus, recent animal studies have emphasized an important role for the midline thalamic nucleus reuniens (NRe) in the long-term consolidation of spatial memory (Loureiro et al., J. Neuro., 32: 9947). By virtue of it's reciprocal connections with the prefrontal cortex, we have shown that the NRe is involved in certain aspects of executive function (Prasad et al, 2013, Brain Struct Funct. 218:85). In addition to cognitive control operations of response inhibition that enable adaptation to a changing environment, efficient executive control requires the capacity to hold information on-line in working memory, and use it to guide on-going behavior. Surprisingly however, we recently showed that selective NRe lesions fail to disrupt performance in a working memory task modeled on the operant delayed response paradigm (Chudasama and Prasad, 2012, SFN Abstr. #599.07). Contrary to our negative result, other studies have shown that lesions or inactivations of the midline thalamus that include the NRe have detrimental effects on spatial tests of working memory (e.g., Hembrook and Mair, 2011, Hippocampus, 21:815). One possibility is that the NRe is sensitive to spatial contexts, in which case its ablation will impair working memory performance in tasks that rely on the use of spatial cues. To test this hypothesis, we tested rats with NRe lesions on a standard win-shift working memory task in the 8-arm radial maze. During the training phase, four of the eight arms were 'closed' and rats were allowed to retrieve pellets from the four 'open' arms. In the test phase (after a 0-second delay), the remaining four arms were opened. Food

pellets were only available if the rat entered a previously 'closed' arm. Unlike sham controls, rats with NRe lesions made several re-entries into the previously 'open' arms, although they were no longer baited [sham: 5.36±1.25; NRe: 9.95±0.99; $p<0.01$]. In contrast, however, the same NRe-lesioned rats showed normal performance in reversal learning and delay discounting tasks. These data therefore suggest that thalamic NRe lesions impair spatial working memory but not other aspects of prefrontal executive function.

Title: Functional disconnection of the ventral hippocampus and nucleus accumbens affects decision-making

Authors: *A. R. ABELA, Y. CHUDASAMA;
Psychology, McGill Univ., Montreal, QC, Canada

Abstract: Recently, we showed that rats with ventral hippocampal (vHC) lesions are intolerant to reward delay, and will opt more often for a small immediate reward, instead of a large delayed alternative (Abela and Chudasama, 2013, EJN, 37:640). Rats with lesions of the nucleus accumbens (NAcc) are also intolerant of delay (Cardinal et al. 2001; Science, 292:2499), suggesting that these two structures are concurrently engaged in the assessment of decision costs associated with delay. In line with this speculation, the NAcc receives a direct, excitatory projection from the vHC (Groenewegen et al., 1987, Neurosci, 23:103). However, unlike the vHC, the NAcc is sensitive to the effects of reward uncertainty thereby biasing choices that lead to safe small rewards, rather than large uncertain rewards. Accordingly, in line with optimal choice behavior, rats with vHC lesions and sham controls, reduce their choice of large rewards as the probability of receiving it is decreased, whereas rats with NAcc lesions choose the large reward option significantly less suggesting they are 'risk averse' (Cardinal and Howes, 2005, BMC Neurosci, 6:37; Abela and Chudasama, 2013, EJN, 37:640). This disparity prompted us to examine the interdependent function of the vHC and NAcc in decision making using a

disconnection lesion approach. Rats received unilateral lesions of both the NAcc and vHC, either in the same hemisphere ("ipsilateral") or in opposite hemispheres ("disconnection"), or sham control surgery. Using a touchscreen testing method, rats made choices on two decision-making tasks. In the delay discounting task, rats chose between two visual stimuli, where one stimulus delivered a small, immediate reward and the other a large delayed reward. The delay to the large reward was progressively increased from 0 to 8, 16 and 32 seconds within a session. In the probability discounting task, a new pair of visual stimuli indicated instead a small, certain reward or a large, uncertain reward. The probability of receiving the large reward was systematically reduced from 1 to 1/3, 1/9 and 1/15 every 10 sessions. The results show that all groups of animals preferred the large reward when it was delivered immediately, and shifted their preference to the small, immediate reward as the delay to the large reward increased. However, the group of animals with the disconnection lesion exhibited higher rates of discounting than the other groups. Furthermore, none of the groups were affected by changes in reward uncertainty. These results demonstrate the conjoint importance of the vHC and NAcc in decision making with a delayed outcome.

Title: Cognitive dysfunction in a transgenic rat model of Alzheimer disease before and after amyloid beta plaque deposition

Authors: E. N. WILSON JR[1], A. R. ABELA[2], V. KNIGHT[2], Y. CHUDASAMA[2], *A. CUELLO[1];
[1]Dept Pharmacol & Therapeut., [2]Psychology, McGill Univ., Montreal, QC, Canada

Abstract: We have developed and characterized a transgenic rat model that recapitulates amyloid beta neuropathology observed in individuals with Alzheimer disease (Leon et al. 2010, J Alzheimer's Disease, 20:113). In these rats, soluble, intracellular amyloid beta accumulates as early as two weeks after birth. Following a conversion to fibrillar form, amyloid beta deposits as extracellular plaques at 6 months of age in the subiculum, and deposition spreads from the dorsal to the ventral hippocampus, and throughout the prefrontal cortex. Our initial studies found that both oligomeric and fibrillar amyloid beta in the hippocampus and entorhinal cortex negatively affect performance on a spatial memory task. Further to it we are interested in how this hippocampal neuropathology affects cognition mediated by hippocampus-prefrontal cortical circuits important in guiding executive function. Accordingly, we examined the performance of Alzheimer transgenic rats with their wild type controls on both one-pair visual discrimination and reversal leaning tasks. In these tasks, rats were required to learn a stimulus-reward association by indicating responses via nose-poke to touch sensitive screens. Separate groups of rats that were either three months old (i.e., before after plaque deposition) or 8 months old (i.e., after plaque deposition) were evaluated on their ability to acquire the stimulus-reward contingency. At the post-plaque stage, relative to their wild type controls, the transgenic rats with Alzheimer-like amyloid beta neuropathology required many training sessions and committed many errors to reach criterion, but were eventually able to acquire the stimulus-reward contingency. In contrast, the transgenic rats at the pre-plaque stage were severely impaired, and were unable to acquire the stimulus-reward association. This difference is likely due to the time-dependent progressive accumulation of toxic amyloid beta oligomers including their deposition as amyloid plaques.

Title: What's different in fast and slow learning rats on a directional control task?

Authors: *B. CHENG, Y. YUAN, A. SPINRAD, E. HERRING, J. SI;
Arizona State Univ., Tempe, AZ

Abstract: Individuals differ when dealing with decision uncertainties, developing elaborative strategies during learning a new task or skill.
The present study used a rat model to reveal neural correlates underlying fast or slow learning of a directional control task. Eight male Long-evans rats at the same age were studies. They were handled and trained to become familiar with paddle pressing prior to learning the directional control task. The task required a rat to choose and press one of the two directional control paddles in response to a respective directional light cue - left cue with a left control press and vice versa. Sugar pellets were delivered after successful trials. The rats were originally naïve and achieved an average behavioral accuracy of 80% in about 30 sessions. Rat's behavior parameters were recorded on video, synchronized with the rat's single unit neural activities from the PM and M1 areas. The rat's physical movement appeared rather stereotypical accompanied with rather consistent reaction time.
The eight recorded rats were divided into fast and slow learning groups. Rats in the fast group usually reached 60% or higher performance accuracy around the 15th session. The remaining four rats are considered slow rats. A pre-learning stage refers to the first several sessions in which the rats' performance accuracies fluctuated between 20% and 70% without displaying a clear and steady upward trend; the learning stage corresponded with the period when the rat's behavioral performance accuracy steadily increased before they reached 80%.
The rats' behavioral performance accuracies and the rats' neural activities were analyzed. During the pre-learning stage, the fast learning rats (dubbed FP rats for fast learning during pre-learning stage) exhibited strong behavioral adaptation after committing an error. The rats were more likely to complete a successful trial after a failure rather than after a success; the post-error accuracy R_es was compared with R_ss using paired t test, $p<0.05$, while no such strong adaptation or only weak adaptation was found for the slow rats (SP rats). During the learning stage, both FL (fast learning during learning stage) and SL (slow learning during learning stage) rats exhibited strong behavioral adaptation. A smaller fraction of neurons (23%) encoded the previous trial outcome for SP rats as compared to the SL (52%), FP (48%), and FL (55%) rats. Taken together, the fast and slow rats differed the most during the pre-learning stage. The fast rats behaviorally adapted quicker post-error trials and a larger fraction of neurons encoded previous trial outcome than slower rats.

Title: Neuronal circuitry for cost-benefit decision in foraging in Pleurobranchaea and its agent-based simulation

Authors: *R. GILLETTE[1], K. TIAN[2], N. RYCKMAN[2], J. BROWN[3];
[1]Dept Physiol., Univ. Illinois, URBANA, IL; [2]Mol. & Integrative Physiol., [3]Biophysics and Computat. Biol., Univ. of Illinois, Urbana, IL

Abstract: Predator-prey interactions where predators learn to distinguish the sensory cues of valuable versus well-defended prey provide clear examples of cost-benefit decision in foraging. The cognitive adaptations for such distinctions both lend flexibility to the generalist's foraging strategy and add complexity to the animal's behavioral economy. The predatory sea-slug *Pleurobranchaea* is one such simple generalist which can rapidly learn with experience to selectively avoid the odor of dangerous prey (Noboa and Gillette, 2012). Notable exceptions are animals with extremely high or low feeding thresholds that either ignore the dangerous prey or completely consume it, respectively.

What are the computations of this foraging strategy and how are they mediated in the nervous system? We elucidated neuronal circuitry mediating appetitive state in terms of integrating sensation, motivation and memory, and we showed how it controls a neuronal switch for approach-avoidance decision (Hirayama and Gillette, 2013). A neural model for cost-benefit decision was derived from these relations. Here we test the model in computational simulation. In it, sensory modalities and learned associations are integrated in incentivizing and deterrence network circuits that feed separately to a leaky integrator embodying satiation and summing inputs to express appetitive state, and to premotor turn circuitry organized by default for avoidance responses. Reciprocal feed-forward interactions between appetitive state and turning motor output produce a diversity of behaviors, reproducing well the real animal's responses based on sensory modality, learning and motivational state.

Successful reproduction of adaptive cost-benefit decision relations in a simple forager provides an arena for testing effects of varying behavioral and ecological factors on reproductive fitness and environmental change. It also suggests a foundation for the directed development of more complex cognitive and social abilities in computational entities, paralleling their evolutionary acquisition in real animals.

Title: Assessing the multidimensional integration of reward value in the pigeon

Authors: *N. KASTIES, O. GUNTURKUN, M. STUTTGEN;
Inst. of Cognitive Neuroscience, Biopsychology, Bochum Univ., Bochum, Germany

Abstract: Decision making - choosing a single behavioral option to the exclusion of all others - is a fundamental process underlying all behavior. Naturally, the range of available options is not uniform but rather spans across a vast range of dimensions. Behavioral choice thus involves deciding between options that are in few ways alike and difficult to compare to each other. Current theory holds that this process involves assigning a subjective, unidimensional value to each available option. These values can then be compared easily with the best-scoring option being subsequently executed.
Neuronal correlates of subjective value have been shown in several species, among them primates and rodents. More recent studies have investigated how neuronal activity integrates value across multiple dimensions such as reward probability, effort or delay. Here, we introduce a simple sign-tracking task for pigeons in which discrete stimuli predict a food reward varying along three dimensions: reward amount, time to reward and reward probability. We find that both the probability of responding to a given stimulus as well as the rate of responding monotonically increase with reward value along each dimension: More specifically, stimuli indicating large rewards elicit higher response frequencies than those indicating small rewards; stimuli indicating sooner rewards are likewise favored over those predicting later rewards, and likewise for high vs. low reward probability. This ordinal relation holds true across stimuli differing along more than one reward dimension. We thus identify response frequency to be a reliable behavioral indicator of the animal's reward expectancy. We have begun to record single-neuron spiking activity in the nidopallium caudolaterale (NCL) during this task. The NCL presents an analog of the mammalian prefrontal cortex (PFC), a structure in which reward-related neuronal activity has been repeatedly demonstrated. This experiment aims to identify a neuronal representation of multidimensionally integrated value in the pigeon NCL.

Title: Inhaling oxytocin increases contagious yawning in rhesus macaques

Authors: *D. L. XIE[1,2,3], J.-F. GARIEPY[1,2], E. DU[1,3], M. L. PLATT[1,2,3];
[1]Ctr. for Cognitive Neurosci., [2]Duke Inst. for Brain Sci., [3]Dept. of Neurobio., Duke Univ., Durham, NC

Abstract: Watching another individual yawn induces yawning in humans and other highly social animals such as dogs, macaques and chimpanzees. Such contagious yawning is thought to relate to group coordination or empathy. It has also been shown that individuals with autism fail to yawn in response to seeing others yawn, further suggesting a relationship between yawning contagion and processes such as empathy and social attention. Despite its potential role in social behavior, the neural basis of social yawning remains mysterious. Notably, oxytocin (OT) is known to favor pro-social behaviors, yet its effect on contagious yawning is unknown. Here, we used a behavioral paradigm designed to identify contagious yawning in rhesus macaques during live social interactions and its modulation by exogenous OT. In our experiment, a subject male monkey (M1) is paired for social confrontations of 5 minutes duration with all other male monkeys (M2) from a group of eight. The monkeys sit in primate chairs and face each other, but are otherwise free to behave, and all interactions are recorded on video. Video records are then coded by 2 condition-blind experimenters, using the Tinbergen software suite (Geoff K. Adams) to identify pro-social behaviors, threat displays and yawns. On one half of the sessions, one subject monkey (M1) is given intranasal OT using a nebulizer before the experiment, whereas on the other half he is given intranasal saline via the same method. We use granger causality analysis to determine whether the yawns of M2 are followed by yawns in M1. We found that some monkeys in the control condition show contagious yawning while others do not, similar to individual variations in yawning contagion in humans (F-statistics of granger causality for 3

subject monkeys: 0.03, 4.6, 3.9; significant causality when F > 3.3-3.5). More importantly, we found that OT increases yawning contagion in all subjects tested, including those who did not show yawning contagion in the saline condition (F-statistics, oxytocin condition: 5.4, 5.2, 4.6). This effect was not accompanied by an increase in the frequency of yawning in subject monkeys (5.36 ± 0.51 yawns per five minutes on oxytocin days vs 4.87 ± 0.53 on saline days; $p > 0.05$). These results show that exogenous OT increases yawning contagion in rhesus macaques. This novel experimental paradigm will allow us to understand the neurophysiology and pharmacology of contagious yawning. We will also use this paradigm to identify possible links between yawning and other social behaviors such as threat displays and dominance.

Title: Activation of granule cells increases neurogenesis in the adult dentate gyrus

Authors: *S. BLANKVOORT[1], M. UEMURA[1], A. TASHIRO[1,2,3];
[1]Kavli Inst. For Systems Neurosci., Norwegian Univ. of Sci. and Technol., Trondheim, Norway; [2]Warwick-NTU Neurosci. programme, Sch. of Biol. Sciences, Nanyang Technological Univ., Singapore, Singapore; [3]Warwick-NTU Neurosci. programme, Sch. of Life Sciences, Univ. of Warwick, Coventry, United Kingdom

Abstract: In the dentate gyrus, new neurons continue to be generated to modify the existing neuronal circuits. The amount of newly-generated neurons is regulated by a variety of factors including animal's experience and neural activity in the dentate gyrus. However, it is not well understood whether there is any functional relevance to where the birth of neurons occurs within the dentate gyrus. Previously we reported that spatially-modulated activity, so called place-cell activity, in the dentate gyrus was found in the proximity of immature neurons (Uemura et al.,

Soc. Neurosci. Abstr. 2011). From this finding, we hypothesized that adult neurogenesis is locally induced by activation of granule cells, a cell type in the dentate gyrus believed to show place cell activity. In order to test this, we experimentally activated granule cells by optogenetic stimulation and examined its effect on adult neurogenesis. First, we established transgenic mice in which ~10% of the granule cells express channelrhodopsin-2 (ChR2). To induce specific activation of granule cells, we delivered light (wave length: 473nm) to the dentate gyrus by connecting an implanted fiber connector to a laser source. 90 minutes after light stimulation (1800x10ms pulses at 10Hz, 6-30mW at the fiber tip) we detected the expression of activity-dependent protein FOS in over 90% of the granule cells, indicating that the light stimulation activated granule cells. Subsequently, we investigated an effect of the light-induced activation on proliferation. For this purpose, the granule cells were stimulated, with the same protocol of light delivery and, after three days, the mice were injected with a proliferation marker BrdU. One day after the BrdU injection, we found an increase in proliferation (3011+/-271 BrdU+ cells/mm3 in ChR2+ mice (n=8), 1547+/-153 BrdU+ cells/mm3 in ChR2- mice (n=8), data given in mean+/-s.e.m., $p<0.001$ in t-test). Further, we found an increase in DCX+ cells/mm3 (4721+/-480 DCX+ cells/mm3 in ChR2- mice (n=8), 9522 +/-856 DCX+ cells/mm3 in ChR2+ mice (n=8), $p<0.001$ in t-test), indicating an increase in neurogenesis. The result demonstrates that activation of granule cells facilitates cell proliferation and neurogenesis in the dentate gyrus, supporting the possibility that certain patterns of neuronal activity such as place-cell activity may locally enhance neurogenesis, by creating a niche for fostering the recruitment of new neurons. The local regulation of neurogenesis by behaviorally-driven neuronal activity may conduct strategic recruitment of newly-generated neurons into behaviorally-relevant neuronal circuits.

Title: Role of immature neurons in the adult dentate gyrus for spatial memory processing after initial acquisition

Authors: *A. LUCHETTI[1], M. UEMURA[1], F. OSCHMANN[1], L. ČULIG[2,3], A. TASHIRO[2,3,1]; [1]Kavli Inst. for Systems Neuroscience, Norwegian Univ. of Sci. and Technol., Trondheim, Norway; [2]Warwick-NTU Neurosci. programme, Sch. of Biol. Sciences, Nanyang Technological Univ., Singapore, Singapore; [3]Warwick-NTU Neurosci. programme, Sch. of Life Sciences, Univ. of Warwick, Coventry, United Kingdom

Abstract: Neurogenesis persists in few regions of the adult mammalian brain including the dentate gyrus. Studies employing various ablation methods have shown that adult born neurons contribute to hippocampus-dependent forms of memory. Memory involves multiple steps starting from initial acquisition, being maintained and finally recalled. Recent studies point towards the involvement of relatively mature adult-born neurons (> 4 week old) in memory process after initial acquisition. Although it was claimed that younger immature neurons do not contribute to the memory process, the issue has not been thoroughly investigated. In this work, we focus on the role of younger cohorts of immature neurons in memory process after initial acquisition.

For this purpose, we constructed a lentiviral vector expressing diphtheria toxin receptor (DTR) and green fluorescent protein (GFP) under the control of 3,5kb promoter sequence from human doublecortin (DCX) gene, which is known to be expressed in late neuronal progenitor cells and immature neurons. The expression of DTR renders infected cells in mice vulnerable to the otherwise harmless diphtheria toxin (DT), which interferes with protein synthesis and leads to cell death. By examining the distribution of GFP expression, we found that, with a single stereotaxic injection into the dentate gyrus of adult mice, the viral vector transduced into about 40% of DCX+ cells in the dentate gyrus. A systemic DT injection into these animals reduced the number of DCX+ cells by 35-45% and that of GFP+ cells to virtually none. We found that immature neurons around two weeks old, but not ones older than four weeks, were ablated by the manipulation.

Using this manipulation, we tested spatial memory retention in a water maze task. Two groups of nine mice each underwent a water maze paradigm consisting of 24 trials in a single day. Immediately after the completion of the training, the mice were given a systemic injection of DT to ablate immature neurons. In a probe trial performed at one week after the training/DT injection, a significant reduction in time spent near the platform position was observed in the manipulated group compared with controls ($p < 0,031$, two-tailed t-test). Our results support that immature neurons aged around 2 weeks old at the time of memory formation, contribute to long-term memory processing after initial acquisition.

Title: NMDA receptor mediates learning-induced circuit formation associated with adult neurogenesis in the dentate gyrus

Authors: *R. R. NAIR[1], A. LUCHETTI[1], I. ÅMELLEM[1], A. TASHIRO[1,2,3];
[1]The Fac. of Medicine, NTNU, The Kavli Insitute for Systems Neurosci. and Ctr. for the Biol. of Memory, Trondheim, Norway; [2]Warwick-NTU Neurosci. programme, Sch. of Biol. Sciences, Nanyang Technological Univ., Singapore, Singapore; [3]Warwick-NTU Neurosci. programme, Sch. of Life Sciences, Univ. of Warwick, Coventry, United Kingdom

Abstract: Dentate gyrus is one of the regions in mammalian brain where new neurons are generated throughout life. Many newly-born neurons die during initial weeks after neuronal birth, while the survived ones are functionally integrated into neuronal circuitry contributing to hippocampal functions. Previously, we reported that NMDA-type glutamate receptor (NMDAR) is involved in the survival (Tashiro *et al., Nature* 442:929-933, 2006) and dendritic growth/maintenace (Nair and Tashiro, *Soc Neurosci. Abst*., 2011) of immature new neurons, which are also known to be affected by hippocampus-dependent memory formation. Here we examined whether NMDAR mediates the learning-induced changes in survival and dendritic morphogenesis of adult-born neurons. For this purpose, we injected a retroviral vector co-expressing Cre recombinase and GFP to the dentate gyrus of floxed-NR1 mice, thereby knocking out the NR1 gene, encoding an NMDAR subunit required for functional receptors, and visualizing dendritic morphology of the NR1 knockout (KO) neurons. Effects of spatial learning on the morphology and survival of new neurons were investigated by subjecting the virus-injected mice to a ***delayed-match-to-place*** version of water maze task at different periods after the injection. Four-day trainings during 10-13 or 15-18, but not 8-11, days after the injection significantly increased dendritic complexity and spine density measured in 21 days old wildtype neurons. Thus, the effects are dependent on the age of immature neurons during spatial learning. We found none of the training paradigms caused the effects in NR1KO neurons, suggesting the involvement of NMDAR. Spatial learning during 10-13 days after the injection significantly

increased the survival of wildtype new neurons (learners; 1302 ± 197 neurons/mm^3, swimmer control; 851 ± 140 neurons/mm^3, $p < 0.006$, group x genotype in repeated measures ANONA, $p<0.05$ in post hoc LSD test), which was not found in NR1KO new neurons. Thus, the results indicate that NMDAR is involved in learning-dependent regulations of the survival and dendritic development of new neurons, which are critical steps to determine new circuits formed by the new neurons. These two circuit forming events seem to be tightly coupled as they have three common features, 1) being mediated by NMDAR, 2) an overlapping maturation stage where they occur, and 3) an overlapping maturation stage where spatial learning affects them, suggesting a mechanistic relationship between the two phenomena. These learning-dependent regulations of circuit formation mediated by adult-born neurons may contribute to information storage in the adult dentate gyrus.

Title: Chronic fluoxetine treatment increases the dendritic complexity of immature granule cells in the adult dentate gyrus

Authors: *I. AAMELLEM[1], A. TASHIRO[1,2,3];
[1]Kavli Inst. For Systems Neurosci., Norwegian Univ. of Sci. and Technol. and St. Olavs Hosp., Trondheim, Norway; [2]Warwick-NTU Neurosci. programme, Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore; [3]Warwick-NTU Neurosci. programme, Sch. of Life Sci., Univ. of Warwick, Coventry, United Kingdom

Abstract: Adult neurogenesis in the dentate gyrus has been implicated in the therapeutic action of monoaminergic antidepressant drugs, such as fluoxetine. It has been shown that chronic antidepressant treatment requires intact neurogenesis to exert the behavioural effects of monoaminergic antidepressants. A previous study showed that chronic fluoxetine treatment

increases the dendritic complexity of immature neurons. This morphological effect is observed only after chronic, but not acute, treatment as is the case for therapeutic effects in patients, suggesting that the increased dendritic arborization of newborn neurons may be involved in the therapeutic effects of antidepressants.
To characterize the effect of chronic fluoxetine treatment on the morphology of new granule cells at different time points after neuronal birth, a retroviral vector expressing GFP was injected into the dentate gyrus of adult C57 mice. The injection was followed by daily injections of fluoxetine (18 mg/kg body weight) for either two, three, or four weeks until the day of euthanasia. Two morphological criteria were measured to analyse the dendritic arborization of the new neurons, the total dendritic length and the number of branch points.
We found that two-week chronic treatment with fluoxetine increases dendritic complexity of two week-old new neurons. This effect is transient during early maturation because we found that the difference was no longer present in three or four week-old neurons after three or four week chronic treatment. Next, to separate the effect of treatment duration from the age of the neurons, chronic treatment with fluoxetine started two weeks before the injection of the retroviral vector. Fluoxetine was applied for two additional weeks until mice were euthanized for analysis. We found dendritic arborization of the two week-old neurons in mice with four-week treatment was more extensive compared to that in vehicle-treated mice. These results suggest that the morphological effects seem to persist after two weeks of chronic treatment at the level of the whole dentate gyrus, although the morphological effect is restricted to early maturation stage and transient at the level of individual neurons. As a population of immature neurons pass the early maturation stage, younger populations would enter the stage and start showing extensive dendritic arborisation. The observed increase in dendritic arborization may be a result of accelerated maturation. This developmental stage of adult born neurons might be critical for their involvement in therapeutic effects of antidepressants.

Title: Chronic antidepressant treatment enhances the capacity for context discrimination in the hippocampus

Authors: *A. SURGET[1], Y. IBARGUEN-VARGAS[1], M. H. BLYSTAD[1], A. TASHIRO[1,2,3]; [1]Kavli Inst. For Systems Neurosci., Norwegian Univ. of Sci. and Technol. and St. Olavs Hosp., Trondheim, Norway; [2]Warwick-NTU Neurosci. programme, Sch. of Biol. Sci., Nanyang Technological Univ., Singapore, Singapore; [3]Warwick-NTU Neurosci. programme, Sch. of Life Sci., Univ. of Warwick, Coventry, United Kingdom

Abstract: Although the hippocampus has been shown to be critically involved in antidepressant (AD) effects, the underlying mechanisms are poorly understood. The effects of ADs on the hippocampus have been found by molecular, cellular and behavioral analyses. However, much less is known about the effects on neuronal activity in behaving animals, which are essential for understanding how ADs alter brain functions to exert its therapeutic effects. Here we examined how AD treatments affect neuronal activity in the hippocampus, using place-cell activity in the CA3 area as a model.

For this purpose, male Long Evans rats were implanted with 14-tetrode arrays for multiple unit recording. Following 4-week fluoxetine AD treatment (10mg/kg/day) and training in a familiar environment (an enclosure in a room), recordings were conducted under conditions in which (1) the distal but not proximal cues were changed (the familiar enclosure in a new room) and then (2) the proximal but not distal cues varied (enclosures with walls with familiar versus novel colors in the familiar room). Spatially-modulated activity was assessed from putative CA3 pyramidal cells.

In condition (1), we observed changes in spatial firing patterns and peak firing rates between two rooms (i.e. global remapping) as shown in previous studies. We did not find a significant difference between vehicle- and fluoxetine-treated rats.

In condition (2), while the spatial firing patterns remained unchanged between the different enclosures, the peak firing rates significantly varied between them (i.e. rate remapping), as expected from previous studies. The effect was found to be significantly greater following AD treatment. Moreover, the firing rate changes between the first and last sessions in the familiar enclosure were found to be as high as that between enclosures with different colors in vehicle-treated rats, indicating that an experience in a slightly-modified context may interfere with the representation of the familiar context. This effect was suppressed in fluoxetine-treated rats.

The results indicate that chronic fluoxetine treatment may affect information processing in the CA3 area, by enhancing a difference in the neuronal response to subtle contextual changes and by reducing interferences between representations. We propose that such enhancement in disambiguating equivocal contextual information in the hippocampus may result in providing downstream brain regions with a better discriminating capacity, enabling behavioral response to be appropriately set with the context. This effect may be essential for patients to cope with stressful situations and to alleviate depression.

Title: Optogenetic identification of granule cell activity in the dentate gyrus of behaving mice

Authors: *N. Z. BORGESIUS[1], A. TASHIRO[1,2,3];
[1]Kavli Inst. For Systems Neurosci., NTNU, Trondheim, Norway; [2]Warwick-NTU Neurosci. programme, Nanyang Technological Univ., Sch. of Biol. Sci., Singapore, Singapore; [3]Warwick-NTU Neurosci. programme, Sch. of Life Sciences, Univ. of Warwick, Coventry, United Kingdom

Abstract: The extracellular unit recording technique with tetrodes (a bundle of four electrodes) is a widely used method for recording neuronal activity in behaving animals. Simultaneously recorded spikes from different neurons are separated by spike sorting based on the amplitudes and shapes of the spikes as they appear differently on each of the four channels. While the technique can identify neuronal types based on their firing properties, its limitation is the inability to determine which anatomically defined cell is the source of the spikes. In the dentate gyrus (DG), unit recording technique detected a few electrophysiologically-defined cell types which are proposed by different studies to correspond to different anatomically-defined cell

types (Neunuebel, 2012 (J Neuro); Leutgeb et al, 2007 (Science); Jung and McNaughton, 1993 (Hippocampus)). Thus, it is unknown how granule cells (GCs), the major anatomically-defined type of output neurons in the dentate gyrus, are activated even though we have information on distinct firing patterns recorded in the dentate gyrus. In this study, we aim to implement a technical approach overcoming this limitation (Lima, 2009; Zhang et al., 2013) and to record from identified GCs in the DG of behaving mice. We expressed the Channelrhodopsin-2 (Chr2) gene encoding a light-sensitive cation channel in GCs. In this way, these neurons are tagged so that they respond to light stimulation by generating spikes. Light-induced firing can then be used to identify the activity of targeted neurons in behaving animals. We have been working with transgenic animals that sparsely express Chr2 in DG GCs (POMC-Cre x B6;129S-Gt(ROSA)26Sortm32(CAG-COP4*H134R/EYFP)Hze/J). We used a chronically implanted micro drive with four independently moveable tetrodes and a separately implanted optic fiber. Light pulses (472nm) of 3ms induced spikes with short latency (5-10ms) in the transgenic animals but not in Chr2 negative controls. This short latency suggests that light-induced activation is not synaptic but direct. Variability in spiking latency is substantial in most cases and spiking probability low. With increasing light intensity the variability in spiking latency is reduced and the probability increases. Taken together these results suggest we can indeed directly activate GCs that express Chr2 and record the light-induced activity. This result represents a major step towards our goal by showing that this is a promising approach to identify GCs in behaving mice. We are optimizing the tetrode and optic fiber configuration to target them more precisely to the same area of the DG.

Title: Role of synaptic plasticity in controlling information flow in the hippocampus during novelty

Authors: *T. KITANISHI[1], S. UJITA[2], M. FALLAHNEZHAD[1,3,4], N. KITANISHI[1], Y. IKEGAYA[2,5], A. TASHIRO[1,3,4];

Abstract: Synaptic plasticity is believed to be a general cellular mechanism by which neurons acquire and store information. The learning experience induces dynamic rearrangement of neuronal firing patterns in the brain, which may reflect the acquisition of learned information in neuronal network. Although the changes in neuronal firing are often assumed to be mediated by synaptic plasticity, direct evidence for the causal relationship is scarce. Here we devised a novel virus-mediated approach to perform unit recording from genetically manipulated neurons in the intact brain environment and examined a role of synaptic plasticity in novelty-induced changes of neuronal activity, using place cells in the hippocampal CA1 area as a model. We show that a form of synaptic plasticity dependent on the GluR1 subunit of AMPA receptor mediates rapid formation of spatial firing patterns in place cells upon exposure to novel environments. Further we show that, during novel experience, GluR1-dependent synaptic plasticity determines how temporal firing patterns of CA1 neurons are modulated by slow gamma oscillations, which is thought to originate from the CA3 region. These results suggest that GluR1-dependent synaptic plasticity at CA3-CA1 synapses is a cellular mechanism by which neurons acquire spatial and temporal firing patterns during novel experiences. We propose that GluR1-dependent synaptic plasticity determines information flow between subregions in the hippocampal-entorhinal system, which may be a general role of synaptic plasticity at the circuit level.

Title: Using virtual reality to study hippocampal remapping in rats during 2D navigation

Authors: *D. ARONOV, D. W. TANK;
Princeton Univ., Princeton, NJ

Abstract: Hippocampal remapping is a process by which hippocampal place cells change their spatial representation whenever the animal's environment or the behavioral context changes. This process is thought to reflect the expression of distinct spatial memories within the hippocampal network. To understand the neural mechanisms of remapping, it is beneficial to study the animal in different contexts that can be switched or modified in a temporally precise way.

Because virtual reality (VR) is a technique that allows such manipulations, we designed and implemented a VR system for rats. In this system, animals navigate by walking on a spherical treadmill and viewing a projected image of a virtual environment on a full-surround screen. Instead of being head-fixed, rats in our setup are body-tethered to a commutator (Hölscher et. al. 2005), which allows them to freely rotate and walk in any direction on the treadmill. We found that, in this setup, rats perform a wide range of natural 2D behaviors, such as walking in direct paths to targets, making abrupt stops and sharp turns, and avoiding walls of the virtual environment.

To evaluate our system as a tool for studying remapping, we designed two virtual environments that differed in shape (square, 1x1m or circle, 1.4m diameter) and the visual cues. Animals were trained on separate 30-min sessions in the two environments. Each environment was divided into 7-16 invisible equal-area zones, and one of the zones was randomly designated as the "reward zone." When a rat successfully entered the reward zone, a reward was delivered, and a different reward zone was selected. Animals successfully learned to obtain >100 rewards per session and produced full coverage of each environment.

We recorded CA1 neurons using tetrodes and a multiplexing extracellular recording system built into the VR setup. We observed 2D place fields that were similar in size and shape to those reported in real-world environments. We also observed global hippocampal remapping across the two environments: some cells exhibited a place field in only the square or the circular environment, whereas other cells exhibited fields in both, but at different relative locations. In a separate group of rats, we recorded neurons in the superficial layers of the medial entorhinal cortex and observed grid cells with hexagonally-arranged firing fields, similar to those reported in real-world environments.

The virtual-reality apparatus that allows well-controlled changes in environment, combined with neural recordings of place cells and grid cells, creates new opportunities to study the neural mechanisms by which different contexts are represented in the hippocampal network.

Title: Selective activation of M1 and M4 muscarinic receptors and object recognition memory performance in rats

Authors: *C. R. GALLOWAY[1], E. P. LEBOIS[1], N. A. HERNANDEZ[2], S. L. SHAGARABI[1], J. R. MANNS[1];
[1]Emory Univ., Atlanta, GA; [2]Georgia State Univ., Atlanta, GA

Abstract: Acetylcholine (ACh) signaling through muscarinic receptors (mAChRs) can improve memory performance on some tasks, but peripheral side effects often accompany pan-mAChR activation. Drug therapies that selectively activate M_1 or M_4 muscarinic receptors at allosteric binding sites may be able to improve memory performance without causing the peripheral side effects that are primarily associated with the M_2 or M_3 mAChR subtypes. The ability of drugs selective for M_1 or M_4 receptors to improve memory performance was tested by giving long-Evans rats subcutaneous (*s.c.*) injections of three different doses of the M_1 allosteric agonist VU0364572, the M_1 positive allosteric modulator (PAM) BQCA, or the M_4 PAM VU0152100 before performing an object recognition memory task. Each rat also completed three different sessions with 0.9% saline *s.c.* injections to establish baseline performance. The lowest dose (3.0 mg/kg) of VU0152100 markedly improved memory performance of rats who performed poorly at baseline without altering the general tendency of rats to explore novel objects. These results offer support that drug therapies that selectively target M_4 receptors show promise to improve memory performance of individuals with impaired memory, such as patients with Alzheimer's disease or schizophrenia. Future studies will use *in vivo* electrophysiology to examine if and how these muscarinic activators affect hippocampal function during object recognition memory performance.

Title: Effects of selective activation of M1 muscarinic receptors on hippocampal oscillations and spatial representations in rats

Authors: *E. P. LEBOIS[1], M. J. HAMM[2], A. I. LEVEY[1], J. R. MANNS[2];
[1]Neurol., [2]Psychology, Emory Univ., Atlanta, GA

Abstract: Muscarinic acetylcholine receptors (mAChRs) are a family of five cholinergic G-protein coupled receptors expressed throughout the brain and periphery. The M_1 receptor is heavily expressed in several forebrain regions, including those important for memory such as the hippocampus. Pharmacological work has shown that selective M_1 activation improves spatial memory, and *in vitro* studies with M_1 knockout mice have indicated that M_1 activation suppresses transmission at CA3-CA1 synapses. However, the effects of selective M_1 activation on spatial representations and CA3-CA1 functional connectivity in awake, behaving animals remains unclear. The present work used *in vivo* tetrode recording from dorsal CA3 and CA1 subregions to obtain spiking and local field potential data in adult rats during open field exploration. During exploration, the walls of the recording enclosure were incrementally reshaped to assess the influence of spatial changes on hippocampal place fields. The M_1 agonist, VU0364572, and the M_1 positive allosteric modulator, BQCA, were used to examine the impact of selective M_1 activation on hippocampal place fields and CA3-CA1 synchrony. Consistent with prior pharmacological and *in vitro* findings, the present results indicated that M_1 activation can decrease measures of CA3-CA1 functional connectivity yet benefit spatial representations. Specifically, selective M_1 activation decreased CA3-CA1 spike-field synchrony in the theta range. However, selective M_1 activation also increased responsiveness of hippocampal place fields to changes in the shape of the recording enclosure. CA1 receives input from both CA3 and entorhinal cortex (EC), and EC-CA1 synaptic transmission is thought to be modulated by nicotinic acetylcholine receptors more so than muscarinic receptors. Thus, one possible interpretation of the present results is that less coherent CA3-CA1 synaptic transmission resulting from M_1 activation might act to prioritize information coming from entorhinal cortex about current spatial stimuli. As the current work involved systemic administration of the drugs, further research will be needed to determine the extent to which M_1 receptor activation specifically in the hippocampus mediated the observed effects. Nevertheless, the results provide insight as to how muscarinic receptors mediate the balance of network dynamics in the

hippocampus and highlight potential therapeutic targets for treating age-related cognitive decline and Alzheimer's Disease.

Title: Temporal context and recognition memory in rats

Authors: *J. B. TRIMPER[1], C. R. GALLOWAY[1], N. A. HERNANDEZ[2], S. L. SHAGARABI[1], P. B. SEDERBERG[3], J. R. MANNS[1];
[1]Psychology, Emory Univ., Atlanta, GA; [2]George State Univ., Atlanta, GA; [3]The Ohio State Univ., Columbus, OH

Abstract: Memories for events are influenced by the spatial context in which the events occur. These event memories can also be influenced by memories for preceding events, which can be considered a form of temporal context. The present experiment used an object recognition memory paradigm in rats to ask how memory for an object encounter might be influenced by prior object encounters. Rats (n=10) encountered separately three junk objects on each of two laps around a circular track. Performance was evaluated by measuring the amount of time rats voluntarily inspected objects. A key question centered on the extent to which exploration of the third object on the second lap was influenced by whether the first two objects presented were novel or repeated. The results indicated that, when the third object was novel, rats explored it more if the preceding two objects had been encountered on the previous lap as compared to if the preceding two objects were also novel. One interpretation for this pattern of results is that encountering a repeated initial pair of objects elicited the memory of the third object from the previous lap. By this view, the longer exploration time resulted from a mismatch between the current object and the memory of the third object from the previous lap. If true, the results would highlight a tractable means to operationalize and test the influence of temporal context on object recognition memory in rats and would enable future studies to investigate the role of the hippocampal memory system in this aspect of memory.

Title: Electrical stimulation of the amygdala elicits Gamma coherence between CA1 and CA3 in the hippocampus

Authors: *D. I. BASS[1], Z. NIZAM[2], A. WANG[2], M. JOSEPH[3];
[1]Grad. Program in Neurosci., [2]Neurosci. and Behavioral Biol., [3]Psychology, Emory Univ., Atlanta, GA

Abstract: Emotionally arousing events can lead to activation of the basolateral complex of the amygdala (BLA), often enhancing consolidation of memory for these events. Research in rats has shown that direct¬ly manipulating the BLA can enhance memory for non-arousing, emotionally-neutral events, as well. For example, we previously reported that brief electrical stimulation of the BLA in rats enhanced object recognition memory in a stimulus-specific manner (Bass, D.I., Partain, K.N., and Manns, J.R., 2012, Behav Neurosci, 126:204-8). In particular, only objects whose initial exploration was immediately followed by electrical stimulation of the BLA were remembered one day later. One possible interpretation of those results was that stimulation of the BLA benefitted memory by modulating activity in the hippocampus. Indeed, a single pulse to the BLA can elicit an evoked potential in regions of the hippocampus that receive direct projections. In the present study, rats performed a novel object recognition memory task while local field potentials and single-unit activity were recorded in the hippocampus. As in our original study, the initial exploration of some of the objects was immediately followed by brief electrical stimulation to the BLA. Preliminary analyses indicate that electrical stimulation of the BLA did not modulate the gross firing rate of hippocampal neurons. However, BLA stimulation corresponded to increased coherence in the low gamma band (30-40Hz) between CA1 and CA3 ipsilateral to the side of stimulation. This finding is consistent with previous studies that have found gamma synchrony in the hippocampus is associated with improved performance on hippocampus-dependent memory tasks. Further

experiments will be needed to determine whether CA1-CA3 gamma coherence is necessary for the improved memory consolidation associated with BLA activation.

Title: Deliberative decision making: Is the hippocampus necessary for vicarious trial and error behaviour and performance in a spatial delay discounting task?

Authors: *D. BETT[1], L. H. MURDOCH[1], S. ANASTASSIOU[1], E. R. WOOD[1], P. A. DUDCHENKO[1,2];
[1]CCNS, Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Dept. of Psychology, Univ. of Stirling, Stirling, United Kingdom

Abstract: Vicarious trial and error (VTE) is a side to side movement of the head displayed when a rodent faces a choice-point on a maze. This behavior has been linked to spatial learning and the hippocampus (HPC) (Amsel, 1993) and has been associated with forward sweeps of CA3 place cells at a choice point (Johnson and Redish, 2007). Previous work from our group showed that HPC damage does not abolish VTE behaviour on a serial reversal double Y-maze task (Bett et al., 2012). However, in control rats (but not rats with HPC damage), VTE was higher during exploration trials compared to trials once the food was located. In the current experiment, we investigated hippocampal involvement in VTE and performance on a spatial delay discounting task.
Rats were trained on a spatial delay discounting task (Papale et al., 2012) prior to receiving ibotenic acid lesions of the HPC or sham lesions. Rats were trained to collect food rewards at the end of each arm on a continuous T-maze; a high reward (HR; 3 food pellets) was available on one arm after an adjustable delay and a low reward (LR; 1 food pellet) was available on the opposite arm after a fixed delay of 1 s. After choosing the HR the delay was increased by 1 s, whereas after choosing the LR arm the delay was decreased by 1 s; alternation resulted in a no change in delay. The initial delay value was changed daily between 1 and 30 s. Rats typically biased their choices to one side or the other, thereby changing the adjustable delay value up or down until an indifference point (IP) was reached between the HR and LR. VTE behaviour was

significantly higher during trials in which the rats repeated their choice of arm compared to trials in which the rats alternated their choice, suggesting more VTE during the titration of the HR value.
Following surgery, there was no difference between the two groups in IP or VTE across all initial delays. However, a mild effect of hippocampus lesion was found. The mean IPs of the lesion group was lower than the control group at short initial delays. VTEs were also lower at short initial delays for the hippocampus lesion group. This suggests that the HPC may modulate VTE behaviour and also delay discounting but only when the initial delay is low.
The rats were then tested on a spatial delay discounting task on a simple T-maze. In this task, rats received either a HR or LR at the end of each arm. When a 10 s (non-adjusting) delay was introduced before receiving the HR, rats with hippocampus damage were as likely as control rats to choose the HR arm, contrary to previous findings (McHugh et al., 2006). This may be an effect of prolonged training in the adjusting-delay spatial delay discounting task.

Title: Hippocampal place cells in CA3 encode future destinations on a double Y maze

Authors: E. ALLISON[1], P. A. DUDCHENKO[2], *E. R. WOOD[1];
[1]Univ. of Edinburgh, Edinburgh, United Kingdom; [2]Univ. of Stirling, Stirling, United Kingdom

Abstract: Place cells in the hippocampus fire in specific locations within an environment. In addition to spatial modulation, place cell activity can also be modulated by relevant features of a task. For instance, in a task in which rats are trained to run along a common path on their way to spatially distinct goal locations, a significant proportion of CA1 place cells with fields in the common path show activity which is modulated by which goal the rat is going to. This differential activity has also been recorded in the entorhinal cortex and in CA3 but it is not known where and how it originates. The purpose of this study was to determine whether prospective place cell activity occurs in CA3 in a hippocampus-dependent serial reversal task on the double Y maze and to compare it with that seen in CA1. We recorded simultaneously from

single cells in CA3 and CA1 in rats trained on a serial reversal task on a double Y maze. Rats were trained to run from a start box through two Y-junctions to one of four goal locations. After 10 trials the reward was moved to a new location, until all the boxes had been rewarded. Previous research has found that 44% of CA1 place cells with fields in the start areas of the maze show trajectory dependent activity in rats trained on the task. The new result that we observed is that a similar proportion of CA3 place cells also show trajectory dependent activity in rats trained on this task. This result confirms previous findings of trajectory dependent activity in CA3 and extends it to a novel task.

Title: Do place cells encode goals or routes?

Authors: R. M. GRIEVES[1], E. R. WOOD[2], *P. A. DUDCHENKO[1];
[1]Univ. Stirling, Stirling, United Kingdom; [2]Ctr. for Cognitive and Neural Systems, Univ. of Edinburgh, Edinburgh, United Kingdom

Abstract: In a previous study, Ainge et al. (2007) found that place cell firing on the initial stem of a double Y-maze predicted which goal box a rat would navigate to. However, the four goals on this apparatus differed not only in their location, but also in the route taken to each. Therefore, it was unclear whether this anticipatory place cell firing reflected the encoding of a specific goal box, or the encoding of a specific route.
To distinguish between these alternatives, we constructed a modified double Y-maze, where two routes lead to the same goal box. If place cell activity encodes goals, then firing on the common stem of the maze should occur regardless of which route the rat takes to the common goal box. Conversely, if place cells encode specific trajectories, anticipatory firing on the common stem of the maze should occur for one route, and not the other.
To date, we have recorded from 113 place cells with place fields in the start box or the initial stem of the maze. Out of 46 cells that fired when the animal ran to the common goal box, 45 (98%) fired when the rat took one route to the common goal box, and not the other. Only one cell has shown similar firing for both routes to the common goal. Therefore, when rats are trained to

use a specific trajectory to reach a goal, anticipatory place cell firing reflects the trajectory being followed rather than (or as well as) the ultimate goal destination. One possibility is that because rats were trained on a route strategy, their place fields reflected the encoding of routes. To test this, we are training a second group of rats where the common goal box is reinforced regardless of the route taken to reach it.

Title: Saccadic eye movements are phase aligned to a low frequency oscillation in the macaque hippocampus

Authors: *R. MONTEFUSCO-SIEGMUND, T. K. LEONARD, K. L. HOFFMAN;
York Univ., Toronto, ON, Canada

Abstract: Active sensing generates repetitive movements that can modulate or entrain oscillatory activity in the brain. In active vision, saccadic eye movements align intrinsic ~3 Hz oscillations in visual cortex to their optimal phase and lead to faster response times. The effects of active sensing are not limited to primary sensory areas. In rodents, hippocampal theta-band activity (centered around 8 Hz) is modulated by whisking and sniffing, as well as locomotion. In primates, the role of active sensing on hippocampal oscillations is unclear, though the dependence on visual exploration suggests that saccades may be an important rhythmic movement to align to. The effects due to eye movements might be seen in slower frequencies, based on visual cortex modulation (3 Hz) and the slower, less periodic movement of saccades compared to other active sensing movements.
To study the relationship between low frequency oscillations of the hippocampus and visual exploratory behavior, we examined the hippocampal local field potentials (LFPs) aligned to

fixation onset in the macaque during a flicker change blindness visual search task. We found the strongest oscillatory modulation at 1.7 Hz during search behavior, with the strongest, significant phase consistency occurring 70 ms prior to fixation onset, near the trough of the 1.7 Hz oscillation. Shuffling saccade intervals within a trial removed the effect. One likely stimulus-related artifact was the onset times of the flashing images, which occurred at the same frequency as our oscillation of interest. If saccades occurred with an uneven distribution around image onset, and if image onset produced an evoked response, then a spurious phase concentration to eye movements would emerge. To control for such image-evoked effects, we measured phase concentration of LFP locked to fixations that occurred during the 20-second inter-trial interval, when the screen was an unchanging black, in a darkened booth. We found the same modulation as during scene search, suggesting the effect was not a direct reflection of the changing visual stimulus. If the oscillation is present irrespective of task or visual stimulus dynamics, it may reflect an intrinsic process that may pace the physical sampling of the environment, bringing movement and ongoing neural activity into register.

Title: Cross frequency interactions in macaque hippocampus surrounding sharp wave ripple events

Authors: *J. M. MIKKILA, T. K. LEONARD, R. MONTEFUSO-SIEGMUND, K. L. HOFFMAN;
York Univ., North York, ON, Canada

Abstract: Oscillations in neural populations occur in distinct frequency bands, and these bands may show a higher-order nesting - or cross-frequency coupling - that varies by brain region,

cognitive processing, and performance. One well-described example of cross-frequency coupling is the amplitude of gamma oscillations which are modulated by the phase of theta oscillations in the hippocampus of rodents during spatial exploration [1]. Another canonical hippocampal event known as a sharp-wave ripple (SWR) was shown to be amplitude-modulated by the phase of oscillations in the 20-50 Hz frequency band, in the rodent performing a spatial alternation task [2]. SWRs have also been described in the primate, albeit primarily during quiet wakefulness and sleeping behaviors. We observed SWRs during visual exploration in the macaque, and asked whether they act independently or are coupled with other hippocampal oscillations. During the search task [3], power was concentrated around 10 Hz, 20-35 Hz and >50 Hz, including SWR events. Similar to findings in the rodent, we observed a coupling of ripple amplitude with the phase of a 20-25 Hz oscillation. In contrast to the phase-amplitude coupling results, power was decoupled between the ripple and all non-sharp-wave bands at the time of the ripple event. After the ripple, power in a 20-25 Hz band increased relative to pre and inter-ripple levels, and co-varied with the power of the immediately preceding ripple. These findings reveal a segregation of phase and amplitude effects in cross-frequency interactions, and will be discussed in the context of their possible relevance to behaviour.

Title: Imaging Ca2+ activity in GABAergic septo-hippocampal projecting axons during awake behaviour

Authors: *P. KAIFOSH, M. LOVETT-BARRON, G. F. TURI, A. LOSONCZY;
Dept. of Neurosci., Columbia Univ., New York, NY

Abstract: Hippocampal interneurons are selectively targeted by subcortical GABAergic projections. To characterize the population dynamics of the GABAergic septo-hippocampal projection in awake behaving animals, we developed a system for 2-photon imaging of axon terminals from this projection in the hippocampus of head-fixed mice walking on a treadmill while engaged with external sensory stimuli. We virally expressed GCaMP.5 in GABAergic septal neurons, and imaged Ca2+ dynamics in their identifiable axonal boutons making putative synaptic contacts with somatic or dendritic profiles of tdTomato-labeled interneurons in hippocampal area CA1. We found subgroups of boutons that behaved coherently during resting, locomotion, and/or sensory stimulation, but were silent under anesthesia. With local application of baclofen through a hole in the imaging window, and by tracing axon segments between boutons, we found that GABA-B receptor-mediated presynaptic inhibition modulates the amplitude, but not the tuning properties, we demonstrated that these highly correlated activitiy patterns resulted from shared presynaptic origin, rather than local neuromodulation of septo-hippocampal bouton responses. We also developed techniques for simultaneous bouton imaging and hippocampal LFP recording, which we applied to investigate the relationship between sensory-evoked bouton activity and hippocampal theta rhythms.

Title: Field potential and unit activity from hippocampal regions in urethane anesthetized fruit bats, Carollia perspicillata

Authors: R. ORMAN, M. STEWART, *S. E. FOX;
Dept Physiol & Pharmacol, Downstate Med. Ctr., Brooklyn, NY

Abstract: Several species of bats have received attention as model animals for studies of navigational brain systems in hippocampal and parahippocampal regions. Similarities in spatial firing properties of hippocampal place cells and medial entorhinal grid cells in bats and rats are contrasted with evidence that bats do not exhibit theta frequency activity.
Histological studies of hippocampal formation regions were done to establish stereotaxic coordinates for our forebrain atlas (Scalia, Rasweiler, Scalia, Orman, Stewart, Forebrain atlas of the short tailed fruit bat Carollia perspicillata, Springer, in press). We anesthetized male and female fruit bats with urethane and explored hippocampal regions with field potential and unit recordings. In this initial survey we have recorded theta frequency local field potentials (LFPs) from area CA1.
We conclude that bats may generate hippocampal theta activity, but completion of our ongoing single unit and current source density analyses will be necessary to conclusively demonstrate the hippocampal origin of these field potentials in bats.

Title: Hippocampal remapping involves competition between entorhinal inputs

Authors: *J. DICKINSON[1], A. WEIBLE[2], D. ROWLAND[3], C. KENTROS[3];
[1]Inst. of Neurosci., [2]Univ. of Oregon, Eugene, OR; [3]NTNU, Trondheim, Norway

Abstract: Both medial entorhinal cortex (MEC) neurons and their downstream pyramidal targets in the hippocampus have spatial receptive fields. “Grid” cells of the MEC have multiple receptive fields arranged in a hexagonal pattern which largely stay the same in different environments, whereas hippocampal place cells have single, environmentally-specific place fields. This leads to the question of whether, and how, grid cells may create place fields. Exposure to environmental novelty leads to drastic, unpredictable changes in place cell firing patterns (remapping). To investigate how grid cells contribute to place cell remapping, we expressed the hM3Dq DREADD (Designer Receptor Exclusively Activated by Designer Drugs), a modified muscarinic G-protein coupled receptor exclusively activated by clozapine-N-oxide (CNO, an otherwise inert metabolite of the antipsychotic clozapine) in MEC layer II projection

neurons. Since binding of CNO to hM3Dq results in a depolarization lasting for several hours, CNO injection in these mice allows us to investigate the network response to manipulating a random subset of upstream entorhinal inputs against the backdrop of a fully formed and consolidated spatial map. Previously, we showed that increasing MEC LII activity caused some CA1 place fields to remap, while others expanded their firing fields or were unaffected, much like the response to environmental novelty. This "artificial remapping" allows the investigation of how the grid-like inputs to the hippocampal network affect place cells, and help evaluate theoretical models of the putative grid-to-place cell transformation. To address these questions, we analyzed CA1 place fields of the same cells during multiple CNO injections over multiple days. Our data show a range of responses of CA1 neurons to depolarizing a subset of entorhinal inputs. CNO often induced clear remapping to a new field, but we also saw a variety of intermediate responses such as multiple fields, alternation between two place fields, and place field expansions. This suggests that there are instances where the network-level competition does not go to completion, which enables us to effectively identify intermediate states of the network that reveal part of the grid-to-place cell transformation. These results suggest that the inputs to pyramidal neurons compete to determine a single place field in an attractor-like manner.

Title: Olfactory-driven oscillations in the mouse hippocampus

Authors: *A. B. TORT[1], Y. YANOVSKY[2], M. CIATIPIS[3], A. VYSSOTSKI[4], A. DRAGUHN[2], J. BRANKACK[2];

Abstract: Olfaction is the dominant sense in rodents. Local field potentials (LFP) in the olfactory bulb (OB) exhibit prominent respiration related oscillations. Although the OB sends projections to the entorhinal cortex, little is known about the influence of olfactory inputs on network oscillations in the hippocampus, a region that integrates polymodal information required for memory formation. Here we report a robust 2 to 4 Hz LFP rhythm in the hippocampus of urethane-anesthetized mice that is highly coherent with the OB rhythm and respiratory activity. The amplitude of the hippocampal olfactory rhythm varied across the CA1-dentate gyrus (DG) axis and was maximal at the hilus. In contrast, simultaneous theta (4 to 6 Hz) oscillations were maximal near the hippocampal fissure. Concurrent theta and olfactory oscillations could be further disentangled: (1) atropine abolished theta oscillations but did not alter the olfactory rhythm; (2) bypassing nasal airflow through tracheotomy abolished the olfactory rhythm but not theta oscillations. Extracellularly-recorded hippocampal spiking activity phase-coupled to both rhythms. Intracellular recordings from DG neurons revealed subthreshold membrane potential which oscillated at the same frequency and in anti-phase with the olfactory LFP rhythm. Finally, we found similar 2 to 4 Hz oscillations in the hippocampus of awake mice that also exhibited strong coherence with the OB rhythm. These results demonstrate that nasal airflow leads to hippocampal oscillations phase-locked to respiratory activity, which are likely generated by entorhinal cortex inputs to DG. This olfactory-driven oscillation is clearly different from the hippocampal theta rhythm.

Title: Involvement of prelimbic cortex cannabinoid type-1 receptors in the disruptive effect of cannabidiol on contextual fear memory reconsolidation

Authors: *C. J. STERN[1], L. GAZARINI[1], M. S. HAMES[1], A. W. ZUARDI[2], R. N. TAKAHASHI[1], L. J. BERTOGLIO[1];
[1]Pharmacol., Univ. Federal De Santa Catarina, Florianopolis, Brazil; [2]Univ. de São Paulo, Ribeirão Preto, Brazil

Abstract: The medial prefrontal cortex (mPFC) has been implicated in fear memory processing. The prelimbic (PL) part of the mPFC is connected with brain regions controlling memory reconsolidation, a process that occurs after the retrieval/reactivation of a consolidated memory and that makes it susceptible to interferences. Several pharmacological agents have been shown to disrupt memory reconsolidation, but the neural substrate underlying this effect remains unclear. The objective of the present study was to investigate the potential role of PL in fear memory reconsolidation. It was also of interest to investigate whether PL is a neural substrate for the disruptive effects of the phytocannabinoid cannabidiol (CBD) on this memory stage. The protocol consisted of familiarization, fear conditioning (0.8 mA, 3 s, inter-shock interval: 30 s), memory reactivation and test A in the context A. A neutral chamber B was used in the non-reactivated protocol and a chamber C was used to the reinstatement protocol. Contextual fear memory was inferred from the percentage of freezing behavior. Immediately after reactivation, male Wistar rats received a bilateral PL infusion of vehicle (VEH) or muscimol (MUS; 4.0 nmol/side), a gamma-aminobutyric acid type-A receptor agonist that temporarily inhibit the synaptic transmission. During reactivation, all groups equally expressed freezing. However, on Test A, MUS-treated group expressed significantly less freezing than VEH (VEH: 72 ± 3; MUS: 43 ± 7). After ten days, no spontaneous recovery was observed (VEH: 67 ± 5; MUS: 33 ± 5). One day after the spontaneous recovery test, the animals were submitted to an extinction session (VEH: 23 ± 2; MUS: 18 ± 5) and on the next day received a mild footshock in the context C. As a result, reinstatement could be observed in VEH-treated group, with increased fear response (VEH: 42 ± 5) while MUS-treated animals presented low levels of freezing (MUS: 23 ± 4), confirming that PL inactivation impaired the reconsolidation. When the reactivation was omitted and the PL was inactivated, no significant reduction of freezing was observed in the Test A. Further, to verify whether PL could be one of the neural substrates for the CBD effect, CBD (10 mg/kg) was systemically administered after the blockade of cannabinoid type-1 (CB1) receptors in PL with AM251 (50 pmol/side). Confirming a previous result, CBD blocked the reconsolidation step (VEH-VEH: 75 ± 9; VEH-CBD: 40 ± 9). This effect was abolished by the PL CB1 blockade (AM251-VEH: 71 ± 9; AM251-CBD: 70 ± 10). Altogether, the present work suggests that PL activity subserves fear memory reconsolidation and its CB1 receptors mediate the disruptive effects of CBD on this process.

Title: Comparing the role of α1- and β-adrenoceptors in consolidation and reconsolidation of adaptive and inappropriate contextual fear memories

Authors: *L. GAZARINI, C. A. J. STERN, A. P. CAROBREZ, L. J. BERTOGLIO; Farmacologia, Univ. Federal De Santa Catarina, Florianopolis, Brazil

Abstract: It has been shown that α1- and β-adrenoceptors have a distinct contribution during consolidation and reconsolidation of a weak and adaptive fear memory. For strong fear memories, the noradrenergic enhancement of consolidation or reconsolidation might underlie the formation of inappropriate memory traces, but it is unknown whether that outcome would recruit a different subset of adrenoceptors. Using the α2-adrenergic antagonist yohimbine to increase brain noradrenaline release, the present study sought to compare the relative contribution of α1- and β-adrenergic receptors to consolidate and reconsolidate contextual fear memories of different magnitude in rats. The consolidation protocol consisted of familiarization to the context A on day 1, a weak or strong training session (1 or 3 0.7 mA, 3 s footshocks) in the familiarized context on day 2, a re-exposure to that context (Test A) on day 3, and an exposure to a neutral context (Test B) on day 4. In the reconsolidation protocol, a 3-min session to retrieve/reactivate the memory trace was added 24 h before Test A. Freezing behavior was measured as an index of fear memory. The pretreatment with the α1-adrenergic antagonist prazosin (PRAZ; 0.5 mg/kg), the β-adrenergic antagonist propranolol (PROP; 10 mg/kg) or vehicle took place after the training (consolidation) or reactivation (reconsolidation) sessions. Yohimbine (YOH; 1 mg/kg) or vehicle (VEH) was given 10 min later. As observed during test A, the yohimbine-induced noradrenergic enhancement facilitates both the memory consolidation (VEH/VEH: 25 ± 3 %; VEH/YOH: 73 ± 7%) and reconsolidation (VEH/VEH: 24 ± 2 %; VEH/YOH: 55 ± 5 %) of a weak training. While propranolol prevented such effect in consolidation (PROP/YOH: 32 ± 2 %) and reconsolidation (PROP/YOH: 29 ± 3 %), prazosin was only able to prevent it during reconsolidation (PRAZ/YOH: 35 ± 2 %). Yohimbine caused fear generalization, as observed in

test B, when given during consolidation (VEH/VEH: 19 ± 3 %; VEH/YOH: 41 ± 6 %) or reconsolidation (VEH/VEH: 17 ± 2 %; VEH/YOH: 43 ± 4 %) of a strong training only. This effect was prevented by propranolol, but not prazosin, when given during consolidation (PROP/YOH: 20 ± 3 %) or reconsolidation (PROP/YOH: 13 ± 2 %). Altogether, present results highlight that while α1- and β-adrenergic receptors are differentially required during the consolidation and reconsolidation of an adaptive fear memory, there appears to be a preferential role of β-adrenergic receptors for the formation of inappropriate memories that subsides fear generalization.

Title: Fear extinction and reinstatement are dependent on distinct changes of cellular basis in medial prefrontal cortex

Authors: *N. IMAMURA, Y. MIURA, C. TESHIROGI, H. SHEN, N. MATSUKI, H. NOMURA;
Lab. of Chem. Pharmacol. Grad. Sch. of Pharmaceut. Sci., Tokyo Prefecture, Japan

Abstract: Anxiety disorder is a blanket term covering several different forms of a type of mental illness of abnormal and pathological fear and anxiety. In some cases, despite successful reduction of fear through exposure psychotherapy, inappropriate fear responses reappear with passage of time, presumably caused by re-exposure to the stimulus or stress. In contrast with extensive studies on the neuronal circuitry and neurochemical mechanisms leading to fear acquisition and extinction, few studies have focused on fear reinstatement. In this study, we investigated neuronal circuitry of reinstatement. Mice were conditioned with footshocks in a chamber, and 1 day later, they were re-exposed to the chamber without footshocks for 40 min. This long-term re-exposure, extinction training, extinguished conditioned fear responses. After that, they received a weak immediate shock in a different chamber, and then, fear responses were measured in the original conditioning chamber. As a result, the conditioned fear was reinstated. c-Fos immunostaining study revealed that an exposure to the conditioned chamber activated infralimbic (IL) region of medial prefrontal cortex (mPFC) after extinction training but not after

reinstatement. Microinjection of an NMDA receptor antagonist APV into mPFC before the weak immediate shock attenuated reinstatement. To investigate cellular basis of reinstatement, patch-clamp recordings were made from IL neurons. Extinction training elevated intrinsic excitability, whereas fear reinstatement was followed by reduction of mEPSC frequency. These results suggest that fear reinstatement as well as extinction is dependent on plasticity of IL neurons, but they are dependent on distinct changes of cellular basis in IL.

Title: Peripheral stress impairs acquisition of fear memories via vagal afferents

Authors: *E. TOMIKAWA, H. NOMURA, N. MATSUKI;
pharmaceutical, The Univ. of Tokyo, Tokyo, Japan

Abstract: It is known that peripheral activities such as stress can affect learning and memory but exact mechanism is still unknown. In this study we used lipopolysaccharide (LPS) to induce abdominal discomforts in mice. LPS (250 ug/kg, i.p.) attenuated learning of inhibitory avoidance task tested the next day. Since LPS is known to stimulate the vagal afferents, the same task was tested in vagotomized mice. The LPS-induced suppression was completely abolished in vagotomized animals, indicating that peripheral information via vagal afferents is enough to affect hippocampus-dependent learning. To elucidate the mechanism in which vagal afferents impair memory formation, we analyzed c-Fos expression after LPS injection. As expected, LPS caused massive induction of c-Fos expression at the nucleus tractus of solitalius. Chronic electrical stimulation is clinically used to treat epilepsy and depression, and we have shown that electrical stimulation of vagal afferents augmented the perforant pass-CA3 neurotransmission via activation of the locus coeruleus (Shen et al. 2012). Therefore, LPS-induced activation of vagal afferents may affect hippocampal activities different from that of direct electrical stimulation.

Title: The frontal association cortex is critical for formation but not retrieval of contextual fear memory

Authors: *H. NOMURA, D. NAKAYAMA, Z. BARAKI, A. NONAKA, N. MATSUKI;
Lab. Chem. Pharmacol, Grad Sch. Pharm, Univ. Tokyo, Tokyo, Japan

Abstract: The frontal association cortex (FrA) has reciprocal connections with the amygdala and is implicated in fear conditioning. The dendritic spines of FrA neurons are modified by fear learning and extinction. Inhibiting FrA activities after conditioning prevents the formation of the memory. However, the memory process in which the FrA is involved remains poorly understood. In this study, we examined the effect of inhibiting each memory process on contextual fear expression. Pre-conditioning infusion of APV, an NMDAR antagonist, or post-conditioning infusion of anisomycin, a protein synthesis inhibitor, into the mouse FrA impaired freezing behavior that was measured 1 day later. Pre-test infusion of muscimol, a GABAA agonist, into the FrA had no effect on the freezing behavior that was measured 1 day or 30 days after conditioning. Infusion of muscimol into the FrA had also no effect on the locomotor activity. These findings indicate that the FrA is involved in formation but not retrieval of contextual fear memory.

Title: Late Arc/Arg3.1 synthesis after retrieval is necessary for persistence of contextual fear memory

Authors: *D. NAKAYAMA, Y. YAMASAKI, N. MATSUKI, H. NOMURA;
7-3-1, Lab. of Chem. Pharmacol., Tokyo, Japan

Abstract: Memory retention requires long-term maintenance. Retrieved memory undergoes stabilization via de novo protein synthesis around the time of retrieval. However, the mechanisms underlying stabilization at
longer delayed time have not been explored. The activity-regulated cytoskeletal-associated protein (Arc/Arg3.1) is an immediate early gene that has been widely believed to play a role in synaptic plasticity. Here, we show late Arc/Arg3.1 synthesis contributing to persistence of reactivated fear memory. Arc/Arg3.1 synthesis in the basolateral amygdala (BLA) was examined at several time points after retrieval of contextual fear memory. The western blotting showed biphasic increase in Arc/Arg3.1 synthesis. Arc/Arg3.1 synthesis increased at 2 and 12 h after retrieval. Late Arc/Arg3.1 synthesis was not increased when mice did not learn the association between context and footshock. To examine the role of late Arc/Arg3.1 synthesis in memory retention, *Arc/Arg3.1* antisense oligodeoxynucleotide, an Arc/Arg3.1 translation selective inhibitor, was infused into the basolateral amygdala. Inhibition of late Arc/Arg3.1 synthesis attenuated fear memory 7 days later, but not 2 days later, suggesting that late Arc/Arg3.1 synthesis is required for memory persistence. Mice showed intact fear memory when mice received *Arc/Arg3.1* antisense in the absence of the retrieval session. These data indicate that late Arc/Arg3.1 synthesis is necessary for persistence of reactivated fear memory.

Title: Measuring hippocampal gene expression in NFIL3 Knock-Out mice during consolidation and reconsolidation using CAGE sequencing

Authors: *L. R. VAN DER KALLEN[1], M. M. LENSELINK[1], I. M. C. BAKKER[2], L. M. PARDO CORTES[2], L. S. VIJFHUIZEN[3], A. M. J. M. VAN DEN MAAGDENBERG[3], S. SPIJKER[1], A. B. SMIT[1], R. E. VAN KESTEREN[1];
[1]Mol. and Cell. Neurobio., VU Univ., Amsterdam, Netherlands; [2]Dept. of Human Genet., VU Med. Ctr., Amsterdam, Netherlands; [3]Dept. of Human Genet. and Neurol., Leiden Univ. Med. Ctr., Leiden, Netherlands

Abstract: Long term changes in connectivity between neurons in the hippocampus are necessary for memory formation, and are regulated by transcription factors (TFs) such as CREB. NFIL3 is a TF related to CREB, and we previously showed that NFIL3 provides negative feedforward inhibition of CREB target gene expression in the context of regeneration after nerve injury. Moreover, NFIL3 is upregulated in hippocampal neurons by both CREB activation in vitro and fear conditioning in vivo. We hypothesize that NFIL3 and CREB co-operate to regulate gene expression in the hippocampus, which is necessary to make the long term changes in neuronal connectivity that are required for memory formation. We subjected wild-type (WT) or NFIL3-Knock-Out (KO) mice to fear conditioning, and measured context-dependent freezing responses 24 hours later. Freezing levels were subsequently also measured in a neutral context to measure generalized fear. Next we measured gene expression during fear conditioning induced consolidation and reconsolidation by Cap Analysis of Gene Expression (CAGE)-sequencing. Groups differed on 4 levels: 1) we compared WT and KO mice, 2) we measured during consolidation or reconsolidation, 3) we measured at 0, 0.5 and 6 hours after stimulation, and 4) we used mice that received the shock immediately upon entering the conditioning cage instead of after a 3 minute delay as a negative control group. In the immediate shock condition it has been shown that no memory is formed. We show that NFIL3 KO mice show comparable freezing levels when tested in the shock compartment, but increased freezing when subsequently tested in a neutral compartment, indicating increased generalized fear or decreased behavioral flexibility. CAGE sequencing data are currently being analyzed as to determine the molecular underpinnings of this behavioral deficit. Increased generalized fear or decreased behavioral flexibility in NFIL3 KO mice might be explained by the hypothesized role of NFIL3 as a negative regulator of plasticity gene expression. Lack of NFIL3 would lead to prolonged activation of plasticity genes, resulting in the formation of persistent or incorrect associations. The CAGE sequencing experiments will offer new insight into altered cascades of transcriptional activation in NFIL3 KO mice during memory processes with a resolution that is only recently available. Additionally we can tease apart gene activation that is specific to shock effects and memory processes, as well as consolidation or reconsolidation specific effects.

Title: A role for amyloid-beta in memory stabilization

Authors: *P. S. FINNIE, J. PERDRIZET, K. NADER;
Psychology, McGill Univ., Montreal, QC, Canada

Abstract: The accumulation of Amyloid beta (Abeta) in the brain has been strongly implicated in the pathogenesis of Alzheimer's Disease (AD). However, it has been proposed that this peptide might also serve important functions in normal brain physiology. Abeta levels have been observed to increase in response to neuronal stimulation and following acute or chronic stress, and may even facilitate memory consolidation. Furthermore, accumulating evidence indicates that elevated Abeta may influence the subunit composition of N-methyl-D-aspartate (NMDA) receptors, potentially lowering the NR2B:NR2A ratio. Given the well-documented function of reduced GluN2B:GluN2A ratio in closing developmental critical periods in sensory cortices, we theorized that endogenous Abeta could potentially contribute to metaplastic processes throughout the brain. Here we evaluated the role of Abeta in the stabilization of auditory fear memories. We observed that manipulating Abeta levels during fear conditioning can modulate the susceptibility of these memories to subsequently enter a labile state following their reactivation. These findings suggest that Abeta may contribute to the stabilization of consolidating memories against their future modification. An extension of this idea would predict that AD could be at least partially initiated by a change to how and when experience-dependent synaptic plasticity will occur. Our findings also highlight that unidimensional measures typically used to assess mnemonic ability in animal studies of Abeta and AD may obscure important aspects of this pathology.

Title: Investigating the mechanism of memory reconsolidation in fear associated memories

Authors: S. BHATTACHARYA[1], W. KIMBLE[2], D. BHATTACHARYA[1], M. BUABEID[1], A. ALHOWAIL[1], M. DHANASEKARAN[1], M. ESCOBAR[2], *V. D. SUPPIRAMANIAM[1]; [1]Harrison Sc Pharm., Auburn Univ., AUBURN, AL; [2]Dept. of Psychology, Auburn Univ., Auburn, AL

Abstract: Retrieval of a previously-acquired memory renders it 'labile' until the memory is once again consolidated. This reconsolidation process has received much attention in recent years because labile memories may be prone to permanent alteration. Although much is known about the cellular processes that underlie reconsolidation, there are no available models of how synaptic plasticity changes through the reconsolidation period. Using rodents in conditioned fear preparations (retrieval, Rtv group), we investigated how synaptic plasticity change as a function of time through the reconsolidation period.We investigated changes in LTP, as well as the associated changes in glutamate receptor expression on a time-dependent manner through the reconsolidation period. Our data suggests that field Excitatory Post synaptic Potential (fEPSP) slopes are decreased in Schaffer Collateral pathway of the hippocampus in 1h post-Rtv animals (110.8+/-5%, p<.001, n=8) and improved in 4h post-retrieval animals (140.6+/-6%, p<.001, n=8) compared to controls. In 7h post-retrieval animals, the slopes corresponded to that of the control animals (180+/-10%, p<.001, n=8). A similar but more pronounced trend was seen in Dentate Gyrus recordings in the behaviorally intervened animals (n=8), which might be due to direct fear inputs from lateral amygdala to DG. Expression of N-Methyl-D-Aspartate (NMDA) and α-Amino-3-hydroxy-5-Methyl-4-isoxazole-Propionic Acid (AMPA) receptor subunits NR1, NR2A, NR2B, GluR1/2/3 were assessedat different time points/regions of the brain. GluR1 and NR1 subunits were downregulated in 1h animals, but returned to normal at 4h in the hippocampus and cerebellum. GluR2 subunits of AMPARs were downregulated in 1h animals in the hippocampus but not in cerebellum. Surprisingly, NR2B levels were above normal in 1h animals and decreased to control levels in 4h animals in all of the three brain regions. This effect might be due to synaptic NR2Bs role in memory destabilization. We further quantified synaptic receptor expression by using immuno-precipitated Post Synaptic Density 95 (PSD95) fraction. The trend was more distinct in PSD95 fractions of NR2B/GluR1in hippocampus. These results indicate a time dependent synaptic receptor expression pattern during fear input related memory reconsolidation. Currently, we are investigating the relationship between changes in synaptic plasticity and overt behavior.Successful accomplishment of the project will lead to betterment of

quality of life for Post Traumatic Stress Syndrome (PTSD) patients through selective erasure of fear-associated memories.

Title: Nuclear Factor κB-dependent histone acetylation of Camk2d gene is specifically involved in memory persistence

Authors: N. FEDERMAN[1], V. DE LA FUENTE[2], G. ZALCMAN[2], *A. ROMANO[2]; [1]Univ. of Buenos Aires, Buenos Aires, Argentina; [2]Univ. of Buenos Aires, FCEN, FBMC, Buenos Aires, Argentina

Abstract: Previously, we have demonstrated that histone acetylation is a specific molecular signature of enduring memories consolidation. To gain insight into the specific gene expression effect of the induction of this epigenetic mechanism, we studied the participation of Nuclear factor κB (NF-κB) transcription factor in the process of acetylation during novel object recognition (NOR) memory persistence. To address this question, we used three different strength of training for NOR task in mice: one group of animals received a weak training protocol which did not induce long-term memory (LTM); animals which received a standard training which lead to 24hs LTM, and the last group of animals received a strong training which induced 7 weeks LTM. We found that only after strong training, NF-κB inhibition impaired memory persistence and, concomitantly, prevented the induction of general H3 acetylation. To determine the level of histone acetylation in specific genome locations, we studied promoter regions of particular genes that are associated with neural plasticity and memory. We studied two

genes that codify important proteins involved in memory formation: Zif268 and CaMKII. Accordingly, we found an important increase in H3 acetylation at a specific NF-κB-regulated promoter region of the Camk2d gene, which was reversed by NF-κB inhibition. This H3 acetylation increment leads to δCaMKII mRNA induction 6h after strong training, but not after weaker training protocols. This result shows that δCaMKII expression is only induced during consolidation of persistent forms of NOR memory. Our work presents a molecular link between transcription factor activation, epigenetic mechanism, and late gene expression in the regulation of memory persistence.

Key words: memory consolidation, memory persistence, histone acetylation, NF-κB, CamKIId.

Title: Transcriptome analysis reveals differences in processes that regulate gene expression during memory consolidation and retrieval

Authors: *L. PEIXOTO[1], M. WIMMER[1], S. POPLAWSKI[1], N. R. ZHANG[2], T. ABEL[1]; [1]Biol., [2]Wharton Sch., Univ. of Pennsylvania, Philadelphia, PA

Abstract: Long term memory reflects the persistent changes in the brain that result from learning. Molecular defects in synaptic function are thought to be responsible for cognitive disorders, although those defects are yet to be fully understood. Several findings using learning paradigms in mice (such as contextual fear conditioning) have shown that long term memory formation requires transcription and protein synthesis. Previous research has shown that this requirement is limited to specific time periods sensitive to administration of anisomycin (a protein synthesis inhibitor) in the hippocampus (a brain region critical for memory storage). Transcriptional changes in several genes (fos, arc, zif268, dusp1, nr4a1) have been associated with memory formation, but outside a limited set of genes, little agreement exist between current genome-wide studies of memory consolidation and no study before has examined all defined

sensitive periods. In this study gene expression was examined using whole genome microarrays before training and during the established critical periods: 30 min., 4 hrs and 12 hrs and 24 hrs after contextual fear conditioning and after memory retrieval in C57BL/6J mice. A similar time-course was performed at the same time points without the learning experience to model the effect of circadian time in gene expression patterns in the mouse hippocampus (n=9 for all samples). Principal component (PC) analysis reveals that the strongest influences in gene expression in the hippocampus are pheromone response and time-of day and likely explains the lack of agreement and power of previous studies. After PC normalization, our study shows that the biggest changes in gene expression happen 30 min after learning and after retrieval of memory. Up-regulated genes after acquisition and retrieval overlap greatly and are involved in transcriptional control, including known transcription factors fos, zif268, junB and nr4a1. This was verified by q-PCR of known genes induced at 30 minutes. Several novel genes induced after contextual fear conditioning were identified and confirmed by qPCR in an independent cohort of animals. Interestingly, genes down regulated at the first sensitive period in consolidation and retrieval do not overlap in functions. Memory consolidation down regulates chromatin assembly while retrieval down-regulates RNA processing. Almost no-transcriptional changes can be detected 4 and 12 hours after learning. In addition, our study revealed a novel role for specific microRNAs in memory formation as well as differences in microRNA regulation between consolidation and retrieval.

Title: Histone acetylation enhances hippocampus- or perirhinal cortex-dependent non-affective memory consolidation and retrieval

Authors: *F. D. DUTRA, A. CRESTANI, F. BOOS, J. HAUBRICH, R. SIERRA, J. DURAN, Q. ZANONA, F. SANTANA, L. FLORES, J. QUILLFELDT, L. DE OLIVEIRA ALVARES; Dept. de Biofísica, Univ. Federal do Rio Grande do Sul, Porto Alegre, Brazil

Abstract: Neuroplastic mechanisms, including memory, are widely influenced by epigenetic marks (changes on genetic content not involved with nucleotides sequences alterations).

Currently, studies show that histone acetylation is one of epigenetic mechanisms that more influence memory consolidation. However, these studies use mainly behavioral paradigms with affective components (aversive or appetitive). Our present study verified histone acetylation epigenetic mechanism involvement over hippocampus- or perirhinal cortex-dependent non-affective memory consolidation and retrieval. To test this hypothesis, we injected Trichostatin A (TSA, HDAC inhibitor) or Garcinol (HAT inhibitor) directly over male adults Wistar rats' hippocampus or perirhinal cortex, immediately after training or before test of spatial object recognition (SOR - hippocampus-dependent) or object recognition (OR - perirhinal cortex-independent) tasks. We observed that TSA-injected animals showed both, SOR and OR, memories consolidation enhancement, when compared with respective controls. When animals were injected with Garcinol, however, these memories' consolidation was strongly impaired. In another experiment, animals injected with TSA showed SOR and OR memory retrieval enhancement, while animals treated with Garcinol showed information retrieval impairment. H3K9K14 levels biochemical analysis, by western blot, corroborates our behavioral findings. Taken together, these data show that histone acetylation actively participate of non-affective memory consolidation process. Other studies comparing different non-affective memory protocols are unknown. Moreover, this is the first time that HDAC's and HAT's actions over memory consolidation are showed together, in the same study. Furthermore, we showed that there is no difference in histone acetylation occurrence over hippocampus or other brain regions during memory consolidation and retrieval. Finally, we observed that, surprisingly, histone acetylation seems to act also over memory retrieval. Epigenetic action over memory retrieval is very interesting - and unexpected - and opens a wide range of investigation, where more studies are needed.

Title: Arc expression in the insular cortex is involved in the updating after retrieval of an aversive memory trace

Authors: *K. R. GUZMAN-RAMOS[1], A. VENKATARAMAN[2], P. MORIN[3], F. BERMUDEZ-RATTONI[4];
[1]Inst. de Fisiologia Celular UNAM, Mexico, Mexico; [2]IFC, MEXICO, Mexico; [3]Inst. de Neurobiología, Juriquilla, Mexico; [4]Inst. de Fisiologia Celular, Mexico, Mexico

Abstract: The formation and storage of a memory trace is a dynamic process that involves molecular changes and depending on the type of information the memory trace can be reinforced or updated upon reactivation. Memories of taste stimuli are remarkably plastic since the ability to learn if a certain food is safe to eat or became toxic is vital. We are interested in looking at the expression of Arc/Arg3.1, one of the immediate early genes that have been reported to be involved in learning induced long-term synaptic plasticity. Arc/Arg3.1 specifically accumulates in the dendrites that exhibit synaptic activity, thereby marking neurons that bear memories, however some evidence indicate that the hedonic value of the information is determinant to engage Arc expression within different brain structures. We hypothesized that the expression of Arc in the insular cortex would be related to the formation of an appetitive taste memory trace during the acquisition stage and during an updating process. In this study, we assessed the effect of the knock-down of Arc/Arg3.1 by the intracortical administration of an antisense oligodeoxynucleotide (ODN) on male Wistar rats before the acquisition phase of an aversively conditioned taste (saccharin followed by LiCl to induce gastric malaise), and before the acquisition of an appetitive "safe to consume" taste (saccharin followed by NaCl). The decrease of Arc/Arg3.1 expression affected only the formation of the appetitive saccharin and had no effect on the aversive trace formation. Additionally, we assessed the effect of the ODN administration on the hedonic value shifting (updating) of the saccharin memory trace from aversive to safe and vice versa. The results suggest that not only the initial formation of a "safe to consume" taste requires Arc/Arg3.1 expression, but the updating from aversive to safe also involves upregulation of Arc/Arg3.1. Interestingly, we were able to make this dissociation in a brain structure that is activated during the formation of both aversive and appetitive taste memory traces, indicating that the specificity of the information value incorporated to the trace might have a molecular signature involving Arc/Arg3.1.

Title: Rac in the basolateral amygdala is crucial for the reconsolidation of auditory fear memory in rats

Authors: *Z. DING, P. WU, W. ZHU, H. SHEN, L. LU;
Natl. Inst. On Drug Dependence, Beijing, China

Abstract: Background: Acute and chronic changes in the stress response are major characteristics of post-traumatic stress disorder (PTSD), manifested as a conditioned fear memory. It has been reported that disruption of fear memory contributes to ameliorate PTSD. Consolidated fear memories that are susceptible to be disrupted immediately after retrieval undergo a reconsolidation process to become persistent, Rac (Ras-related C3 botulinum toxin substrate) plays an important role in the acquisition and extinction of fear memory. We hypothesized that Rac in the amygdala is crucial for the consolidation and reconsolidation of auditory fear memory.
Methods: The auditory fear conditioning procedure (1 s, 3 footshock, 0.75 mA) were used to explore the role of Rac in the amygdala in the consolidation and reconsolidation of auditory fear memory. Immediately after auditory fear conditioning or reexposure to a single tone previously paired with footshock in another context, we microinjected NSC23766 (the specific inhibitor of Rac1, 10 μg/μl or 27μg/μl, 0.5 μl per side) into the BLA or CeA. Then, the auditory fear memory performance was tested 24 hours after the microinjection.
Results: Microinjection of NSC23766 into the basolateral amygdala (BLA) but not central nucleus of the amygdala (CeA) immediately after memory reactivation disrupted the reconsolidation of auditory fear memory. Microinjection of NSC23766 into the BLA or CeA after auditory fear memory training had no effect on the consolidation of auditory fear memory.
Conclusions: Our results indicate that Rac in the BLA is crucial for the reconsolidation of auditory Pavlovian fear memory.

Title: Memory consolidation and reconsolidation in starlings: Exploring the interaction between interference and sleep

Authors: *T. P. BRAWN, H. C. NUSBAUM, D. MARGOLIASH;
Univ. of Chicago, Chicago, IL

Abstract: Memory consolidation strengthens newly encoded memory traces and stabilizes them against interference, a process widely believed to benefit from sleep. Behavioral evidence of sleep-dependent memory consolidation is well established in human memory tasks but is limited in adult animals. We previously demonstrated sleep-dependent memory benefits in European starlings that were trained on a Go/No-Go task to classify pairs of 5-second segments of novel starling songs. Classification accuracy improved after retention intervals that included sleep but not after waking retention (Brawn et al., Journal of Neuroscience, 2010). Furthermore, learning two similar classification tasks (tasks A and B) interfered with each other during the day, resulting in performance impairments for both tasks after waking retention. Yet, performance on both tasks improved after sleep (Brawn et al., Psychological Science, 2013). Here we explore if the consolidated memories are resistant to interference encountered after sleep, or if post-consolidation retrieval makes memory once again labile and therefore susceptible to interference. Auditory classification performance of starlings was examined across three days, with interference on the second day. Starlings in the Control (no interference) condition only learned task A, whereas starlings in the interference conditions also learned task B either before (Early-Interference) or after (Late-Interference) being retested on task A on day 2. Each condition, as expected from our prior work, resulted in a performance improvement after the first night of sleep. Control condition performance remained stable across the second day and second night of sleep. Performance in the Early-Interference condition also remained stable across the second day but additionally showed enhanced performance after the second night of sleep. In contrast, performance in the Late-Interference condition decreased across the second day but recovered after sleep. The pattern of results suggests that the retrieval of task A made the memory of task A susceptible to subsequent interference. Furthermore, the learning of task B instantiated a second night of sleep consolidation for task A. These results demonstrate a robust system for memory consolidation and reconsolidation in European starlings. We are now incorporating EEG recordings and auditory forebrain multisite recordings into the behavioral paradigm to determine the sleep states and sleep-dependent changes in neural activity associated with sleep consolidation.

Title: Retrieval and reconsolidation of object recognition memory are independent processes in the perirhinal cortex

Authors: *I. BALDERAS, M. SANTOYO-ZEDILLO, C. RODRIGUEZ-ORTIZ, F. BERMUDEZ-RATTONI;
IFC-UNAM, Mexico city, Mexico

Abstract: Reconsolidation refers to the destabilization/re-stabilization process upon memory reactivation. However, the parameters needed to induce reconsolidation remain unclear. Memory retrieval is held as requisite to initiate reconsolidation. Here we evaluated the dissociation between memory reactivation and its behavioral expression by transient pharmacological disruption of memory retrieval of object recognition memory in rats. To assess whether retrieval is indispensable to trigger reconsolidation, we injected CNQX in the perirhinal cortex to block retrieval of object recognition, and APV to impede reconsolidation. We observed that APV impaired reconsolidation in the absence of retrieval. Therefore, stored memory underwent reconsolidation even though it was not recalled. These results indicate molecular dissociation between retrieval and reconsolidation and that retrieval is a dispensable condition to undergo reconsolidation in the declarative memory model of object recognition memory.

Title: Effects of dopamine D1 receptor antagonism on the reconsolidation of contextual fear memory

Authors: *C. STEVENSON[1], J. L. C. LEE[2], J. P. VOIGT[1], F. C. HEATH[1];
[1]Univ. Nottingham, Loughborough, United Kingdom; [2]Univ. of Birmingham, Birmingham, United Kingdom

Abstract: Once encoded, memories can be updated through reconsolidation to maintain their relevance. This process entails retrieval-induced destablization of the memory followed by its restabilization. Memory updating is thought to involve prediction error signalling which, in turn, is associated with dopamine cell activity. However, the role of dopamine transmission in memory reconsolidation remains unclear. Here we investigated the effects of the D1 receptor antagonist SCH 23390 on the reconsolidation of contextual fear memory in rats. In Experiment 1, animals were subjected to contextual fear conditioning (4 shocks). The next day SCH 23390 was given systemically 30 min before or immediately after brief (2 min) memory reactivation. Post-reactivation long-term memory was tested one day (PR-LTM1) and again one week (PR-LTM2) later. Freezing behaviour during memory testing served as a measure of contextual fear. We found no effects of SCH 23390 given before or after memory reactivation on freezing during reactivation, PR-LTM1 or PR-LTM2 testing. These results suggest that D1 receptor signalling is not involved in the retrieval or post-reactivation restabilization of contextual fear memory. It is also possible that the lack of effect of SCH 23990 was related to potential boundary conditions associated with our behavioural parameters; using weaker conditioning or longer reactivation may have allowed SCH 23390 to affect reconsolidation. Thus, in Experiment 2, we examined the effects of the NMDA receptor antagonist MK-801 on the retrieval and post-reactivation restabilization of contextual fear memory with the same behavioural parameters used in Experiment 1. Rats were conditioned and the next day MK-801 was given systemically 30 min before memory reactivation. We found that MK-801 decreased freezing during reactivation, PR-LTM1 and PR-LTM2 testing. These results confirm previous findings showing that NMDA receptor antagonism disrupts the post-reactivation restabilization of contextual fear memory. They also suggest that the lack of effect of SCH 23390 shown in Experiment 1 was unlikely due to any boundary conditions related to the behavioural parameters used. Ongoing experiments are examining if SCH 23390 given before reactivation prevents the disruptive effects of MK-801 on post-reactivation restabilization; this would suggest that D1 receptor signalling plays a role in memory destabilization, in keeping with emerging evidence linking this reconsolidation process with prediction error signalling, dopamine transmission and memory updating.

Title: Transcriptional repression of the S1P Receptor Gpr12 regulates memory

Authors: *D. G. WHEELER, D. ELOW, R. JOHNSON, C. O'CARROLL, J. LAPIRA, W. JIANG, R. BARIDO, R. PETROSKI, E. MASSARI, R. SCOTT, T. TULLY, M. PETERS; Dart NeuroScience, San Diego, CA

Abstract: Activation of *de novo* transcription of plasticity genes by behavioral experience is required for long-term memory. However, it is unknown if the opposing process, activity-dependent transcriptional repression, plays a role in memory consolidation. Here, we show that mRNA expression of the g-protein coupled receptor Gpr12 is suppressed by synaptic activity in cultured hippocampal neurons. We also show enhanced long-term memory in heterozygous Gpr12 knockout mice, supporting a modulatory role for Gpr12 down-regulation *in vivo*. Consistent with these observations, RNA interference-mediated knockdown of Gpr12 in the hippocampus is sufficient to enhance memory. Our results link activity-dependent transcriptional repression of Gpr12 to memory formation. We suggest that targeting Gpr12 by small molecule antagonists may be a treatment for memory associated disorders in humans.

Title: Social memory persistence in socially isolated adult mice is supported by hippocampal neurogenesis

Authors: *G. S. PEREIRA[1], B. M. M. MONTEIRO[1], F. A. MOREIRA[2], A. R. MASSENSINI[1], M. F. D. MORAES[1];
[1]Physiol. and Biophysics, [2]Pharmacol., UFMG, Belo Horizonte, Brazil

Abstract: Social memory comprehends the information necessary to identify and recognize co-specifics and it is essential for many forms of social interactions. The social memory persistence is strongly modulated by animal's experiences. We previously showed that social isolation (SI) during adulthood impairs the social memory persistence and the enriched environment (EE) prevents this deficit. However, the mechanisms involved in the effects of SI and EE on social memory persistence are still unknown. We hypothesized that the mechanism by which SI and EE are affecting social memory persistence is through modulation of neurogenesis. To address this issue, adult mice were submitted to seven days of one of the following conditions: group-housed in standard (GH) or enriched environment (GH+EE); social isolation in standard (SI) or enriched environment (SI+EE). We found an increase in the number of newborn neurons in the dentate gyrus of the hippocampus (DG) and glomerular layer of the olfactory bulb (OB), in both GH+EE and SI+EE mice. However, the increasing of newborn neurons in the granule cell layer of the OB was restricted to GH+EE group. Furthermore, both SI and SI+EE groups showed less neurogenesis in the mitral layer of the OB. Interestingly, SI mice had a worse performance in the buried food-finding task compared to GH mice, which was improved by EE. However, the latencies reached by both SI and SI+EE to find a hidden piece of chocolate were higher than the observed in the GH groups. To further analyze if increasing neurogenesis is the mechanism by which the EE is recovering the social memory persistence in SI mice, we administered the mitotic inhibitor AraC or saline, directly into the lateral ventricle of SI+EE mice. We found that AraC treatment decreased cell proliferation in both DG and OB and impaired social memory persistence in SI+EE mice, strongly suggesting that neurogenesis is supporting social memory persistence in socially isolated mice.

Title: Megamap: Continuous attractor model for place cells representing large environments

Authors: *K. R. HEDRICK, K. ZHANG;
Biomed. Engin., Johns Hopkins Univ., Baltimore, MD

Abstract: Several continuous attractor models have been proposed for the CA3 subregion of the hippocampus due to the prevalence of recurrent collaterals among its place cells. In their standard form, the models assume that each place cell has a single place field in a given environment. However, recent experiments conducted in large environments indicate that multiple fields is a fundamental characteristic of place cells, where the number of fields increases with the size of the environment. This characteristic may be crucial, as models with one field per cell are limited by the size of the environment, and there is no natural way to extend the attractor when the rat moves beyond the artificial boundaries of the cognitive map. Furthermore, continuous attractor models appear to be inconsistent with the partial remapping observed among place cells.

We propose that place cells form a *megamap*, or a continuous attractor in which each cell has multiple, irregularly spaced place fields within a large environment. When the simulated rat is stationary at any location, relatively weak external input drives the system to an attractor state in which a localized activity bump is centered at the rat's location. As the rat moves, this weak input moves the bump along the rat's trajectory. Unlike previous models, the attractor has no artificial boundaries and can be extended naturally to include contiguous regions using a supervised learning rule. Consistent with standard attractor models, a single activity bump emerges given competing input patterns. However, as the strength of cross-excitation increases due to interactions among multiple place field pairs, the behavior shifts to a normalization mode in which two input patterns of similar strength give rise to two stable activity bumps. The former mode enables the network to perform pattern separation, while the latter mode gives the network the propensity for partial remapping. Developing a continuous attractor model for place cells that applies to large enclosures and is consistent with partial remapping is an important step forward as attractor networks create a stable spatial framework on which non-spatial information can be encoded.

Title: Differential effects of diazepam, zolpidem and THIP on non-REM sleep neurophysiology in the rat

Authors: *F. KERSANTÉ, M. W. JONES;
Univ. of Bristol, Bristol, United Kingdom

Abstract: Coordination of cortical slow-wave activity (SWA), thalamocortical spindles and hippocampal sharp wave-ripples (SWR) is believed to enable consolidation of memories across hippocampus and neocortex during mammalian non-REM sleep. These oscillations are driven by interactions between principal glutamatergic neurons and local GABAergic interneurons. Activation of $GABA_A$ receptors by allosteric modulators can induce sleep, but the differential actions of drugs with varied $GABA_A$ receptor pharmacologies on sleep neurophysiology and function remain relatively unexplored.
We compared the effects of diazepam (non-selective benzodiazepine), zolpidem (non-benzodiazepine enhancer, selective for α1 subunit containing $GABA_A$ receptors) and THIP (an agonist of extrasynaptic δ containing - $GABA_A$ receptors) on SWA, spindles, SWR and the temporal inter-relationships between them. Adult male Lister hooded rats were implanted with either two 32-channel silicon probes spanning medial prefrontal cortex (mPFC) and dorsal hippocampus or 16-tetrode drives targeting mPFC and dorsal CA1. LFP/multiple single units were recorded for 90 min following intra-peritoneal injection of either diazepam (4 mg/kg), zolpidem (3 mg/kg), THIP (4 mg/kg) or their vehicles.
In mPFC, slow wave density and amplitude were reduced by diazepam but increased by zolpidem. THIP decreased slow wave density but had no effect on amplitude. Diazepam induced a slight increase in the amplitude of spindles but neither THIP nor zolpidem changed spindle occurrence or amplitude. Whilst neither zolpidem nor THIP impacted the temporal relationship between spindles and delta oscillations, diazepam delayed the increase in spindle power subsequent to slow wave DOWN to UP-state transition, suggesting a change in synchronisation between spindles and SWA.
In CA1, diazepam decreased the density and amplitude (by 25%) of ripples whilst zolpidem increased ripple density and amplitude (by 30 %). THIP had no effects on ripples. The effects of

the drugs on ripple-spindle correlations and single unit activity in the PrL and CA1 are currently under investigation.
These data highlight differential roles of $GABA_A$ subunits in sleep neurophysiology and suggest differential consequences of hypnotics for sleep-dependent memory consolidation.

Title: Recognition errors suggest quick familiarity and slow recollection in rhesus monkeys

Authors: *B. M. BASILE, R. R. HAMPTON;
Emory Univ., Atlanta, GA

Abstract: One influential model of recognition posits two underlying memory processes: recollection, which is detailed but relatively slow, and familiarity, which is quick but lacks detail. Whether the hippocampus is necessary for both recollection and familiarity, or only for recollection, has been a topic of debate in the past decade, and animal models are needed to provide a definitive answer. Most of the evidence supporting this dual-process model in nonhumans has come from analyses of receiver operating characteristic (ROC) curves in rats, but whether ROC analyses can demonstrate dual processes has been repeatedly challenged. Here, we present independent converging evidence for the dual-process model from analyses of recognition errors made by rhesus monkeys (Macaca mulatta). Recognition choices were made in three different ways depending on processing duration. Short-latency errors were disproportionately false alarms to familiar lures, suggesting control by familiarity. Medium-latency responses were less likely to be false alarms and were more accurate, suggesting onset of

a recollective process that could correctly reject familiar lures. Long-latency responses were guesses. A response deadline sped responding and selectively increased false alarms, suggesting that limiting processing time weakened the contribution of recollection and strengthened the contribution of familiarity. Together, these findings suggest fast familiarity and slow recollection in monkeys, that monkeys use a "recollect to reject" strategy to countermand false familiarity, and that primate recognition performance is well-characterized by a dual-process model consisting of recollection and familiarity.

Title: Temporary inactivations of the hippocampus and prefrontal cortex impair memory for sequences of events

Authors: *C. R. QUIRK[1,2], T. A. ALLEN[1,2], N. J. FORTIN[1,2];
[1]Ctr. for the Neurobio. of Learning and Memory, [2]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA

Abstract: Memory for sequences of events is critical to episodic memory. However, the neurobiology of this form of sequence memory is poorly understood. Previous research has shown that lesions to the hippocampus or prefrontal cortex impair sequence memory. Additionally, we have reported that neurons in the hippocampus and prefrontal cortex code for sequences of events, representations that may underlie sequence memory. However, it is difficult to directly compare these lesion and neurophysiology studies as they involved markedly different behavioral paradigms. To address this, we used localized inactivations to examine the contributions of the hippocampus and prefrontal cortex in the same sequence task used in our previous neurophysiological experiments. On each trial, rats were presented with a sequence of four odors through an odor port. On most trials, odors were presented in the correct sequence (A-B-C-D). On probe trials, one odor was presented in an incorrect sequence position (e.g., A-B-D-D). Rats were required to hold in the odor port for 1sec if an odor was presented "in sequence," or withdraw prior to 1sec if an odor was presented "out of sequence." A water reward was given for correct responses. Sequence memory was demonstrated when rats correctly discriminated

between “in sequence” and “out of sequence” odors. After reaching criterion, rats were implanted with six cannula targeted at the hippocampus and prefrontal cortex. Infusions of fluorophore-conjugated muscimol, a $GABA_A$-agonist, were used to temporarily inactivate target regions. Inactivations of each brain region examined the individual contributions of the hippocampus and prefrontal cortex to sequence memory, while disconnection inactivations (i.e., ipsilateral or contralateral hippocampus and prefrontal cortex) examined potential functional interactions between the regions. Saline infusions were used as within-subjects controls on alternate days. Results show that inactivations of the hippocampus alone or prefrontal cortex alone impaired performance, indicating that both structures are critical to sequence memory. Further, disconnection inactivations also impaired performance suggesting that the hippocampus and the prefrontal cortex interact to support sequence memory. These results are consistent with the neural data previously recorded in the same task, which suggested that the hippocampus and prefrontal cortex provide complementary representations to support performance. Overall, these experiments strongly support the hypothesis that the hippocampus and prefrontal cortex are part of a system from which the memory for sequences of events emerges.

Title: Pathological high frequency oscillations in a chronic model of temporal lobe epilepsy occur during movement-related theta oscillations

Authors: *L. A. EWELL[1], K. B. FISCHER[1], L. LIANG[1], S. LEUTGEB[1,2], J. K. LEUTGEB[1]; [1]Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UC-San Diego, La Jolla, CA; [2]Kavli Inst. for Brain and Mind, Univ. of California, San Diego, CA

Abstract: In temporal lobe epilepsy, the hippocampal network generates several pathological activity patterns including ictal spikes, interictal spikes, and pathological high frequency oscillations (pHFOs). Of these, pHFOs have gained recent interest because they serve as biomarkers for seizure focus, and thus research has focused on the relation between pHFOs and seizure. However, very little is known about how they might impact hippocampal function between seizures. Furthermore, it is unclear whether pHFOs are intensified versions of normal HFOs (ripples) or if they are mechanistically distinct. We were interested in whether pHFOs would occur during periods defined by movement-related theta, which would distinguish them from normal ripples. Furthermore, if pHFOs occurred during movement, it is likely that they would recruit spiking at inappropriate locations and negatively impact spatial coding. To study these questions, male Wistar rats with chronic epilepsy (those that experienced > 2 spontaneous seizures, low dose kainite model) were implanted with an electrode assembly that consisted of 14 independently movable tetrodes. Animals were trained to forage in an open field while hippocampal local field potentials and CA1 single units were recorded. Of the 5 epileptic rats, 4 exhibited pHFOs (> 200 Hz) in the CA1 region. Collectively, 13 ten-minute foraging sessions with ongoing pHFOs (n = 1117 pHFO events) were recorded. First we confirmed that animals were moving when pHFOs were detected. The median running speed at the onset of pHFOs was 4.1 cm/s, and pHFOs occurred over a wide range of running speeds including periods when animals were running quickly. Next we measured power in the theta band (6 -12Hz) around pHFOs during high running speeds (>4 cm/s), testing whether pHFOs were preceded by the cessation of local circuit dynamics that generate the theta rhythm. Average theta power 500 ms before the onset of pHFOs did not change from baseline segments (mean ± SEM =-37±71, n = 13 sessions, paired t-test, n.s.), suggesting that pHFO generation is not preceded by disruptions in theta. Finally, we asked whether CA1 pyramidal cells were recruited when pHFOs occur during foraging. Of the 65 pyramidal cells recorded in 3 rats during foraging, 47 were active during pHFO epochs. For these cells, the probability of firing at least one spike during a pHFO event was 6 ± 1 % higher than before the pHFO, and 8 ± 2 % higher than after the pHFO ($p < 0.01$, $p < 0.001$, one-way ANOVA). Such aberrant spiking would likely lead to degradation of place coding by those neurons, and may partially account for memory impairment associated with temporal lobe epilepsy.

Title: Optogenetic control of the hippocampal theta rhythm

Authors: *M. P. BRANDON[1], M. L. DONEGAN[1], J. K. LEUTGEB[1], S. LEUTGEB[1,2];
[1]Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., UC San Diego, La Jolla, CA; [2]Kavli Inst. for Brain and Mind, UCSD, La Jolla, CA

Abstract: Physiological studies suggest that theta oscillations temporally coordinate cell assemblies by virtue of segregation into different theta phases and theta cycles. Computational models have described how these processes may support spatial and episodic memory function. More recently, debate has centered on whether theta oscillations play a supporting role in generating the spatial code in entorhinal grid cells and hippocampal place cells. Thus far, most experimental evidence driving this debate is correlational. Moreover, current manipulations of theta oscillations rely mostly on pharmacological innervations that have poor temporal resolution. Here, we use an optogenetic strategy to target and control the medial septal area, which is thought to be the neural circuitry that functions as the 'pacemaker' of the theta rhythm, to gain precise temporal control of theta oscillations during behavior.
We used a cre-dependent viral vector (AAV1.EF1a.DIO.hChR2(H134R)-eYFP.WPRE.hGH) in transgenic mice (129p2-Pvalbtm1(cre)arbr/j) to obtain expression of channelrhodopsin selectively in parvalbumin positive interneurons in the medial septum. A fiber optic was positioned above the medial septum and an 'optetrode' (fiber optic surrounded by four recording tetrodes) was implanted above the right hippocampus. Once animals recovered from surgery, tetrodes were lowered into the hippocampus, and blue light was delivered through the fiber optic into the medial septum. As animals ran on a linear track, we found that rhythmic square-wave stimulation with blue light (50% duty cycle) directly controlled the frequency of hippocampal theta oscillations up to and exceeding 40 Hz. The endogenous theta rhythm was no longer apparent, and there was a 1 to 1 relationship between the light pulse frequency and local field potential frequency. Upon cessation of light stimulus, theta frequency immediately returned to its baseline frequency (~8 Hz) suggesting that endogenous septohippocampal circuit dynamics recovered instantaneously. In addition, we found that single brief light pulses (10 ms) caused a reliable phase reset to the trough of the theta cycle. This optogenetic strategy in freely behaving mice can be used to elucidate the role of theta oscillations in spatial coding of grid cells and place cells, and to test the role of theta oscillations in episodic and spatial memory tasks with fine temporal precision.

Title: Role of hipppocampal AMPA receptors in the retrieval of long-term spontaneous object recognition memory

Authors: *E. TAKANO, K. YAMADA, Y. ICHITANI;
Univ. of Tsukuba, Ibaraki-Ken, Japan

Abstract: Research on the role of hippocampus (HPC) in object recognition memory has produced conflicting results. Previous studies using hippocampal lesions suggest the possibility that HPC is important for object recognition memory when the delay between the sample and test phases is long enough. Alpha-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptors are one of the main excitatory neurotransmitter receptors. In this study, we examined the role of hippocampal AMPA receptors in the retrieval of long-term (up to 3 wk) spontaneous object recognition memory by using 2,3-dioxo-6-nitro-1,2,3,4-tetrahydrobenzo[f]quinoxaline-7-sulfonamide (NBQX)-disodium, an AMPA receptor antagonist.
Male Wistar-Imamichi rats, 8-9 wk old at the beginning of the experiment were used. On the first day of the sample phase, the rat was allowed to explore a pair of identical objects (A) in an open-field arena (90×90×45 cm) for 5 min repeatedly for five times. On the next day, another pair of objects (B) was used for the sample phase. After the delay (1 or 3 wk), novel object preference was assessed by comparing the amount time spent exploring the familiar versus novel objects in the test phase. Exploration of an object was defined as directing the nose to the object at a distance of <2 cm and/or touching it with the nose. The time spent exploring the novel and familiar objects was recorded for 5 min, and the first 2 min was analyzed. We calculated the discrimination ratio (DR), the time spent exploring the novel object divided by the total time spent exploring the objects. Test phase was conducted for 2 days, one day for object A (A vs. C) and the other day for object B (B vs. D). Rats received bilateral hippocampal injection of either phosphate buffered solution (PB) or NBQX (2.5 mM, 1 μL) 15 min before the test phase . For the microinjection, rats were implanted with guide cannulae in the dorsal HPC 1 wk before the test phase (3-wk delay group) or 1 wk before the sample phase (1-wk delay group). After these long-term tests, the same rats were then given two 24-h delay tests using different object pairs.

One test was for NBQX treatment, and the other was for PB treatment.
Under PB treatment, rats showed significantly higher level of DRs compared with chance level (50%) in both 1-wk (71%) and 3-wk delay (68%) groups. However, under NBQX treatment, DRs in both groups (57%, 52%) were not significantly different from chance level. NBQX also decreased DRs in 24-h delay test (54%) compared with PB treatment (74%).Results suggest that AMPA receptors in the dorsal hippocampus are important for retrieval process of spontaneous object recognition memory regardless of the length of delay from 1 day to 3 weeks.

Title: Non-spatial computations throughout the longitudinal dentate gyrus axis in support of working memory performance

Authors: *V. C. PIATTI[1], E. HWAUN[1], L. A. EWELL[1], M. JOSIC[1], S. AHMADI[1,2], S. LUM[1], R. BRAR[1], S. LEUTGEB[1,3], J. K. LEUTGEB[1];

Abstract: Inputs from the dentate granule cells to downstream CA3 pyramidal neurons are known to be necessary for rats to perform spatial working memory (WM) tasks, which incorporate a high degree of complexity. We have recently determined that WM performance is not selectively supported by distinct regions of the dentate gyrus (DG) along the longitudinal hippocampal axis (Piatti et al., SFN 2012). In these studies granule cells were selectively lesioned with colchicine. Only lesions with a 60 - 80% volume reduction of the granule cell layer along the entire longitudinal axis resulted in impaired spatial WM on an eight-arm radial maze

task. However, lesions with corresponding % volume reduction specific to the rostrodorsal DG (rdDG) or the caudoventral DG (cvDG) did not impair WM, suggesting that network computations of remaining dentate neurons were sufficient for WM regardless of the anatomical location of the remaining circuits. We therefore sought to determine the mechanisms by which any DG region can support WM. We first asked whether lesions restricted to either rdDG or cvDG are compensated for by increasing the number of active neurons in the remaining network during WM. We used the immediate early gene *c-fos* to label active granule neurons in each group (control, rdDG lesions, cvDG lesions). In rats with rdDG or cvDG lesions, stereological methods showed that the fraction of *c-fos* labeled granule neurons in the remaining DG regions did not change during WM (n = 4 animals per group, n.s.). WM is thus supported in animals with rdDG or cvDG lesions without the compensatory activation of cells, but rather with a network in which sparsity is retained. Next, we assessed whether rdDG and cvDG neurons had shared firing patterns such that the same neuronal computations could be supported by any region. Rats were pretrained to perform the eight-arm spatial WM task and were implanted with electrodes. Local field potentials and DG single units (n = 50) were recorded along the longitudinal axis. As expected, a fraction of cells (~30 %) in rdDG had precise place fields on the maze while spatial selectivity in cvDG was only found in a small proportion of cells (~10 %; 0 of 19 cells for analysis restricted to the granule cell layer). However, most DG cells (87 % in rdDG, including those with fields, and 85 % in cvDG) showed spikes at the reward location, where distinct changes in the local field potential were observed (see Ahmadi et al., SFN 2013). Reward-related rather than spatial computations are thus found along the entire longitudinal DG axis. The primary function of DG is thus not limited to spatial pattern separation but to also update the network with information that is encoded at reward locations.

Title: 4-Hz and beta oscillations coordinate dentate network activity in a dentate-dependent working memory task

Authors: *S. AHMADI[1,3], V. C. PIATTI[1], L. A. EWELL[1], S. LEUTGEB[1,2], J. K. LEUTGEB[1]; [1]Neurobiol. Section and Ctr. for Neural Circuits and Behavior, Div. of Biol. Sci., [2]Kavli Inst. for Brain and Mind, UCSD, La Jolla, CA; [3]Cognitive Sci. Ctr. Amsterdam, Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The hippocampus is critical for memory formation, including spatial working memory. Dentate circuits along the entire dorsoventral axis were found to be sufficient for supporting spatial working memory (Piatti et al., SFN 2013). The dentate gyrus is also known to be particularly important for memory encoding. We therefore asked how local field potentials and neuronal firing patterns change at reward sites, where information is updated during working memory. We used an 8-arm radial maze task to record local field potentials (LFPs) throughout the hippocampus and single units in the dentate gyrus (n = 6 rats). The first four arms were presented in random order by the experimenter, after which the animal was presented with all eight arms and could optimally solve the task by visiting the remaining four arms. We analyzed LFPs in three different bands, 4-Hz (2-5 Hz), theta (6-12 Hz) and beta (18-35 Hz). As expected, LFP power in the theta band decreased at the transition from running to stopping. Most dentate granule cells were strongly phase-locked to LFP theta oscillations. While theta decreased when rats stopped at reward sites, we detected an increase in power in the 4-Hz band (61.1% in dorsal DG, 20.7% in intermediate DG) and in the beta band (28.3% and 46.2%, respectively) at the same transition. The average increase did not differ between trials with and without errors. The peak increase in the beta band occurred earlier than the peak increase in the 4-Hz band. The increase in beta power was limited to recording sites in the dentate gyrus, while the increase in the 4-Hz band was found for all hippocampal recording sites and could thus coordinate firing patterns between subregions. We then asked whether the higher LFP power was indicative of increased coordination of neuronal firing patterns at reward sites. Most putative dentate granule cells showed significant phase coupling to 4-Hz and to beta, and the coupling was much higher at reward locations compared to elsewhere on the maze. Furthermore, phase locking was stronger in intermediate/ventral compared to dorsal DG. In addition to analyzing LFP power in working memory trials, we performed the same analyses on foraging trials with no memory demand. Without memory demand, fluctuations of LFP power were at chance levels (n.s.; shuffle test). The increases in LFP power in the 4-Hz and beta band and the phase locking of DG cells to these oscillations suggest that dentate circuits contribute to memory encoding at reward sites. The effects were observed throughout the dorsoventral axis and could thus reflect neural network dynamics for processing mnemonic rather than spatial information during working memory performance.

Title: Role of astrocytes connexin in the regulation of sleep oscillatory pattern

Authors: *M. M. LACROIX[1], L. ROUX[2], C. GIAUME[3], K. BENCHENANE[1];
[1]CNRS UMR7637, Paris, France; [2]Neurosci. Inst., New-York Univ., New-York, NY; [3]Inst. of Biol., Collège de France, Paris, France

Abstract: Coordination across brain structures is thought to be crucial for the appropriate consolidation of memory trace. Cortical slow oscillations modulate the timing of hippocampal sharp wave-ripples (SPW-Rs) occurrence which support neuronal reactivations. Hippocampal SPWR-s are then followed sequentially by cortical reactivation, cortical delta waves and finally cortical spindles.
Our project aims at challenging the classic view of the "neurocentric" concept in brain rhythms regulation during sleep. Indeed, recent evidences showed that astrocytes can regulate cortical slow oscillations during sleep and are involved in brain processes related to memory deficits induced by sleep deprivation, both mechanisms being mediated by the activation of A1 adenosine receptors.
One of the key feature of astrocytes is their expression of connexins that form either hemichannels (leading to the release of neuroactive molecules) or gap junction (making astrocytes organized into networks of communicating cells).
We therefore investigated the role of connexins in the fine regulation and coordination between hippocampal, cortical and thalamic oscillations during natural sleep, by multi-site recordings in wild-type mice or transgenic mice double knock-out for astrocytic connexins Cx43 and Cx30 (dKO).
Our results show that there is a massive decrease of slow oscillations during sleep in dKO mice in the olfactory bulb, confirming the results obtained in vitro by Lisa Roux, but also a change in the coordination between other brain structures oscillations.

Our results support the involvment of astrocytes in regulation of neuronal network functioning and brain oscillatory activity.

Title: Hemispheric asymmetry of hippocampal memory processes in mice

Authors: *O. SHIPTON[1,3], J. APERGIS-SCHOUTE[3], D. BANNERMAN[2], K. DEISSEROTH[4], O. PAULSEN[3], M. KOHL[3];
[1]Dept. of Physiology, Anat. and Genet., [2]Dept. of Exptl. Psychology, Univ. of Oxford, Oxford, United Kingdom; [3]Univ. of Cambridge, Cambridge, United Kingdom; [4]Stanford Univ., Stanford, CA

Abstract: To investigate the behavioural consequences of the recently-uncovered hemispheric asymmetry in long-term potentiation (Kohl et al. Nat. Neurosci. 2011), we used acute optogenetic silencing of CA3 pyramidal cells in the left or right mouse hippocampus during two hippocampus-dependent memory tasks. Mice received injections of a viral construct encoding halorhodopsin (eNpHR3.0: a light-sensitive chloride pump) under the control of the CaMKIIα promoter into the left or right CA3; this gave expression of eNpHR3.0 in excitatory CA3 neurons of one hemisphere and their projections to CA1 neurons both ipsilaterally and contralaterally. Control mice received injections of a viral construct that did not encode NpHR3.0. All mice had an optical fibre implanted on the injected hemisphere to illuminate the dorsal CA3 during behavioural testing. We found that unilateral silencing of only the left CA3 impairs the acquisition of a hippocampus-dependent spatial long-term memory task that requires multiple trials to learn: main effect of transgene $F(1,76) = 6.01$; $p = 0.017$; significant transgene by side interaction $F(1,76) = 11.46$; $p = 0.001$ due to significant effect of transgene on left side $F(1,76) = 16.62$; $p < 0.001$). As controls we used a hippocampus-dependent short-term memory task and

a hippocampus-independent visual discrimination task. Overall, our results showed a within-subject dissociation of hippocampal memory processes between hemispheres, with the left CA3 being required for a spatial long-term memory task. This suggests that mice may have differences between left and right CA3 in the information received, how it is processed and stored, or a combination of both.

Title: A cross-species approach to investigating memory for sequences of events

Authors: *A. M. MORRIS[1,2], T. A. ALLEN[1,2], A. T. MATTFELD[3], C. E. L. STARK[1,2], N. J. FORTIN[1,2];
[1]Ctr. for the Neurobio. of Learning and Memory, [2]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA; [3]McGovern Inst. for Brain Res., MIT, Cambridge, MA

Abstract: The ability to learn and remember sequences of events is a key feature of episodic memory shared by a variety of species including humans, non-human primates, and rodents. However, the neurobiological substrates of this form of sequence memory are not well understood. While rodent studies indicate the hippocampus and the prefrontal cortex are critical for this capacity, it has proven difficult to translate findings from animals to humans due to large differences in task demands across studies. Although progress has been made using complementary approaches, there is currently no single task that allows for direct comparisons across species. To address this important issue, we used an integrated cross-species approach to develop a sequence task designed to test the ability of humans and rats to learn and remember the order of serially experienced items. The task involved the presentation of sequences of items (fractal images for humans, pure chemical odorants for rodents) and required subjects to make a judgment as to whether items were presented “in sequence” or “out of sequence”. Probe trials were used to assess the cognitive strategies used by humans and rats supporting successful

sequence memory. Results show that rats and humans (1) were able to learn and remember arbitrary sequences at similar levels of accuracy, (2) displayed similar response times when making “in sequence” or “out of sequence” decisions, and (3) used similar cognitive strategies supporting sequence memory judgments. These findings strongly validate the human and rat sequence tasks as homologous, i.e. involving the same cognitive processes. This novel cross-species sequence memory task should prove useful in future investigations examining the neurobiology of the memory for sequences of events. In addition, preliminary data shows that the sequence task is sensitive to aging, and may therefore serve as a potential diagnostic tool for detecting cognitive dysfunction in older adults with age-related neurodegenerative diseases. This approach will also allow the use of rodent models of age-related neurodegenerative diseases to explore the cellular basis of the deficits seen in human patient populations.

Title: Maternal exercise during pregnancy improves object recognition memory in adult male offspring

Authors: *A. M. ROBINSON, D. J. BUCCI;
Psychological and Brain Sci., Dartmouth Col., Hanover, NH

Abstract: Maternal exercise during pregnancy has been shown to be beneficial for the offspring. However, most studies have looked at the effect of maternal exercise on anxiety and spatial cognition in juvenile or adolescent pups. The present study was designed to test the effect of maternal exercise during pregnancy on recognition memory that relies on the perirhinal cortex (PER) in adult offspring. Male and female Long Evans rats were allowed to mate during a 72-hour period. Pregnant female rats were then assigned to exercise or non-exercise conditions. Rats in the exercise condition had 24 hr access to a running wheel inside their homecages during gestation and rats in the non-exercise condition were housed in cages without wheels. Once pups were born, the wheels were removed and pups stayed with their mothers until being weaned on PND 21. When they were 60 days old, object recognition memory was assessed in 10 male

offspring from exercising mothers and 11 male offspring from non-exercising mothers. After being habituated to the testing environment, rats were placed in a plastic tub for 5 min and allowed to explore two identical sample objects. Twenty-four hours later (test session), rats were returned to the tub, which contained one of the sample objects as well as a new, unfamiliar object and given 2 min to investigate the items. A discrimination ratio served as the dependent variable of interest and was calculated as the time spent exploring the novel object divided by total time spent exploring both objects. There were no group differences in time spent exploring the objects during the sample session ($p>0.15$). During the test session, however, the offspring of exercising mothers were able to successfully discriminate between novel and familiar objects ($p<0.03$) in that they spent more time exploring the novel object than the familiar object. The offspring of non-exercising mothers were not able to successfully discriminate between objects ($p>0.6$) and spent an equal amount of time with both objects. This result was obtained again when rats were tested two weeks later with a different set of objects. A subset of rats underwent a third object recognition test and were euthanized 1 hr later to assess c-FOS expression in the PER. There was a significant group difference in that the offspring of exercising mothers had more c-FOS expression in the PER than the offspring of non-exercising mothers ($p<0.006$). These results indicate that maternal exercise during pregnancy can improve object recognition memory that relies on the PER in male offspring and these effects last into adulthood.

Title: Inception of a false memory in the hippocampus

Authors: *S. RAMIREZ[1], X. LIU[2], P.-A. LIN[2], J. SUH[2], M. PIGNATELLI[2], R. L. REDONDO[2], T. J. RYAN[2], S. TONEGAWA[2];

Abstract: Memories are usually excellent guides for cognition and behavior. However, they can also be unreliable, and false memories in particular have had severe legal consequences. Despite these social ramifications, the lack of relevant animal models has largely hindered our understanding of the neural basis of false memories. Here, we describe the inception of a false memory in mice by optogenetically manipulating memory engram-bearing cells in the hippocampus. Mice were allowed to explore a particular environment and dentate gyrus (DG) or CA1 neurons activated by the exposure to this context were labeled with channelrhodopsin-2 (ChR2). These neurons were later optically reactivated during fear conditioning in a different context. The DG experimental group showed increased freezing in the original context in which a foot shock was never delivered compared to: the control groups not expressing ChR2, a group in which light was omitted, and a group that underwent a similar manipulation in CA1. The recall of this false memory was context-specific, activated similar downstream regions engaged during natural fear memory recall, and was also capable of driving an active fear response in a conditioned place avoidance paradigm. The formation of a false memory interfered with the concurrent formation of a natural memory and could have either an additive or competitive effect during the recall of the natural fear memory. Together, our data demonstrate that it is possible to substitute a natural conditioned stimulus (CS) with artificially reactivated DG cells that bear contextual memory engrams to incept an internally represented false fear memory.

Title: Burst phase offsets among hippocampal theta cells do not vary with position or movement trajectory: Implications for spatial coding by oscillatory interference

Authors: *R. M. DE GUZMAN, L. R. HALLADAY, H. T. BLAIR;
UCLA, Los Angeles, CA

Abstract: Oscillatory interference models hypothesize that spatially tuned neurons derive their positional firing properties by detecting location-specific synchrony among inputs from velocity-controlled theta oscillators (VCTOs).

Here, we recorded pairs of hippocampal theta cells to investigate whether they behaved like VCTOs. Theta cells were recorded from CA1, CA3, and dentate gyrus of the dorsal hippocampus as rats (n=4) foraged freely for food pellets in a cylindrical chamber measuring 80 cm in diameter. Each recording session was 120-180 min long. Theta cells were identified on the basis of high tonic firing rates (>10 Hz), low spatial information (<0.1 bits/spike), and a significant peak in the 6-9 Hz band of the spike train autocorrelogram's power spectrum. A total of 42 well-isolated theta cells were recorded simultaneously with at least one other theta cell, and 58 unique pairs of theta cells were stably held for >2.0 h. Directional burst frequency tuning curves (DBFTs) were plotted to estimate the vector along which each theta cell's burst frequency was modulated by movement direction. Most pairs of simultaneously recorded cells had similar DBFTs, and showed a similar correlation between burst frequency and running speed, implying that their preferred movement vectors were the same. Burst phase offsets between cell pairs were estimated from crosscorrelograms between their spike trains, by measuring deviation of the center peak from zero phase lag. Multiple crosscorrelograms were generated for each cell pair from spikes generated at different locations and movement trajectories. It was found that all 58 pairs of theta cells exhibited a rigidly stable burst phase offset from one another (which differed for each pair of cells), which did not change with the rat's position or movement trajectory. These findings suggest that if hippocampal theta cells do function as VCTOs, then they are a homogeneous population sharing the same preferred movement vector (thus encoding different phases of the same VCTO signal). Such theta cells could generate a globally synchronized inhibitory 'reference oscillation' in the hippocampus; individual place cells may be driven to fire when they receive excitatory inputs from VCTOs that are synchronized in antiphase with the global inhibitory reference.

Title: Hippocampal subregional firing correlates for parametric alterations in distal cue-configuration in a goal-directed task

Authors: *I. LEE, PhD, S.-B. PARK;
Brain and Cognitive Sci., Seoul Natl. Univ., Seoul, Korea, Republic of

Abstract: Several studies have reported that, depending on the amount of changes induced to the distal cues in the environment, a place cell changes firing patterns in various ways (e.g., spatial remapping, rate modulation, etc.) presumably to reflect the environmental changes. It is still unknown, however, whether such physiological changes in the hippocampus directly relates to the animal's behavior when the rat is required to use those cues to make spatial choices in a goal-directed task. In order to test whether there are functional relationships between the amount of change in distal cues and the firing patterns of place cells related to spatial choice behavior, we recorded single units simultaneously from the hippocampus while rats (n=5) ran along a linear track at the end of which a choice should be made between two food wells. A correct choice-response was contingent upon the angular distance between two sets of visual cues with each set attached to a curtain (cue-curtain) that was movable along a circular curtain track in the ceiling. Three distinct visual cues were attached to each cue-curtain and the medial edges of the curtains were separated by one of the following angular distances: 0º, 14º, 66º, and 80º. Rats were initially trained in a standard task in which "standard cue-configurations" (i.e., 0º and 80º) were associated with the left and right food wells. Our previous study has demonstrated that the dorsal hippocampus is indispensable to normal performance in this task. Once trained to criterion, a hyperdrive was implanted and tetrodes were lowered to target regions while the rat was still being trained. Once tetrodes were all in the target regions, recording commenced in the standard task for several days. Afterwards, an ambiguous task began in which two "ambiguous cue-configurations" (i.e., 14º and 66º) were introduced in a session (randomly mixed with the standard cue-configurations and sharing reward contingencies of closer standard cue-configurations), and the single-unit recordings were made. Among well-isolated putative principal cells (n=1636), ~20% of cells exhibited place-specific firing patterns during outbound journeys in the behavioral sessions. Preliminary findings suggest that the centroid of a place field shifted backwards as the cue-curtains were separated from each other between trials. It appears that the significant separations of the field centroid associated with the 0º-configuration from the centroids associated with the other configurations (14º, 66º, and 80º) could explain performance differences between 0º cue-condition (~96%) and the others (79%, 87%, and 89%).

Title: Towards a fully flexible system for studying hybrid networks with controlled topology

Authors: *L. DEMKO, V. HOOP, A. POPERT, H. DERMUTZ, J. VOROS;
Lab. of Biosensors and Bioelectronics, ETH Zurich, Zurich, Switzerland

Abstract: The use of cultured neuronal networks as a model for their in vivo counterparts allows researchers to study the central nervous system, especially the brain, in a controlled environment. Specific neuronal connectivity patterns in the brain are implicated to play a role in the perception, processing and storage of information, so the building of small neuronal networks with controlled topology is a promising approach to investigate the basic circuits of the nervous system. Realizing such bottom-up systems on multi-electrode arrays (MEA) makes a way to study the dynamics of functional neural networks systematically as a function of the network structure. Here, MEA chips provide an in-situ, bidirectional, non-invasive communication between the individual cells and the microelectrode array, and such localized neurons cultured on the electrodes can act as bio-friendly interfaces for collateral sprouts from an in vivo system. Several surface patterning techniques have been developed in order to control the neuronal connectivity, mostly based on surface chemistry in combination with micro- and nanostructuring. However, most of them have common issues with long-term compliance and clustering, and with these methods the modification of the desired topology involves complex preparatory processes. Our first goal was to develop an inexpensive, flexible, and easy to use setup which is compatible with all the previous patterning solutions, but having extra features such as co-culturing and the ability to probe the system by localized mechanical or chemical stimulus. The main part of the setup is a special hollow cantilever for the FluidFM system. This cantilever enables patterning of selective coatings on cell culture substrates with promoters or inhibitors of cell adhesion and growth, seeding of the cells directly onto the electrodes, and local stimulation - all in a fully controlled, but completely flexible manner. The control over the number and type(s) of seeded cells, local concentrations of specific biochemicals combined with mechanical and electrical stimulation, and the recording of neural activity in networks with predefined topology give platform for the analytical testing of pharmaceuticals and the development of biosensors.
The present work focuses on building of hybrid networks, in which functional neurons interact with artificial model ones, in order to prove, evaluate, and fine tune the models we have for memory and learning. With the results, we aim to provide insights into the role of neural and synaptic properties such as synapse development, plasticity and connectivity, and extract the algorithms that support neurocomputation in brain tissue.

Title: Spatial olfactory learning modifies place field formation in the hippocampus

Authors: S. ZHANG, *D. MANAHAN-VAUGHAN;
Ruhr Univ. Bochum, Med. Faculty,, Bochum, Germany

Abstract: Spatial encoding in the hippocampus is multifactorial, and it is well established that metric information about space is conferred by place cells that fire when an animal finds itself in a specific environmental location. Visuospatial contexts comprise a key element in the formation of place fields. Nevertheless, hippocampus does not only use visual cues to generate spatial representations. In the absence of visual input, both humans and all other vertebrate species studied in this context, to date, are capable of generating very effective spatial representations. However little is known about the relationship between non-visual sensory modalities and the establishment of place fields. Substantial evidence exists that olfactory information can be used to learn spatial contexts. Here, we recorded hippocampal pyramidal neurons in the CA1 region by means of single unit recordings while rats were navigating in a circular arena in darkness where distinct odors were hidden and diffused from multiple locations from below the floor. We observed that learning about a distinct odor constellation in an environment where visual and auditory cues are suppressed, results in global remapping in about one-third of cells by shifting their place fields completely and in about one-third of cells by switching place fields on or off. It also results in more confined and stable place fields. These place fields rotate when the odor constellations are rotated and remap when the odor constellations are shuffled. These data support that the hippocampus can use non-visuospatial resources, and specifically spatial olfactory information, to modify spatial representations.

Title: Mechanisms for transitive inference in monkeys (Macaca mulatta)

Authors: *R. R. HAMPTON, R. P. GAZES;
Emory Univ., ATLANTA, GA

Abstract: Rhesus monkeys live in social groups in which dominance ranks are transitive. If Monkey A is dominant to Monkey B, and Monkey B is dominant to Monkey C, then the fact that Monkey A is dominant to Monkey C can be correctly inferred via transitive inference. The importance of social dominance in these animals may make them especially good models for studying the cognitive processes involved in transitive inference. Monkeys were trained with 6 pairs of overlapping image discriminations (A+B-, B+C-, C+D-, D+E-,E+F-, F+G-.) and correctly selected the higher ranked item in probe tests with non-adjacent novel pairings (e.g. BD, CF). We performed tests to determine the extent to which these choices were controlled by associative values and inferred relations. We measured the associative values of the 7 TI images using concurrent RI-RI schedules and found that these values did not correlate with choice in transitive inference tests. Monkeys linked two previously learned 7-item lists into one 14-item list after training with a single linking pair. Together these findings indicate that implied order explains most transitive inference choices in monkeys. Such relational processing is a more viable mechanism for transitive inference based on observational learning of social dominance relationships, where explicit reinforcement is not present.

Title: Interneurons robustly and consistently increase their firing rates during the minutes preceding behavioral seizures in a chronic model of temporal lobe epilepsy

Authors: *L. LIANG[1], L. A. EWELL[1], C. ARMSTRONG[3], I. SOLTESZ[3], S. LEUTGEB[1,2], J. K. LEUTGEB[1];
[1]Neurobio. Section and Ctr. for Neural Circuits and Behavior, Div. of Biol., [2]Kavli Inst. for Brain and Mind, UC San Diego, La Jolla, CA; [3]Anat. and Neurobio., UC Irvine, Irvine, CA

Abstract: Seizures reflect abnormal synchronized activity of a neuronal network, however, the activity dynamics preceding seizure onset are still poorly understood and algorithms for seizure prediction typically rely on local field potential recordings. Recent research has asked whether single-unit recordings might improve the predictability of seizures. Neuronal activity was found to change inconsistently before behavioral seizure onset such that an increase in variability was observed in the minutes before the onset. GABAergic interneurons integrate excitatory inputs from local and afferent networks. Such convergence of input may allow interneurons to be more sensitive to widespread neural synchrony that leads to seizures compared to principal cells. We asked whether interneurons might be more reliable predictors of seizures than principal cells. To record activity patterns of interneurons and principal cells before behavioral seizures, we used the repeated low-dose kainate model of chronic temporal lobe epilepsy in male Wistar rats. We implanted animals that developed epilepsy ($\geq$ 2 spontaneous seizures) with tetrode arrays and video monitored the rats (n=3) while local field potentials and single unit activity were recorded from CA1 and CA3. We identified a total of 20 behavioral seizures (rat 1: 4 seizures across 4 days, rat 2: 5 seizures across 3 days, rat 3: 11 seizures across 5 days). We assessed the activity patterns of hippocampal pyramidal cells (CA1, n=79 cells; CA3, n=34 cells) and interneurons (CA1, n=13 cells; CA3/DG, n=18 cells) during the 5 minutes preceding the behavioral seizure onset. First, we characterized baseline firing rates during 100 second epochs. We found that only ~10.8% of principal cells exhibited firing rates that deviated by more than 3 standard deviations from the baseline in the minute before the seizure onset, whereas ~50% of interneurons deviated from baseline up to 2 minutes before seizure onset. The average increase in firing rate of all interneurons was +60% during the 2 minutes before the seizure onset compared to baseline. Interneurons are thus a much better predictor of seizures during the minutes before the seizure

onset. Because of the large effect size, even small numbers of recorded interneurons can reliably predict a seizure. Of the cells that were tracked across ≥ 2 seizures (n=14 principal cells and 8 interneurons in two rats), 31 of 32 showed a consistent change in firing rate preceding seizure onset. Together, these data suggest that knowing the change in firing from a previous seizure improves prediction, but that the gains from using interneurons for detection algorithms would be much more robust.

Title: Pre-plaque amyloid pathology causes robust changes in hippocampal function, which does not further deteriorate upon plaque formation

Authors: *A. L. BLACKSHEAR[1], J. DAVIS[1], M. B. MARTINEZ[1], J. K. LEUTGEB[1], S. LEUTGEB[1,2];

Abstract: The robust accumulation of amyloid-beta (Aβ) plaque pathology that occurs late in Alzheimer's disease (AD) progression has long been viewed as the cause of memory loss in the disease. However, recent research has indicated that synaptic toxicity in the AD brain is caused by soluble forms of Aβ and begins well before insoluble Aβ plaques accumulate. Many current Alzheimer's transgenic models accumulate plaque pathology at such an accelerated rate that it is difficult to study physiological changes across the transition from the pre-plaque soluble Aβ stage to the plaque Aβ stage. Indeed, many current models accumulate Aβ so robustly that the pre-plaque stage can only be investigated in juvenile or young adult animals. Here, we used a rat model of Alzheimer's disease (McGill-Thy1-APP) which shows a 15 month long pre-plaque

stage, in order to compare hippocampal firing patterns before and after plaque formation. Our previous research has shown that changes in place field properties preceded plaque formation in this model. Place fields became large, diffuse, and unstable over testing at 6 and 12 months of age. Changes in place fields occurred before measurable changes in mnemonic behavior, as assessed by Morris Water Maze testing at 6 and 12 months of age. Because we have confirmed that plaques did not accumulate for 15 months in these animals, these changes in behavior and place cell function are caused by soluble Aβ species rather than by plaques. When the onset of plaque pathology occurs (at approximately 15-18 months of age) we observed that deposits accumulated throughout the hippocampus, septum, and entorhinal cortex, as well as other cortical areas. We now ask whether the substantial deterioration of hippocampal function during the pre-plaque stage will further progress after Aβ plaques appear. In this set of experiments, chronic recordings of CA1 pyramidal cells and of hippocampal local field potentials were performed in freely behaving 20-24 month old homozygous rats and littermate controls. In these animals, the deterioration in spatial firing was not any more pronounced than in 12 month old animals, despite the advanced progression of Aβ plaque pathology at the later time point. We are currently testing whether local field potentials also show pathological changes during the pre-plaque stage without a further decline at later stages. The pre-plaque dysfunction in spatial firing indicates a major deterioration of hippocampal system function through the effects of soluble Aβ assemblies rather than of insoluble Aβ plaques. The most substantial changes in hippocampal function may therefore occur early in the progression of Aβ pathology and of Alzheimer's disease.

Title: Hippocampal subregions CA2 and CA3 relay complementary information about temporal and spatial context to CA1

Authors: *E. A. MANKIN[1,2], F. T. SPARKS[4], G. W. DIEHL[1], S. LEUTGEB[2,3], J. K. LEUTGEB[2];

Abstract: In many situations the ability to estimate the recency of a remembered event is critically important for guiding behavior, yet the sensory content of the experience alone cannot always provide information about when it occurred. How temporal information might be incorporated into memory has long been a topic of interest in psychology, and one class of computational models has suggested that the comparison or combination of two signals--one stable and one time-varying--may allow the recency of an event to be computed. To address the question of how recency may be represented in episodic memories, we recorded the activity of neurons in hippocampal subregions CA1, CA2, and CA3 while rats randomly foraged in highly familiar square and circular enclosures in the morning and, after an interval of 6 hours, in the afternoon for multiple days. This behavioral paradigm allowed us to compare the neuronal activity patterns for repetitions of the same environment to determine whether they changed over time, as well as to determine to what extent similar contexts were discriminated. We have shown that the representation of identical events remains highly stable in CA3 for at least 30 hours, while representations in CA1 change gradually with time [Mankin et al., PNAS, 2012]. This suggests the possibility that CA1 is playing the hypothesized role of computing elapsed time by comparing a stable memory signal from CA3 with a time-varying signal from another source. We asked whether CA2 might be a source of time-varying information to CA1. We found that the population representation of identical events in CA2 changed markedly with time, with the mean population vector correlation decreasing from 0.59 for sessions less than 1 hour apart to 0.11 for sessions recorded 30 hours apart. The change in activity patterns as a function of time was more pronounced in the CA2 cell population than in either CA1 or CA3 (CA2 vs CA1: $t(14) = 5.7$, $P<0.001$, CA2 vs CA3: $t(14) = 8.4$, $P<0.001$). While representations in CA2 changed rapidly with passing time, we did not observe a difference between distinct shapes any greater than the difference between identical events at any time interval. Our data therefore show that CA2 is the only hippocampal subregion that does not discriminate between similar spatial contexts in the same location but shows only a time-varying spatial firing pattern. Thus it appears that CA2 codes strongly for elapsed time and minimally for spatial context, while CA3 codes strongly for spatial context and minimally for elapsed time. Because CA2 and CA3 inputs converge in CA1, this identifies CA1 as a brain region that can compute elapsed time and integrate the when, what, and where aspects of episodic memory.

Title: A cortico-hippocampal learning rule enhances information flow through the hippocampal circuit by shaping local inhibitory microcircuit activity

Authors: *J. BASU[1], S. A. SIEGELBAUM[2];
[1]Dept. of Neurosci., Columbia Univ., New York, NY; [2]HHMI/Columbia Univ., New York, NY

Abstract: How does coordinated activity between distinct brain regions implement a set of learning rules to sculpt information processing in a given neural circuit? Using interneuron cell-type specific optical activation and pharmacogenetic silencing in vitro, we show that temporally precise pairing of direct entorhinal perforant path (PP) and trisynaptic Schaffer collateral (SC) inputs to CA1 pyramidal cells selectively suppresses SC-associated perisomatic inhibition from cholecystokinin (CCK) expressing interneurons. The CCK interneurons provide a surprisingly strong feedforward inhibitory drive to effectively control the coincident excitation of CA1 pyramidal neurons by convergent inputs. Thus, in-phase cortico-hippocampal activity provides a powerful heterosynaptic learning rule for long-term gating of information flow through the hippocampal excitatory macrocircuit by silencing the CCK inhibitory microcircuit. Studies in progress complement these findings, by exploring how inhibition can shape the integration of timed synaptic inputs to implement temporally precise mnemonic codes.

Title: Long-range projections of medial prefrontal cortex and hippocampus revealed through whole tissue imaging

Authors: *A. J. DIMAURO[1], W. A. LIBERTI, III[2], R. J. ROBINSON, II[1], D. J. SHEEHAN[1], J. M. GAUTHIER[3], H. EICHENBAUM[1];

Abstract: Connections between the rodent medial prefrontal cortex (mPFC) and hippocampus are critical for several learning and memory functions including associative learning tasks (Lee & Solivan, 2008), strategy switching (Rich and Shapiro 2007) and working memory (Churchwell and Kesner 2011), but detailed anatomical information remains elusive, due to the difficulty of using contemporary methods. Previous studies have shown that mPFC receives unidirectional projections from area CA1 of the ventral hippocampus (Hoover & Vertes, 2007) but mPFC projects only indirectly back to the hippocampus. This connection is largely through the nucleus reuniens of the thalamus, an area that also receives input from the hippocampus (Vertes et al 2007). To enhance our understanding of the functional relevancy of mPFC and hippocampal interactions, the precise geometry of these neural projections must be resolved. We show that tissue clearing allows for whole and partial brain imaging at high spatial resolution, while preserving fine cellular structure, even at the spinal level.

Abstract: Hippocampal place cells, neurons that selectively respond to animal position, show impaired function upon a range of manipulations affecting CA1, e.g. disrupting inputs{Brun2008}, abolition of self-motion information {Terrazas2005} and NMDA receptor deletion {McHugh1996, Korotkova2010}. These studies, however, report impaired place field (PF) properties averaged over an entire recording session, but how the instantaneous spatially-related activity is affected is still unknown.
We recorded CA1 place cell activity in control(CTR) and CA1 NMDAR1(NR1)-KO mice shuttling on a circular track and analyzed place field properties on a trial-by-trial basis. Similar to previous studies {McHugh1996}, session-averaged PFs of NR1-KO mice were larger, however when the PF was calculated on a trial-by-trial basis, no difference was observed. Furthermore, we show that NR1-KO PCs ('Place Cells') present a markedly increased inter-trial variability of its firing maps, which explains the larger session-averaged PF size and suggests that the larger PF size is a consequence of a deficit of a PC to consistently spike at the same location across passages. By analyzing the directionality and symmetry, two measures of how much PC firing is driven by distal and local cues/path integration, respectively, we report that NR1-KO are impaired in both, hinting at impairments in hippocampal spatial processing.
Spatial representation in CA1 NR1-KO mice improved, however, with experience on the track, such that it was at the CTR level towards the end of the recordings, possibly due to synaptic plasticity in structures afferent to CA1, (which are unaffected in these mice) and their influence on CA1 activity.
Finally, we show that beta(17-23), low(23-40) and high(55-95) gamma frequency oscillations decrease as mice proceed from the first to the last track traversal, an effect only reminiscently present in NR1-KOs. This effect was present throughout recordings and may parallel a decreased alertness as a session progresses.
These results detail single-trial PC patterns of activity in mice and clarify the causes underlying spatial representation deficits caused by the absence of NMDARs in CA1. We show that, rather than simply having larger PFs, NR1-KO PCs fail to properly integrate different inputs, reflecting allocentric and path integrating processes, which lead to increased jitter across trials.

Title: Parallels between individual variability in hippocampal NR2a expression and Morris Water Maze learning

Authors: J. CHO[1], L. SMITH[3], J. FLINN[2], D. BURDETT[2], *R. F. ACKERMANN[4], S. E. BACHUS[2];
[1]Neurosci., [2]Psychology, George Mason Univ., Fairfax, VA; [3]Psychiatry, McLean Hospital, Harvard Univ., Belmont, MA; [4]Dept. Psychiatry, Univ. Alabama Sch. Med., BIRMINGHAM, AL

Abstract: We have previously found correlations between hippocampal NR2a receptor expression and Morris Water Maze (MWM) learning indices in rat pups (Smith et al., SfN Abstr., 2004), and between nucleus accumbens (NA) D3 receptor expression and MWM learning in their dams (Burdett et al., SfN Abstr., 2010). Here we have explored hippocampal NR2a mRNA levels in the same dams (n=16), and investigated correlations between the pups and their dams.
Spatial reference learning and memory testing was conducted utilizing the submersible Atlantis-style platform. The platform remained stationary 1cm below the surface of the water in the North-West quadrant throughout the testing period, except during probe trials. Testing consisted of three 60 second trials per day over eight days, with 45 seconds between trials. Spatial reference memory was assessed by performance on probe trials conducted every sixth trial. During probe trials, the platform was lowered to the bottom of the pool so that it was undetectable by the rats. Time spent in the target quadrant and number of platform crossings were measured. In situ hybridization histochemistry was used to measure NR2a mRNA levels in dentate gyrus, CA3, CA2, and CA1 in sections from postmortem brains.
NA D3 mRNA was highly positively correlated with hippocampal NR2a mRNA across the dams ($p<.02$). Significant negative correlations between CA2 NR2a and time spent in the correct quadrant on the third trial of days 2-7, for both probe and non-probe trials, were replicated in the dams ($p<.05$). Platform crossings during the final probe trial were also highly negatively correlated with NR2a mRNA throughout the hippocampus ($p<.03$). However, hippocampal NR2a was not significantly correlated between dams and their pups. These data add to evidence implicating NMDA receptor composition in individual variability in learning ability, but argue against heritability of this factor.

Title: Within and between area replay in Hippocampus, Barrel Cortex and Perirhinal cortex

Authors: *J. J. BOS, M. VINCK, A. B. VAN MOURIK-DONGA, C. M. A. PENNARTZ; Swammerdam Inst. for Life Sciences, Cogn NeuroSci, Cognition Systems Neurosci., Univ. of Amsterdam, Amsterdam, Netherlands

Abstract: The brain has a strong hierarchical architecture where information from primary sensory areas is integrated into complex and multimodal sensory representations in the medial temporal lobe and hippocampal formation. We are interested in how sequences of spiking activity in these different brain structures are temporally organized and pre- or replayed during rest/sleep activity. To address this question, we performed simultaneous tetrode recordings from four different brain areas in the awake behaving rat. These four areas comprised the primary visual, barrel, perirhinal cortex, and the dorsal CA1 field of the hippocampus. From each of these four areas, spikes and Local Field Potentials were recorded with eight tetrodes per area. Across these four areas, we recorded >1500 well isolated single units from four rats performing a visual discrimination task. A target (CS+) and distractor stimulus were presented simultaneously on two screens, flanking the two arms of a figure-8 maze. When the rat selected the arm where the target stimulus was presented, a pellet reward was obtained at the end of the arm. Each arm contained additional tactile cues, coupled to reward amount. Four implanted rats performed ~60 trials with on average ~75% correct performance per session. The task period was flanked by pre- and post sleep/rest sessions. We examined reactivation of task related activity in the pre and post sleep phases during periods of slow wave sleep, ripples and spindles. We first analyzed reactivation using explained variance measures to assess similarities in pairwise correlation patterns. Reactivation occurred both within and between different brain areas. In particular, strong reactivation was observed between pairs of cell in hippocampus, perirhinal, and barrel cortex. This occurred both within/around ripple periods and outside ripple periods. In conclusion,

medial temporal lobe structures display a clear offline information trafficking with sensory neocortex that recapitulates previous behavioral experiences.

Title: Neural representations of sequences of events in the hippocampus parallel behavioral performance

Authors: *T. A. ALLEN[1,2], D. M. SALZ[3], S. A. MCKENZIE[3], M. E. HASSELMO[3], H. B. EICHENBAUM[3], N. J. FORTIN[1,2];
[1]Ctr. for the Neurobio. of Learning and Memory, [2]Neurobio. and Behavior, Univ. of California Irvine, Irvine, CA; [3]Ctr. for Memory and Brain, Boston Univ., Boston, MA

Abstract: Memory for sequences of events is a key feature of episodic memory. Prior studies have shown that lesions to the hippocampus impair this form of sequence memory, but the underlying neural mechanisms that contribute to this capacity remain unclear. In a previous report, we showed that CA1 neurons coded for many aspects of an odor sequence task, including neurons that differentiated between odors presented “in sequence” and “out of sequence” (sequence cells). However, the link between these neural representations and performance on the task remains unclear. Here we directly compared hippocampal representations of the sequences of odors between sessions in which animals showed poor (i.e., first session on a specific

sequence) or strong sequence memory (i.e., when they performed at asymptotic levels). In the task, rats were trained to remember a sequence of five odors presented in a single port at the end of a straight alley maze. Odors were either presented in the correct ordinal position ("in sequence;" e.g., A-B-C-D-E), or one odor was presented out of position ("out of sequence;" e.g., A-B-D-D-E). Rats were required to hold in the odor port for 1sec if an odor was presented "in sequence," or withdraw prior to 1sec if an odor was presented "out of sequence." Sequence memory was demonstrated when rats correctly responded to both "in sequence" and "out of sequence" odors. We recorded 235 CA1 neurons in sessions that showed strong sequence memory ("in sequence" accuracy: 88%; "out of sequence" accuracy: 70%). We report that 42% of neurons showed odor selectivity, 46% showed ordinal selectivity, and 33% were sequence cells. Importantly, many of these neurons were responsive to specific combinations of odor and position, a type of conjunctive representation not previously reported. We also recorded 191 CA1 neurons from the same rats during sessions in which they showed poor sequence memory (i.e., the first session on a specific sequence; "in sequence" accuracy: 88%; "out of sequence" accuracy: 23%). We report that the proportion of responsive neurons significantly dropped in all categories: 25% showed odor selectivity, 26% ordinal selectivity, and 11% were sequence cells. These proportions are lower than in strong sequence memory sessions, but higher than expected by chance, presumably because the rats are in the process of learning the sequences. Notably, the proportion of sequence cells recorded in individual rats was positively correlated with sequence memory performance across the sessions ($r = 0.7$, $p < .05$). These results suggest that sequence coding in the hippocampus is directly related to memory for sequences of events.

Title: The medial entorhinal cortex is required for hippocampal phase precession

Authors: *M. I. SCHLESIGER[1,4], C. C. CANNOVA[1], E. A. MANKIN[1], B. B. BOUBLIL[1], J. B. HALES[2], J. K. LEUTGEB[1], C. LEIBOLD[5], S. LEUTGEB[1,3];
[1]Neurobio. Section and Ctr. for Neural Circuits and Behavior, Div. of Bi, [2]Psychology, [3]Kavli Inst. for Brain and Mind, Univ. of California, San Diego, CA; [4]Div. of Neurobiol., [5]Biol. II, LMU, Planegg, Germany

Abstract: The average theta oscillation cycle of individual hippocampal cells is shorter than the theta cycle of the local field potential, which gives rise to phase precession and may enable spike-timing dependent plasticity. Theta phase-precession is observed in all hippocampal subareas and in the medial entorhinal cortex (MEC). Computational models suggest that phase precession either originates in one brain region and propagates through the circuit or that it can be generated locally in multiple subregions within the circuit. It has previously been shown that entorhinal phase precession does not require the hippocampus. To determine whether phase precession can independently arise in the hippocampus and in MEC or whether hippocampal phase precession requires MEC inputs, we recorded hippocampal neuronal activity in rats with bilateral excitotoxic MEC lesions. Place fields were larger and less frequent after the lesion, but the average and peak firing rates of the remaining place fields were comparable to those of control rats. Furthermore, single CA1 cells remained modulated by the theta rhythm although with reduced modulation depth (control mean ± SEM: 25.5 ± 1.58, MEC lesion: 13.8 ± 0.98). Because we found that spatial firing and theta modulation, which are prerequisites for hippocampal phase precession, were preserved, we examined whether this would imply that the spike timing within theta cycles is also preserved after MEC lesions. In control animals, robust phase precession was found with circular-linear regression analysis when pooling repeated passes through each place field during running in a box for 10 minutes (significant precession was detected in 46 % of the fields). The average slope was less than zero in controls ($p < 0.001$, $t = -3.69$), but not in MEC lesioned rats (n.s., $t = 0.026$). The loss of phase precession for pooled data in the MEC lesion group could arise while phase coordination between cells is intact, but when the starting phase with respect to LFP oscillations varies from pass to pass. To examine this possibility, we analyzed phase precession during single passes. For single passes in controls, we found robust phase precession ($p < 0.001$, $t = -23.89$). In the lesion group, the average slope for single passes was not different from zero (n.s., $t = 1.62$), indicating a loss of phase precession. This pattern of results was also observed on the linear track. We thus find that MEC lesions abolish hippocampal theta-phase precession in 1D and 2D environments, independent of whether single-pass data or pooled data were analyzed. MEC is thus not only a source of spatial information to hippocampus but also provides temporal coordination for hippocampal firing patterns.

Title: The role of the hippocampus and the avian "prefrontal cortex" for extinction learning and renewal of appetitive conditioning

Authors: *D. LENGERSDORF, M. STÜTTGEN, O. GÜNTÜRKÜN;
Dept. of Biopsychology, Ruhr-Universität Bochum, Bochum, Germany

Abstract: Research on the extinction of conditioned fear in rodents has implicated prefrontal cortex and hippocampus in context-specific extinction learning. However, to elucidate fundamental mechanisms of learning and refine extinction-based behavior therapy e.g. for drug addiction and addictive gambling, learning under appetitive reinforcement conditions needs to be investigated.
Therefore, we devised an appetitive conditioning within-subject paradigm to investigate context-specific extinction learning. Pigeons acquired responses to a rewarded conditioned stimulus (CS) in context A. Once a defined performance criterion was reached, responding to the CS was extinguished in a different context B. Subsequently responding to the CS was tested in both the context of acquisition (ABA renewal) and in the context of extinction (ABB). Importantly, responding to another CS was acquired in context B, extinguished in context A, and also tested for renewal in both contexts. This within-subject version of ABA renewal thus allows testing each subject in an ABA as well as in an ABB design for direct comparison. In order to characterize neural substrates for extinction learning, we inactivated hippocampus via local administration of tetrodotoxin (TTX) into both hemispheres. The drug was administered via intracerebral cannulas immediately before extinction training. Hippocampal inactivation did not significantly affect responding during extinction or on the test for renewal but led to increased spontaneous recovery. Further experiments employing NMDA receptor blockade and stimulation in the nidopallium caudolaterale, the presumed functional analogue of mammalian prefrontal cortex, are currently underway.

Title: Resveratrol and forced exercise prove beneficial against both neurological and metabolic deficits associated with ageing

Authors: *R. C. HUSSEY, S. M. O'MARA;
Trinity Col. Inst. of Neurosci., Dublin, Ireland

Abstract: The leading risk factor for neurodegeneration is ageing. There are many theories as to precisely what aspects of ageing are causal of this negative effect on cognition and brain function. To date, this answer remains unclear. With whole-body metabolism also naturally decreasing as we age, it seems probable that these parallel deficits may not be entirely dissociated from one another. A wealth of research shows that increasing metabolism has beneficial effects on neurodegeneration, both in prevention and rehabilitation; most likely through increased cAMP levels affecting the AMPK-SIRT1-PGC-1α pathway. Our studies investigate the effects of both natural and pharmacological metabolic alterations on learning and memory in rodents.

We assessed the differences in learning, short-term and long-term memory between Wistar rats treated with a regular dose of resveratrol (20 mg/kg; 5 d/week; p.o.), regular aerobic exercise (forced running; 1h/5d/week), both of these or neither. Animals were assessed on performance in the delayed non-matching-to-sample (DNMS) task over a 4 month protocol, with animals aged 14 months at the beginning. Training and testing in the DNMS task was carried out on the same days as exercise and resveratrol treatment.

We found that rats undergoing regular exercise and/or treated with resveratrol had improved performances compared to age-matched controls. The key improvements were found when assessed in the task with a 25-30 second delay. There was no difference between groups with no delay on the task. Furthermore, no evident side-effects arose from the administration of resveratrol for such a long epoch.

Our results indicate that regular resveratrol treatment and/or exercise help delay the hippocampal-dependent cognitive dysfunction associated with ageing. With no ill-effects observed, we have no evidence to suggest apprehension over regular administration of oral resveratrol with a long time-scale. The improved performance in this task associated with both natural and pharmacological metabolic enhancement highlight the potential use of these factors in delaying the neurological and metabolic deficits associated with ageing.

Title: Age-associated changes in cognition and inhibitory interneuron network integrity in diversity outbred mice

Authors: *M. KOH, A. SPIEGEL, M. GALLAGHER;
Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD

Abstract: Failure of episodic memory, linked to hippocampal dysfunction, is a common but not inevitable feature of aging. Such age-related impairment can worsen to an extent greater than expected for a person's age, leading to a diagnosis of amnestic mild cognitive impairment (aMCI), a condition that increases risk for further progression to Alzheimer's dementia. Recent evidence from animal models and human clinical studies has demonstrated that diminished pattern separation, a computational function mediated by hippocampal circuits involving the dentate gyrus (DG), contributes to these age-related conditions of memory loss. Encoding deficits indicative of diminished pattern separation are associated with weakened input to CA3/DG originating from layer II entorhinal neurons and reduced integrity of somatostatin-positive (SOM+) hilar interneurons in memory-impaired aged rats. Here, we used the newly developed Diversity Outbred (DO) mouse to study individual differences in memory. The DO mouse population was designed to model the genetic diversity found in human populations, maximizing allelic variation throughout the genome while maintaining normal levels of hetereozygosity. The increased genetic diversity in the DO model produces high levels of phenotypic variation rendering it a more powerful system to investigate individual differences in behavior than common laboratory inbred rodent strains. We behaviorally characterized hippocampal-dependent memory performance in young (4-8 mo old) and aged (18-24 mo old) male DO mice in a water maze protocol. Young adult mice exhibited greater proficiency in learning to locate a hidden escape platform during training and stronger spatial memory for the escape location during probe trials compared to the overall performance of aged DO mice. A substantial number of older DO mice, however, performed on a par with the normative

performance of younger adults. Stereological quantification for SOM+ neurons showed that high-performing young and unimpaired aged DO mice had comparable numbers of SOM+ hilar interneurons, while aged mice that were impaired in the spatial task had significantly fewer such neurons. These data in the DO model extend findings that tie loss of SOM+ interneuron integrity to age-related memory impairment, as reported for individual differences in outbred Long-Evans rats, and in models of ApoE4 expression as mice exhibit augmentation of an aging effect on that specific interneuron population. The vulnerability SOM hilar interneurons, given their anatomical and functional attributes, could contribute to impoverished pattern separation as a basis for episodic memory failure in the aged brain.

Title: Voluntary exercise modifies interneuron protein expression in the dentate hilus

Authors: *A. M. SPIEGEL[1], S. SALAS-VEGA[1], A. M. STRANAHAN[2], M. GALLAGHER[1]; [1]Dept of Psych & Brain Sci., Johns Hopkins Univ., BALTIMORE, MD; [2]Physiol. Dept., Med. Col. of Georgia, Augusta, GA

Abstract: Voluntary exercise is associated with enhanced hippocampal dependent memory. Recent behavioral evidence indicates that an improved ability to disambiguate information with overlapping elements (i.e. pattern separation) contributes to this memory enhancement. Proficient pattern separation depends on sparse encoding within the dentate gyrus, with high divergence of cortical input onto granule cells and local circuits within the dentate contributing to this computational property. GABAergic interneurons in the dentate hilus play a critical role in sparse encoding in response to cortical input, as inhibition of these neurons increases the number of activated granule cells and impairs spatial memory. Little is known about the effects of voluntary exercise on the GABAergic network. Here we explored exercise-induced modifications on dentate hilar GABAergic interneurons. We found that voluntary exercise alters the phenotypic expression of markers for hilar interneuron populations in young, male Long Evans rats. Using immunohistochemistry with stereological quantification, the number of hilar interneurons expressing glutamic acid decarboxylase-67 (GAD67), Neuropeptide Y (NPY) and

Somatostatin (SOM) were quantified in sedentary rats and rats exposed to 30 days of voluntary wheel running. Runners reached a maximum daily running average of 3545m ± 857m, with asymptotic running performance from approximately day 12 onward. Running was associated with a 27% increase in the number of hilar neurons expressing GAD67. Voluntary exercise had a similar affect on hilar interneuron subgroups with NPY-expressing neurons exhibiting a 37% increase and SOM-positive neuron number increasing by 17%. Additionally, the total number of NPY and SOM-positive hilar neurons, which likely represent overlapping neuronal populations in the hilus, was highly correlated with GAD67-positive neuron number. Overall these data indicate that voluntary exercise is a strong modulator of the hilar GABAergic network. Given the functional importance of hilar interneurons in sparse encoding, their modulation could contribute to the beneficial effects of exercise on hippocampal dependent memory. The current work may also have relevance to the loss of GAD67 and SOM-positive hilar interneuron number previously reported in aged Long Evans rats with memory impairment. Considering that the reduction in GAD67 and SOM-positive neuron number occurs in the absence of frank degeneration, voluntary exercise may prove to be an effective treatment in the restoration of interneuron protein expression and memory function in aged impaired animals.

Title: Do anabolic steroids impact cognition? An evaluation of androstenedione's effects on cognition in young male rodents

Authors: *B. W. CAMP[1,2], R. HIROI[1,2], L. TORRES[1], L. KARBER[1], H. A. BIMONTE-NELSON[1,2];
[1]Psychology, Arizona State Univ., Tempe, AZ; [2]Arizona Alzheimer's Consortium, Phoenix, AZ

Abstract: Following natural menopause, androstenedione becomes the main hormone secreted by the follicle-deplete ovaries. We have previously shown that higher serum levels of androstenedione are related to spatial memory impairment in female rats; this relationship was shown when androstenedione serum levels were of endogenous (Acosta et al., 2009a) or of exogenous (Camp et al., 2012), origin, and within high physiological levels. Thus, there is mounting evidence in support of androstenedione as a detriment to spatial memory in the female rat. We recognize that androstenedione has grown in popularity as a supplement taken by men, and might possibly impair spatial memory as we have noted in the female rodent model. Since androstenedione-induced memory effects in females cannot necessarily be generalized to effects in males, we applied this question to a male rodent model. This is a clinically relevant question as the use of androstenedione as a physical-performance enhancing steroid has greatly increased in the last 15 years, with little knowledge of the potential effects on brain function. In the current study, young gonadally intact male rats were given a daily injection of either vehicle or androstenedione, followed by a battery of cognitive tasks. Preliminary data suggest that effects in males are in congruence with those we have seen previously in females. Replication studies are underway, and the totality of work will be presented at the conference

Title: Human navigation on a radial-arm maze: Strategy choice and performance outcome

Authors: *H. A. BIMONTE-NELSON[1], I. GRUNFELD[2], S. MENNENGA[1], B. CAMP[1], G. BREWER[1], L. BAXTER[2], M. MCBEATH[1];
[1]Arizona State Univ., TEMPE, AZ; [2]Dept. of Neuroimaging Res., Barrow Neurolog. Inst., Phoenix, AZ

Abstract: This study examined differences in navigational strategy by translating between spatial reasoning models in rodent and human research. We built a 50-foot diameter, 11-arm walk-through Human Radial-Arm Maze (HRAM) to parallel the traditional Radial-Arm Maze (RAM) that has been a mainstay in rodent research to test spatial working memory. 157

participants performed the HRAM along with a battery of other cognitive tests. The HRAM required participants to traverse all 11 arms and recover play money hidden under mats at the end of each arm, with the goal to commit the fewest number of repeat entries into the arms (quantified as errors). Participants were not allowed to use simple ordered chaining strategies of entering adjacent arms, or of every second arm. Performance was evaluated by quantifying number of repeat arm entry errors, order of arm entries, and self-reported use of navigational strategies, such as utilizing external cues. The shape of the working memory load curve of arm-repetition errors over time was similar to rodent performance on the RAM, with more errors as choices progressed and load increased, while also consistent with a higher memory capacity in humans. We found two primary strategies: (1) Systematic procedural heuristics (repeatedly crossing over to opposing arms, or complex chaining such as traversing every third arm), and (2) Unsystematic, brute-force memorization (reliance on remembering intramaze features or global orientation cues). The 44% who used systematic heuristics made fewer errors than the 56% who relied on brute-force memory. 47% stated that they utilized external cues to solve the task; these participants were in both systematic heuristics and brute-force memory groups, therefore, use of extramaze cues did not correspond with that type of group membership. Additionally, we found an effect of learning/practice associated with repeat runs through the maze, and an effect of gender whereby males outperformed females. Sex differences in solving strategies are currently being evaluated. In conclusion, the HRAM resulted in two distinct navigational strategy categories: systematic heuristics and brute-force memory. Testing humans using methodology similar to that employed when evaluating rodent models provides a foundational tool to translate models of spatial cognition and reasoning across species. The HRAM shows promise as a functional translational instrument for testing memory and navigational principals commonly evaluated in rodents, and can be used to translate scientific questions between rodents and humans.

Title: The impact of hormone therapy estrogens on memory, depressive-like, and anxiety-like behaviors: A comparison of conjugated equine estrogens and 17β-estradiol

Authors: *S. V. KOEBELE, R. HIROI, S. E. MENNENGA, L. T. HEWITT, P. K. MENDOZA, C. N. LAVERY, G. WEYRICH, L. F. KARBER, H. A. BIMONTE-NELSON; Psychology, Arizona State Univ., Tempe, AZ

Abstract: Aging and the menopausal transition have each been associated with cognitive impairment, and this is often co-morbid with anxiety as well as affective disorders such as depression. Low or changing levels of estrogens in women, as seen with peri- and post-menopause, have been related to cognitive, anxiety, and affective disorders. Benefits of 17β-estradiol (E2), the most potent naturally circulating estrogen in women and rats, on cognitive, anxiety-like, and depressive-like behaviors have been shown. Although conjugated equine estrogen (CEE) is the most commonly prescribed estrogen component of hormone therapy (HT) in menopausal women, there is a marked gap in knowledge regarding whether CEE affects cognition, anxiety-like, and depressive-like behaviors, and how these effects compare to E2. This is a clinically significant question since bio-identical HT utilizing E2 is gaining recognition as a viable option. For example, both estrogen types are being methodically evaluated and compared in the KEEPS clinical trial (Wharton et al., 2013). Here, using a rodent model, we evaluated the effects of CEE treatment on these behaviors, and compared them to those seen with E2 treatment. Female rats were ovariectomized, administered either vehicle, E2, or CEE, and tested on a battery of cognitive, anxiety-like, and depressive-like behaviors in the following order: Water Radial Arm Maze (spatial working and reference memory), Morris Water Maze (spatial reference memory), Delayed Match-to-Sample (spatial working and recent memory), Visible Platform (overall motor and visual ability), Open Field (anxiety-like behavior and overall locomotion), Elevated Plus Maze (anxiety-like behavior) and the Forced Swim Test (depressive-like behavior). Results showed that both E2 and CEE enhanced spatial working memory, corroborating previous reports in adult and middle-aged ovariectomized rats. Further, E2, but not CEE, decreased anxiety-like and depressive-like behaviors. Collectively, these results indicate that, while both estrogen treatments have functional consequences on behavior, the impact of CEE is not as broad as E2. In conclusion, there seems to be a dissociation between cognitive, anxiety and affective measures.

Title: Estradiol only improves performance when working memory load is very high: Alternative interpretation of poor performance on an easy task

Authors: *S. E. MENNENGA[1], J. E. GERSON[2], S. V. KOEBELE[1], L. T. HEWITT[1], A. S. JORDAN[1], A. A. MOUSA[1], H. A. BIMONTE-NELSON[1];
[1]Arizona State Univ., Tempe, AZ; [2]Univ. of Texas Med. Br., Galveston, TX

Abstract: 17β-Estradiol (E2) is the most potent naturally circulating estrogen, and is the most common estrogen evaluated in rodent learning and memory studies. There is evidence that E2 treatment induces cognitive benefit following ovariectomy (Ovx) in rats; however, this benefit seems to be limited to conditions involving a high working memory load. The Water Radial Arm Maze (WRAM) assesses spatial working and reference memory; there are several WRAM variations, including differences in the number of reinforcers subjects are required to locate within a testing session. The number of reinforcers animals are required to find within a session corresponds to the working memory load that the task requires. We hypothesize that the cognitive benefits of E2 treatment in young animals are specific to working memory tasks with a high memory load and, in fact, performance indicative of impaired memory may be seen in animals treated with E2 when the working memory demand is not high enough. Here, in two studies, the cognitive effects of tonic E2 administration were evaluated in young Ovx rats under different working memory loads. Study I assessed the cognitive effects of low, medium, and high doses of E2 using the WRAM with hidden platforms in 4 of 8 arms, requiring a lower working memory load. Study II assessed the cognitive effects of low and high doses of E2, with hidden platforms in 7 of the 8 arms, requiring a higher working memory load. For each study, animals were given 12 testing days, followed by a delay test. Results showed that, in young animals tested under the current parameters, E2-induced enhancements were only evident when requirements necessitated a high working memory load. There were no differences in reference memory errors regardless of the behavioral task, indicating that effects were specific to the working memory domain. Our data suggest that in young animals, the benefits of E2 treatment

become apparent only at high working memory loads, and that the benefits of E2 are not realized on tasks that do not sufficiently tax the working memory system. These results indicate task difficulty as a factor to be considered when evaluating the impact of female steroids on cognition.

Title: Curcumin supplementation improves certain aspects of cognition and alleviates inflammation, independent of adiposity

Authors: *M. SARKER, M. J. FORSTER, S. F. FRANKS, N. SUMIEN, F. FILIPETTO; UNT Hlth. Sci. Ctr., Fort Worth, TX

Abstract: Midlife obesity has been recently associated with cognitive impairment that may be attributed to chronic, obesity-related inflammation and oxidative stress. The current study addressed the hypothesis that curcumin supplementation, by attenuating obesity and adiposity - related inflammation, would improve cognitive function in a midlife obesity animal model. Commonly used laboratory mice fed ad libitum are an analogue of weight gain in middle aged humans, since accumulating fat is more often the result of food intake exceeding energy expenditure and not solely because of a high fat diet. In this study, C57BL/6J male mice were maintained under ad libitum (AL) feeding until they reached peak weight at 15 months of age, as a model of inactivity-related weight gain. The mice were subsequently assigned in groups of 19 to (i) remain on AL, (ii) receive 30% caloric restriction (CR) or (iii) receive curcumin in their AL diet (1000 mg/kg diet, CURC) for 12 weeks. Mice underwent tail bleeds for the inflammatory markers, interleukin 6 (IL-6) and C-reactive protein (CRP) and, after 8 weeks of dietary treatment, spatial cognitive function was tested using a Morris water maze, followed by testing for cognitive flexibility using a discriminated avoidance, serial reversal task. Visceral and subcutaneous adipose tissue was collected after 12 weeks of the treatments. Mice maintained on

CR weighed significantly less than mice on the CURC and AL diets by the third week of treatment. Food intake of the CURC group was significantly higher than AL. Mice on CR and CURC diets took fewer trials than AL to reach criterion during the second reversal session of discriminated avoidance, suggesting that both conditions improved cognitive flexibility. On the other hand, there were no significant differences between the groups in their spatial cognitive performance. Mice maintained on CR had significantly less visceral and subcutaneous adipose tissue compared to mice on CURC and AL. Curcumin supplementation did not significantly impact IL-6 levels but it did reduce CRP relative to AL mice after 12 weeks of dietary treatment. The results suggest that, in a midlife obesity animal model, curcumin supplementation has positive effects on frontal cortical functions that may be linked to an anti-inflammatory action, but are independent of adiposity.

Title: The effects of HMB on water maze performance in middle-aged and aged male and female rats

Authors: *D. G. KOUGIAS, W. A. KOSS, L. K. SHERRILL, E. R. HANKOSKY, L. R. HAMMERSLAG, J. M. GULLEY, J. M. JURASKA;
Psychology, Univ. of Illinois At Urbana-Champaign, Champaign, IL

Abstract: Beta-hydroxy-beta-methylbutyrate (HMB), a leucine metabolite commonly supplemented in elderly and clinical populations, has been shown to maintain muscle in catabolic states; however, its role in the aging brain remains unknown. In both healthy aging humans and in rat models, there are deficits in several modalities of cognitive functioning. Deficits in Morris water maze performance have been found in healthy aging rats in several labs. The current study explores the cognitive effects of short- and long-term (1 month and 7 month) HMB supplementation starting at 12 months of age in male and female Long-Evans hooded rats. At 11 months of age, female rats are ovariectomized to model the normal human female aging following menopause. Male rats undergo a sham surgery to control for the possible effects of

anesthesia exposure. HMB was administered in a sucrose solution (450 mg/kg twice daily). Short-term HMB supplemented male (n=12) and female (n=10) rats and short-term vehicle treated male (n=11) and female (n=9) rats were run on the water maze (4 trials/day for 4 days). There was a main effect of day ($p<.001$) in water maze performance, but no other effects were found. These results indicate no sex differences and no direct, immediate cognitive enhancing effects on water maze performance with short-term HMB supplementation in middle-aged rats. These data are the baseline from which the long-term HMB supplementation group will be compared to assess whether this nutrient mitigates cognitive decline in aging rats.

Title: Effects of ghrelin knock-out and age on spatial learning, neurogenesis, and spine density in the dentate gryus of rats

Authors: *S. P. CAHILL[1], T. HATCHARD[2], A. ABIZAID[1], M. R. HOLAHAN[1];
[1]Carleton Univ., Ottawa, ON, Canada; [2]Univ. of Ottawa, Ottawa, ON, Canada

Abstract: Work has revealed a high density of ghrelin receptors distributed throughout the hippocampal CA1 and dentate gyrus (DG) subregions. Binding of ghrelin to these receptors is associated with elevated dendritic spine density in the CA1 region and increased neurogenesis in the DG. These ghrelin-induced neuronal changes are paralleled by enhanced learning and memory on a variety of hippocampal and non-hippocampal dependent tasks such as the water

maze after administration of ghrelin. While elevations in ghrelin appear to have consistent enhancing effects on spatial learning and hippocampal connectivity, the effect of decreasing ghrelin, either through antagonists or knock-out, has been less clear.
In the present experiment, we investigated how knock-out of the ghrelin receptor impacted spatial learning and memory as well as how ghrelin knock-out affected neurogenesis and spine density in the DG of the hippocampus. In this experiment, we used genetically modified rats, as opposed to mice, where previous work has been concentrated. To this end, we used both wild type (WT) and ghrelin receptor deficient (KO) Fawn Hooded Hypertensive (FHH) rats and tested them on two water maze (WM) tasks as well as an 8 arm radial arm maze task (8-RAM). To examine neurogenesis, we used double cortin immunohistochemistry to evaluate the number of immature neurons in the DG. Golgi- Cox impregnation was used to evaluate spine density in the DG. As aging is associated with decreased levels of ghrelin and has been shown to contribute to decreased neurogenesis and lead to impairments in learning and memory, we also tested theses WT and KO rats when they were aged.
Results showed there was no difference in acquisition on the water maze task between groups. Age was found to decrease learning and memory on the 8-RAM task, and this effect was exasperated in the aged KO rats. Both spine density and neurogenesis were decreased in the aged groups, with young WT rats having the highest spine density and levels of neurogenesis. Overall, results demonstrate a lack of an effect of ghrelin KO on water maze performance. An effect of ghrelin KO does appear to produce deficits in the performance of the 8-RAM food-motivated task, but only in aged rats. While in aging, there was an overall decrease in immature neurons and spine density, decreased neurogenesis and spine density was also evident in the young ghrelin KO rats. Data suggest that ghrelin KO disrupts hippocampal structural integrity that may manifest in non-spatial-related aspects of hippocampal function.

Title: Aging reduces basal neuronal activation as measured by immediate early gene expression within medial prefrontal cortex

Authors: *M. SEHGAL[1], J. A. DETERT[3], T. S. BULA[1], J. R. MOYER, Jr.[1,2];
[1]Psychology, [2]Biol. Sci., Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [3]Dept. of Anesthesiol., Weill Cornell Med. Col., New York City, NY

Abstract: We have recently demonstrated that aging is accompanied by deficits in medial prefrontal cortex (mPFC)-dependent behaviors such as fear extinction starting in middle age *(Kaczorowski et al., 2012*). Our data also show that aging leads to region-specific changes in intrinsic excitability of mPFC neurons. Specifically, infralimbic (IL) neurons are less excitable and prelimbic (PL) neurons are more excitable in middle-aged and aged rodents. It is likely that these changes in excitability are reflected in reduced basal neuronal activity during normal aging. To measure region-specific changes in neuronal activation, we quantified basal immediate early gene (IEG) expression within mPFC. Basal IEG expression reflects ongoing memory consolidation (*Marrone et al., 2008*). Furthermore, the role of IEGs as markers of neuronal plasticity and their critical role in memory consolidation make them ideal for investigating early cognitive decline. The current study used western blots and immunohistochemistry to test the hypothesis that normal aging alters basal expression of Zif-268 and Arc in mPFC. Beginning in middle age, immunohistochemistry revealed a significant decline in the number of Zif-268 immunoreactive neurons within both IL ($p < 0.01$) and PL ($p < 0.05$). There were no significant differences in Zif-268 immunoreactivity between middle-aged and aged rats for either IL or PL. Western blots indicated a similar pattern of results for Zif-268 within mPFC. Zif-268 expression was reduced within IL for middle-aged and aged rats ($p < 0.05$). Within PL, Zif-268 expression was significantly reduced in both middle-aged ($p < 0.05$) and aged rats ($p < 0.08$). These data suggest that aging is associated with a decrease in both the number as well as the expression levels of Zif-268 protein. Basal expression of Arc followed a distinct pattern of aging-related changes. Western blots revealed that Arc expression was significantly reduced within IL of aged ($p < 0.05$) but not middle-aged rats relative to adult rats. Interestingly, Arc expression is unaltered in PL during normal aging. Since immunohistochemistry revealed a primarily dendritic location of Arc protein within mPFC, cell counts were not obtained. These data suggest that aging results in differential changes in the expression of Zif-268 and Arc within subregions of mPFC. Interestingly, aging-related changes in IEG expression are evident beginning in middle age, suggesting that they may contribute to our observed aging-related extinction deficits as well as deficits in other mPFC-dependent tasks.

Title: Early detection of region-specific changes in immediate early gene expression within hippocampus during normal aging

Authors: *J. R. MOYER, JR.[1,2], M. SEHGAL[1], J. A. DETERT[3], T. S. BULA[1]; [1]Psychology, [2]Biol. Sci., Univ. of Wisconsin-Milwaukee, Milwaukee, WI; [3]Dept. of Anesthesiol., Weill Cornell Med. Col., New York City, NY

Abstract: Normal aging is accompanied by cognitive decline that differs from other aging-related pathological states like Alzheimer's disease. With an increasing proportion of the world population falling in an age group of 65 years and above, a preventive gerontological approach may be essential to ultimately improving the quality of life for the elderly. Especially relevant is identifying markers for early detection of cognitive decline. Although aging-related changes in hippocampal functioning have been well documented, relatively little is known about the age of onset of these changes, and the differential effects of aging on the dorsal (DH) and ventral (VH) subregions of hippocampus. Aging-related changes in the expression of memory permissive genes, e.g. immediate early genes (IEGs), can be especially useful markers in predicting early cognitive decline. Specifically, IEGs are markers of neuronal activity and are critical for long-term memory formation. Here we used Western blots and immunohistochemistry to quantify the expression of two IEGs, Zif-268 and Arc, within hippocampal subregions as a function of normal aging in male F344 rats. Preliminary studies suggest that aging resulted in a significant reduction in the expression of Arc in DH ($p < 0.01$) but not VH. Interestingly, these reductions were first observed in middle-aged animals and no further reductions in Arc expression were observed in aged DH. Immunohistochemistry revealed that basal Arc expression was localized to the dendritic compartment of DH as well as VH subregions. Analysis of Zif-268 revealed region-specific changes during aging. Western blots indicated that the total amount of Zif-268 protein did not change during aging in DH. However, immunohistochemical analyses revealed that in DH the number of Zif-268-ir neurons was significantly decreased in both CA1 ($p < 0.01$) and DG ($p < 0.05$) of both middle-aged and aged rats (no change was observed in CA3). Within VH, there was a trend toward a reduction in total Zif-268 protein expression in middle-aged and aged rats. Interestingly, in VH the number of Zif-268-ir neurons was significantly reduced, but only in DG ($p < 0.001$) of middle-aged and aged rats. These data indicate that the dorsal and ventral

subregions of hippocampus may undergo differential changes in gene expression during normal aging. Furthermore, within dorsal and ventral hippocampus, IEG expression changes were restricted to certain principal cell layers and not others. Given the role of IEG expression in neuronal plasticity, aging-related changes in IEG expression are likely markers for early onset of cognitive decline within these structures.

Title: The molecular and cellular mechanisms behind environmental enrichment

Authors: *R. HULLINGER[1], K. O'RIORDAN[2], C. BURGER[2];
[2]neurology, [1]Univ. of Wisconsin- Madison, Madison, WI

Abstract: Behavioral and pharmacological treatments for cognitive impairments associated with the aging process are becoming a growing focus of concern as the elderly population continues to expand worldwide. Current evidence suggests that environmental enrichment can improve learning and memory, but the age at which enrichment can be effective and the length of enrichment necessary remains unclear. Furthermore, the impact of enrichment on synaptic plasticity and the molecular mechanisms behind enrichment are not completely understood. To address these unresolved issues, we have housed 2 month old, 12 month old, and 20 month old rats in enriched environments and conducted tests of learning and memory formation after 1 month and after 4 months of enrichment. Preliminary results demonstrate that 1 month of environmental enrichment improves performance on the Morris water maze, novel object recognition, and contextual fear conditioning for 20 month old rats, whereas 4 months of enrichment is necessary to improve performance on these tasks in 2 month old and 12 month old rats. Furthermore, we have found that environmental enrichment results in a robust expression of long term potentiation (LTP) within hippocampal area CA1 for all age groups, a phenomenon not observed in rats housed in standard environments. Currently we are investigating the molecular mechanism behind this cognitive and synaptic enhancement, with particular focus on changes in expression of genes known to be involved in LTP following a period of enrichment. The results of these studies will provide insight into the molecular basis of learning and memory

enhancement following environmental enrichment.
Representative data from the Morris water maze hidden platform training in 20 month old rats demonstrates that enriched rats perform significantly better than standard housed rats (Two- way anova, $p<.05$ on day 3, 4, 5, and 6).

Title: Identification of cognitive deficits and brain pathology in a mouse model of normal aging

Authors: *M. WEBER[1], T. WU[1], S. L. DOMINGUEZ[1], H. LIN[1], H. NGU[2], K. SCEARCE-LEVIE[1];

Abstract: While age is the main risk factor for the development of sporadic Alzheimer's disease, age-related cognitive decline in rodents has been relatively less studied. This may in part be due to non-cognitive age-related changes like hearing or vision impairments, or changes in general locomotor activity that can confound cognitive tests in rodents. Here, we have compared 3, 11 and 23-month old female C57BL6/J mice in a battery of behavioral tests. Cognitive tests were complemented by tests of acoustic and visual functioning, and locomotor activity. Age-related impairments were detected in tests of spatial memory (Barnes maze), fear memory (cued fear conditioning), and associative learning (active avoidance). No age-related changes were observed in locomotor activity, and only minimal impairments were detected in visual placing and eye-blink tests. In contrast, physical responses to acoustic stimuli of varying intensities were

impaired in an age-dependent manner, indicating hearing impairments. In order to determine if the active avoidance deficits could be related to the hearing impairments, we assessed mice in an active avoidance variant in which light but no tones were presented as conditioned stimuli. Age-related deficits were again observed. Taken together, these data suggest that neither deficits in hearing, vision, nor locomotor activity are likely to account for the observed deficits in the cognitive measures. We are currently analyzing brain tissue from these mice for markers for inflammation and the effects of a novel environment challenge on c-fos expression in the hippocampus. The identification of robust deficits in cognition in aged mice provides an opportunity for a translational model of normal aging. Such a model would have value in screening for cognitive enhancers, and investigating the biological changes associated with aging-related cognitive decline.

Title: Study of the molecular mechanisms underlying cognitive dysfunction caused by prenatal hypoxia in rats

Authors: *I. A. ZHURAVIN[1], N. M. DUBROVSKAYA[1], S. A. PLESNEVA[1], A. J. TURNER[2], N. N. NALIVAEVA[1,2];
[1]Comparative Physiol. and Pathology of CNS, I.M.Sechenov Inst. of Evolutionary Physiol. and

Biochem. RAS, Saint Petersburg, Russian Federation; [2]Sch. of Mol. and Cell. Biol., Univ. of Leeds, Leeds, United Kingdom

Abstract: To elucidate the molecular mechanisms underlying disruption of cognitive functions caused by pathogenic factors (hypoxia, stress) during embryogenesis we have analysed neurophysiological characteristics of rats at various stages of postnatal ontogenesis as well as expression and activity of some enzymes in brain structures. Prenatal hypoxia (PH) in rats (E14, 3 hours, 7% O_2) led to an impairment of cognitive functions in later ontogenesis correlated with a decrease in the average density of labile synaptopodin-positive dendritic spines in the neocortex (Cx) (*Zhuravin et al, Dokl. Biol. Sci., 2009, 425, 123-5; 2011, 438, 145-8*). PH and ageing also shifted the metabolism of amyloid precursor protein (APP) and expression of a major amyloid-degrading enzyme neprilysin (NEP) towards the amyloidogenic pathway. The PH rats had decreased levels of AChE and NEP activity in the Cx and hippocampus (Hip). Moreover, ageing and administration of NEP or AChE inhibitors also resulted in deterioration of memory. Recently we demonstrated that the APP intracellular domain AICD up-regulates expression of NEP in a histone deacetylase (HDAC)-competitive mode (*Belyaev et al, EMBO Rep, 2009, 10, 94-100*). Injections to HP rats of an HDAC inhibitor valproic acid (VA) resulted in an enhanced NEP activity, increased number of labile spines and improved memory tested in the maze and by a novel object recognition test (*Dubrovskaya et al, Short-term memory: new research, Nova, 2012, 6, 155-173*). Injection of VA to rats also led to an increased binding of AICD and decreased binding of HDAC to the *NEP* promoter in rat Hip (*Nalivaeva et al, J Mol. Neurosci, 2012, 46, 569-577*). Treatment of rats with an antioxidant epigallocatechin gallate (capable of epigenetic regulation of gene expression) also resulted in an increased NEP activity, higher number of dentritic spines in the Hip and improved memory in PH rats. Thus, the impairment of cognitive functions caused by PH (as well as by ageing) involves a decrease in the activity of cholinergic and peptidergic systems accompanied by a reduction in brain synaptic plasticity. Regulation of these systems via epigenetic mechanisms can be a viable therapeutic strategy to improve cognitive functions impaired by prenatal stress.

Title: NMDA receptor subcellular location and memory functions are altered in the APP/PS1 mouse model of Alzheimer's disease

Authors: S. HADZIBEGOVIC[1], J. PORęBSKA[2], Y. CHO[3], N. MACREZ[1], B. BONTEMPI[1], *O. NICOLE[1];
[1]CNRS, Univ. Bordeaux, UMR-CNRS5293, Bordeaux, France; [2]Inst. of Computer Sci. and Nalecz Inst. of Biocybernetics, Warsaw, Poland; [3]UMR-CNRS 5287, Univ. de Bordeaux, Bordeaux, France

Abstract: The cognitive impairments in Alzheimer's disease (AD) are related to degenerative synaptic changes produced by the presence of soluble Aβ oligomers (Aβos) in vulnerable brain regions such as the hippocampus. At the molecular level, Aβos bind preferentially to the postsynaptic density of neuronal excitatory synapses, where the post-synaptic protein-95 (PSD-95) organizes NMDA receptor composition and location as well as its downstream signaling. We speculate that that in AD, early alterations in scaffolding protein expression following synaptic accumulation of Aβos may modify the NMDAR subcellular trafficking, which would in turn alter the plasticity-related events triggered by learning and memory processes. To test this hypothesis, we first analyzed the differential expression of total synaptic proteins in the hippocampus of APP/PS1 transgenic (n=13; 9-10 month old) and wild-type (Wt) mice (n=13). As previously described in patients with mild cognitive impairment (Sultana et al., 2010), we also report a decrease of PSD-95 expression in APP/PS1 mice. Moreover, by using two hippocampal-dependent memory tasks (spatial object recognition and Y-maze), we found that the cognitive performance of APP/PS1 mice was impaired and correlated with the hippocampal expression of PSD-95. Since PSD-95 organizes NMDA receptor trafficking, we next examined the expression and distribution of GluN2 in hippocampal neurons. We provide evidence that the total expression of GluN2A was reduced in APP/PS1 mice whereas the total expression of GluN2B was unaffected. To evaluate the distribution of GluN2B between synaptic and extrasynaptic compartments, we performed a fractionation of synaptosomes and foundthat the reduced expression of PSD-95 was associated to a mislocalization of the GluN2B subunit. Indeed, the synaptic level of GluN2B was lower in APP/PS1 compared to Wt mice whereas the extrasynaptic pools of GluN2B receptors was higher in APP/PS1 compared to Wt mice. Moreover, the cognitive performance of APP/PS1 mice was inversely correlated with the level of extrasynaptic GluN2B receptors. Together, these results suggest that the post-synaptic accumulation of Aβos destabilizes synaptic organization and increases the activation of extrasynaptic NR2B-containing receptors, a reorganization which translates into impaired memory functions.

Title: Protective effects of P2X7 receptor deletion on aging-related cognitive status

Authors: *W. CHO[1], S.-R. LEE[1], J.-C. PARK[1], J.-R. LEE[2], J.-S. HAN[1];
[1]biology, Konkuk Univ., Seoul, Korea, Republic of; [2]Korea Res. Inst. of Biosci. and Biotech., Daejeon, Korea, Republic of

Abstract: P2X7 receptor (P2X7R) is an ATP-gated cation channel predominantly expressed on microglial cells in central nervous system. The P2X7 receptor can modulate cell growth, proliferation, apoptosis, and cell death. Recent studies have shown that inhibition of P2X7R ameliorates memory impairments induced by ischemia. The present experiment was conducted to examine effects of P2X7 receptor deletion on age-related cognitive status. Cognitive status of mice in 4 groups (5 month-old young P2X7R knock-out (KO) group, 11-14 month-old middle P2X7R KO group, two aged-matched wild type group (WT)) was assessed using Morris water maze task. No differences were observed between young WT and young KO mice in the spatial memory. However, middle-aged P2X7R KO mice showed better performance than age-matched WT mice. And levels of inhibitory phosphorylation at Serine-9 were higher in the hippocampus of young KO, middle-aged KO, and middle-aged WT mice compared to those of young WT mice. These results suggest that the deletion of P2X7R have a positive influence on aging-related alternations. The regulation of P2X7R might a potential therapeutic strategy for treatment of aging-related cognitive deficits. Title: The sigma 1 receptor selective ligand ls-1-137 attenuates scopolamine induced impairment in learning and memory

Authors: *M. MALIK[1], C. BARAJAS[1], N. SUMIEN[1], R. MACH[2], R. LUEDTKE[1]; [1]Pharmacol. and Neurosc, Univ. of North Texas Hlth. Sc Ctr., Fort Worth, TX; [2]Div. of Radiological Sci., Washington Univ. Sch. of Med., St. Louis, MO

Abstract: Cognitive deficit is observed in patients with Alzheimer's Disease, Parkinson's Disease, traumatic brain injury and stroke. These types of cognitive deficits are often due to alterations in cholinergic signaling. Currently available therapeutic drugs provide only symptomatic relief and generally become ineffective as a neurodegenerative disorder progresses. Therefore, novel therapeutic agents will be needed to retard and/or arrest the progressive loss of memory forming cells. In this study, C57BL/6J mice injected with scopolamine (1mg/kg) were used as our experimental model to evaluate the ability of a sigma 1 receptor selective compound to improve the cognitive deficits associated with muscarinic antagonist administration. Scopolamine-induced memory impairment provides a relatively rapid and reversible phenotypic screening paradigm for cognition enhancement drug discovery. In this study, we evaluated LS-1-137, which exhibits high affinity (3.9nM) and sigma 1 versus sigma 2 receptor binding selectivity. It also binds with low affinity at D2-like (D2, D3 and D4) dopamine receptors. The cognitive state of the mice was evaluated using the water maze, active avoidance test and novel object recognition tests. Scopolamine treated animals exhibit impaired learning and memory in the water maze and the active avoidance test. C57BL/6J mice pre-treated with test drug at a dose of 3mg or 10mg/kg attenuated the scopolamine-induced cognitive deficit. Therefore, LS-1-137 represents a novel candidate cognitive enhancer for the treatment of cognitive deficits.

Title: Selective deterioration of excitatory synapses in the aged dentate gyrus: Comparisons among hippocampal glutamatergic, GABAergic and cholinergic synapses

Authors: *J. A. MCQUAIL[1,2], J. P. HIBBLE[3], J. L. BIZON[1], B. D. SHUGOLL[3], M. M. NICOLLE[2,4,3];
[1]Dept. of Neurosci., Univ. of Florida, Gainesville, FL; [2]Program in Neurosci., [3]Dept. of Physiol. & Pharmacol., [4]Dept. of Intrnl. Med. - Section on Gerontology, Wake Forest Univ., Winston-Salem, NC

Abstract: Age-related memory decline is associated with alterations to hippocampal synapses. Although various systems change with age, few studies have simultaneously investigated the integrity of multiple neurochemical-specific synaptic markers within the same animal. The current study measured changes in levels of vesicular transporter proteins that package acetylcholine (VAChT), GABA (VGAT) and glutamate (VGluT1) for synaptic release using tissue sections prepared from young (6 mo; n=9) and aged (24-25 mo; n=25) Fisher × Brown Norway F1 hybrid rats that were previously characterized for place learning ability in the Morris water maze. Behavioral analysis revealed that aged rats exhibited a broad range of individual differences in spatial learning performance, including subjects with obvious impairment (aged-impaired), but also a subset of aged rats that were behaviorally similar to young (aged-unimpaired). Histological sections were immunofluorescently labeled for VAChT, VGAT and VGluT1 proteins and scanned on a Typhoon FLA 9500 imaging system at a final resolution of 10 µm. Expression of all 3 markers was measured in the dorsal hippocampus using Image J software. This analysis revealed a significant reduction in VGluT1 expression in the hippocampus of aged rats compared to young, but this reduction was not related to spatial learning performance. Subregional analyses localized these age-related reductions in VGluT1 to the molecular layer of the dentate gyrus but notably, VGluT1 expression was unchanged by age in CA3 and CA1. Hippocampal expression of both VAChT and VGAT did not differ with respect to age or cognitive status. These data indicate that there is a specific, age-dependent deterioration in the biochemical composition of excitatory terminals in the molecular layer of the dentate gyrus. This loss is both system- and subregion-specific, as proteins that serve equivalent functions at cholinergic and GABAergic terminals were not affected by age nor was VGluT1 expression attenuated in CA3 and CA1 subfields. Ongoing analyses combining confocal microscopy and stereological methods are focused on determining whether observed differences

are due to biochemical reductions within synapses or reduced number of biochemically-defined synapses.

Title: The chronic treatment with L-DOPA impairs spatial working memory and increasing the nitrosative stress in the striatum and prefrontal cortex in rats with a 6-OHDA lesion

Authors: *G. RAMÍREZ GARCÍA, V. PALAFOX-SÁNCHEZ, I. D. LIMÓN PEREZ DE LEÓN;
Lab. De Neurofarmacología, Puebla, Mexico

Abstract: L-3,4-dihydroxyphenylalanine (L-DOPA) is administered over long term to improve motor functions in Parkinson‘s disease (PD) patients. Unfortunately, many motor complications such as on-off phenomenon, wearing-off, and dyskinesia arise over the years. There is evidence that metabolism of dopamine formed by L-DOPA generates free radicals such as nitric oxide, which may cause damage by nitrosative stress in the nigro-striatum-cortical pathway. This neuronal circuit has been implicated in cognitive processes such as spatial working memory (SWM). This memory type refers to the cognitive ability to update the information required to resolve a spatial task when contextual conditions change from one trial to the next.
In our work, we evaluated the effects of a L-DOPA chronic administration on SWM and nitrosative stress in SNpc, striatum and cortex prefrontal (PFC) in 6-hydroxydopamine (6-OHDA) lesioned rats. Control group received SSI and another group received orally L-DOPA/Carbidopa (100 mg/kg) for 20 days. After treatment the SMW task in water maze was done and then all animals were sacrificed in order to do the biochemical determinations. The nitrite levels were measured using the Griess method. The 3-nitrotyrosine (3-NT), induced nitric oxide synthase (iNOS) immunoreactivity was evaluated by immunofluorescence in the SNpc, striatum and PFC.
Our results showed that the L-DOPA treatment increases the deficit in SWM task moreover increased nitrites levels (15 %, 75 % and 58 %), the proteins nitration (74 %, 31 % and 118 %)

and up-regulation of the iNOS expression (132 %, 177 % and 155 %) in the SNpc, striatum and PFC respectively. These facts suggest that the L-DOPA induces stress nitrosative which could play a key role in impairment of synaptic communication involves in cognitive process such as SWM in rats with dopaminergic nigral lesion. Furthermore, in early stages of the PD the patients show deficit in SWM, these results propose that nitrosative stress is a probably toxicity mechanism caused by chronic administration L-DOPA in this PD patients.

Title: The neurofibromin directly interacts with the 5-HT6 serotonin receptor and regulates its function

Authors: *W. DERAREDJ[1], L. COBRET[1], F. GODIN[1], S. CHAUMONT[2], P. MARIN[2], H. BÉNÉDETTI[1], S. MORISSET[1];
[1]Ctr. de Biophysique Moléculaire, CNRS, UPR 4301, ORLEANS, France; [2]Inst. de Génomique Fonctionnelle, CNRS UMR 5203, Montpellier, France

Abstract: The serotonin 6 (5-HT6) receptor is almost exclusively localized in the CNS, predominantly in regions involved in the regulation of cognitive processes such as the cerebral cortex, the hippocampus and the striatum. Correspondingly, it has become an increasingly promising target for the treatment of cognitive deficits associated with various CNS disorders including Alzheimer's disease and schizophrenia. Although 5-HT6 receptors are known to signal through Gs-adenylyl cyclase, coupling pathways and mechanisms controlling their activity remain poorly explored. To address these issues, the team of P Marin has recently used proteomic approaches to identify novel signalling proteins associated with the receptor. These studies revealed that 5-HT6 receptor is coupled to the mTor pathway. Furthermore they demonstrated the interaction of the receptor with Neurofibromin (Nf1), which is known to control synaptic plasticity, learning and memory formation. Neurofibromin is a large protein

(280kDa) encoded by the NF1 gene. It is ubiquitously expressed at low levels with highest expression levels in nervous system cells (neurons, Scwhann cells, and oligodendrocytes) and in leucocytes. Mutations of the NF1 gene are responsible of the most common genetic diseases, type 1 neurofibromatosis (NF1), which affects 1 in 3500 individuals. The phenotype of NF1 is highly variable, with benign (neurofibromas) or malignant peripheral nerve sheath tumors, CNS tumors (gliomas, astrocytomas) and cognitive deficits (40% of NF1 patients).
In this study, we characterized biochemically 5HT6 receptor/Nf1 interaction, which, to our knowledge, constitutes the first connection between Nf1 and a GPCR. Co-immunoprecipitation experiments performed from HEK-293 cells coexpressing various Flag-tagged domains of Nf1 and HA-5-HT6 receptor indicated that three different domains of Nf1, the SecPH, the GAP and the C-terminal domains, are capable of interacting with the receptor. Moreover, using Bioluminescence Resonance Energy Transfer (BRET), we demonstrated that the SecPH domain interacts with the 5-HT6 receptor directly and with the highest affinity compared with the other domains. Our data also demonstrated that 5-HT6 receptors can constitutively associate with Nf1 independently of its agonist stimulation. The implications of these interactions on 5-HT6 downstream signalling pathway (cAMP production, mTor pathway activation) are being analysed. In conclusion, 5-HT6 receptor identified as a new partner of neurofibromin constitutes an interesting target to understand signalling pathways involved in cognitive deficits of NF1 patients.

Title: Effect of consumption of T2 dietary supplement in the short and long term memory and spine dentritic formation in mice

Authors: *M. I. TORRES-FLORES[1], C. FÉRNANDEZ-AGUILAR[3], S. GORDILLO-HIGAREDA[2], A. RAMÍREZ-RAMOS[3], E. PORTILLO-NAVARRO[3], M. RAMÍREZ-FLORES[3,2], R. HARO VALENCIA[3], M. APODACA-ARAGÓN[3], E. SÁNCHEZ[3], O.

GARCÍA[3,2];
[2]Psicofisiologia, [1]UNAM, Mexico City, Mexico; [3]Palsgaard Industri de Mexico, S. de R.L de CV, Mexico City, Mexico

Abstract: Down syndrome (DS) or trisomy 21, is the most frequent genetic cause of mental retardation. Several nutritional therapies have been implemented to reduce the cognitive deficits in SD patients. Recently we developed a food supplement named T-2. The consumption of supplement T-2 in DS patients improves attention and sleep quality. However, the cellular mechanisms involved in these improvements, and the effect it could have consumption supplement T-2 on other behaviors are unknown. In this work we explored whether: 1) administration of supplement T-2 in wild type mice has an effect on tasks associated with learning and memory processes and 2) whether the consumption supplement T-2 induce changes in dendritic spines of hippocampus. Our results show that two months after consuming supplement T-2, mice improve the performance on Novel Object Recognition (NOR) task, a model associated to short- term recognition memory; however, had no effect on spatial memory evaluated through aquatic "Y" maze. In addition we observed that consumption supplement T-2 increase the density dendritic spines. These results suggest that the improvements observed by use of T-2 supplement in mice and DS patients could be associated to an increase in the number of dendritic spines.

Title: Dopaminergic and cholinergic mediation of within-session concurrent discrimination learning

Authors: A. WYLIE[1], J. SEIDEMAN[3], D. YU[2], C. BLACKWELL[1], M. MISHKIN[1], *J. N. TURCHI[1];
[1]LN, [2]NIF, NIMH, NIH, Bethesda, MD; [3]Ctr. for Neural Sci., NYU, New York, NY

Abstract: Prior work has shown that monkeys can learn a set of visual discriminations presented concurrently only once daily on successive days (24-h ITI task) based on habit formation, served by a visuo-striatal circuit that is independent of the visuo-rhinal circuits serving one-trial recognition memory. Likewise, it has been reported that systemic antagonism of dopaminergic receptors via haloperidol impairs performance on the 24-h ITI task, but fails to have an impact on recognition memory. Conversely, systemic administration of the muscarinic receptor antagonist scopolamine causes deficits in one-trial visual recognition but has only a negligible impact on concurrent visual discrimination learning. In a recent report, monkeys were trained on a short-ITI version of concurrent visual discrimination learning. Stimulus pairs were repeated not only across daily sessions but also several times within each session (with roughly 4-min ITIs). The baseline discrimination learning rates were substantially reduced in this short-ITI version, from ~11 trials/pair to criterion on the 24-h ITI task to ~5 trials/pair on the 4-min ITI task, and systemic injections of either haloperidol or scopolamine impaired this more rapid learning (~16 trials/ pair and 12 trials/ pair, respectively). In the current study, we compared the effects of local, bilateral, microinfusions of the dopamine D2-selective antagonist eticlopride (6.36 mM) into the tail of caudate nucleus (2 μl/site) and ventral putamen (3 μl/site), combined with microinfusions of scopolamine (20 mM) into the perirhinal cortex (3 μl/site), with the effects of infusing equivalent volumes of saline into these same targets. Preliminary evidence (n=2) indicates that while learning rates were similarly rapid following local saline infusions to these regions (~3 trials/pair), the combined local drug administration impeded learning (~14 trials/ pair). Separate drug infusions within these different regions will enable us to elucidate the visuo-striatal and visuo-rhinal circuits that operate in tandem during within-session concurrent discrimination learning.

Title: FAAH inhibition improves memory performance in APP/PS1 transgenic mice

Authors: *L. E. WISE, B. C. RIEDEL, A. H. LICHTMAN;
Pharmacol & Toxicol, Virginia Commonwealth Univ., RICHMOND, VA

Abstract: The present research evaluated a novel potential treatment for Alzheimer's disease. Specifically, we treated APP/PS1 transgenic mice chronically with an inhibitor of fatty acid amide hydrolase (FAAH), the enzyme that is responsible for the breakdown of the naturally occurring marijuana-like brain chemical (i.e., endogenous cannabinoid) anandamide. This FAAH inhibitor, PF3845, produces up to ten fold increases in brain anandamide levels, elicits anti-inflammatory effects, and is devoid of marijuana's psychomimetic effects. We proposed that PF3845 would have anti-inflammatory and neuroprotective actions and consequently have beneficial effects on memory performance in the water maze in APP/PS1 transgenic mice, an in vivo mouse model of Alzheimer's disease. APP/PS1 transgenic mice and their non-transgenic littermates were administered 10 mg/kg PF3845 or vehicle for eight weeks (once daily for five days each week) starting at five months of age. Memory performance was evaluated in the water maze starting when the mice were seven months of age. We found that the APP/PS1 transgenic mice had memory impairments in the fixed platform water maze task as compared to non-transgenic mice. Repeated treatment with PF3845 improved memory performance in the water maze in the APP/PS1 transgenic mice, but not in the non-transgenic mice. Additionally, we also evaluated whether acute treatment with vehicle or 10 mg/kg PF3845 (i.e., drug administration only before water maze testing) improves memory function in APP/PS1 transgenic mice. In contrast to repeated treatment, acute treatment with PF3845 did not improve water maze performance in APP/PS1 transgenic mice. Our results indicate that PF3845 improves memory performance in APP/PS1 transgenic mice suggesting that FAAH inhibition may have beneficial effects on cognition in Alzheimer's disease. Future studies will determine whether repeated treatment with PF3845 also decreases neuropathological markers associated with Alzheimer's disease in APP/PS1 transgenic mice.

Title: Are pre-training habituation sessions a valid method in the study of learning and memory in rats and mice?

Authors: *R. M. ABUHAMDAH[1], P. CHAZOT[1], S. ABUHAMDAH[2], A. ENNACEUR[3]; [1]Durham Univ., Durham, United Kingdom; [2]Univ. of Jordan, Amman, Jordan; [3]Univ. of Sunderland, Sunderland, United Kingdom

Abstract: In most studies of learning and memory, animals are introduced to a behavioral test with the implicit assumption that pre-training habituation sessions are sufficient to equalize the level of emotionality between groups. However, the number of these sessions is defined a-priori, and varies widely between laboratories. Depending on the number and duration of the habituation sessions, anxiety from novelty and unfamiliarity may be retained over the training sessions, and prevent the acquisition of a cognitive task, particularly in animals that had a brain lesion or that received a chronic drug treatment before introduction to the test apparatus.
In a series of experiments, we exposed mice to a 3D radial-maze without preliminary habituation sessions. In this maze, mice need to cross a bridge radiating from a central platform to reach onto an arm. We used different strains of mice (Balb/c, C57BL/6J and CD-1), aged male and female CD-1 mice, and C57BL/6J mice treated with dizocilpine.
When exposed for the first time to this maze, mice display fear and anxiety. Anxious mice do move beyond the bridges. In our experiments, all mice made numerous entries onto the bridges and took longer time to cross onto the arms of the maze. C57, CD-1 and Balb/c mice made respectively 8 arm choices in the second, third and fifth sessions. Though Balb/c appeared the most anxious strain, they performed better than C57 and CD-1 in subsequent training sessions. In a second experiment, C57 received ip injection of 0.1 mg/kg of MK-801 before each test session. This led to significant increase in the number of crossings onto the bridges, and a decrease in the number of crossings onto the arms. In the third experiment, we used young and adult CD-1 of both sexes. They all required 3 sessions to make 8 arm choices. Male adult made significantly

more bridge entries and more arm repeats compared to the other groups.
The present studies indicate that the number of habituation sessions cannot be determined a-priori. Emotional responses to novelty and test environment vary between strains and could be affected by an experimental manipulation such as lesions, drugs or genetic manipulation.

Title: Effects of methamphetamine on allocentric learning and memory in rats

Authors: *A. GUTIERREZ[1], R. M. AMOS-KROOHS[2], M. T. WILLIAMS[3], C. V. VORHEES[3];
[1]Neurosci. Grad. Program, [2]Mol. and Developmental Biol., Univ. of Cincinnati, Col. of Med., Cincinnati, OH; [3]Div. of Neurol., Cincinnati Children's Res. Fndn., Cincinnati, OH

Abstract: Housing animals in cages with reduced bedding has been shown to increase stress-related glucocorticoid release. Excessive stress adversely affects learning and memory (L&M) whereas moderate stress can have the opposite effect. Neurotoxic doses of methamphetamine (MA) impair some types of L&M but effects on allocentric L&M have been ambiguous. The present study investigated the effects of standard vs. low bedding (barren cage) housing in combination with neurotoxic MA on Morris Water Maze (MWM) L&M using a larger than normal pool size to increase task difficulty (244 cm diameter). After acclimation, male Sprague-Dawley rats were placed in cages with a paper towel only (Barren) or standard bedding (Std.) 3 weeks prior to treatment. Half of the animals in each housing condition received 10 mg/kg MA x 4 at 2 h intervals and half received saline (s.c.) on the same schedule. Testing began two weeks later. Testing began with rats receiving 4 trials in a 244 cm straight swimming channel to acclimate them to swimming and assess swim speed. The MWM consisted of 23 days given in 4 phases. The first 3 phases were hidden platform trials each being 6 days (4 trials/day) with a single probe trial on day-7 with no platform. Platform positions and sizes varied with each phase: acquisition (SW, 10 cm), reversal (NE, 7 cm), and shift (NW, 5 cm). The 4th phase was cued for 2 days (4 trials/day; 10 cm platform) with a ball mounted above the platform to mark its location.

There were no effects on swim speed in the straight channel or on cued trials. On hidden platform trials, MA-treated groups (regardless of housing) were significantly impaired in finding the platform on all 3 phases. There was no effect of MA on acquisition-probe, but MA-treated animals had longer average distance to the platform site on reversal and shift-probe trials. Barren housing only affected acquisition. Barren-housed rats, regardless of treatment, reached the platform more efficiently than Std. housed rats. These data suggest that a greater pool size to platform ratio is able to reveal clear spatial L&M deficits following MA-induced neurotoxicity. (Supported by NIH T32 ES07051)

Title: Discovery of Lu AF58801, a novel, selective and brain penetrant positive allosteric modulator of alpha-7 nicotinic acetylcholine receptors: Attenuation of subchronic phencyclidine (PCP)-induced cognitive deficits in rats following oral administration

Authors: *J. F. BASTLUND[1], C. BUNDGAARD[1], K. DEKERMENDJIAN[1], R. L. PAPKE[3], J. P. REDROBE[1], K. FREDERIKSEN[2], J. ESKILDSEN[2];

Abstract: α7 nicotinic acetylcholine receptors (nAChR*α*7) are expressed in brain areas involved in cognitive processing such as the hippocampus, thalamic nuclei, and frontal cortex, and decreased expression has been reported in diseases associated with memory impairment, including schizophrenia and Alzheimer's disease. To this end, compounds like EVP6124 and TC5619, acting as agonists of the nAChR*α*7's, have recently been shown to alleviate cognitive disturbances associated with schizophrenia and alzheimer's disease in small clinical phaseII studies. In contrast to agonists, nAChR*α*7 positive allosteric modulators (PAM) can reinforce endogenous cholinergic transmission without directly stimulating the target receptor. Accordingly, nAChR*α*7 selective PAMs have emerged as potential superior drug target class. We describe a novel nAChR*α*7 PAM, Lu AF58801, which is a potent, orally available, brain

penetrant PAM of the α7 nicotinic acetylcholine receptor, showing efficacy in a novel object recognition task in rats treated subchronically with phencyclidine (PCP).

Title: The effect of cocaine on delay discounting in the spontaneously hypertensive rat

Authors: M. CLASEN[1], S. SEQUEIRA[1], J. J. O'MALLEY[1], A. SHEMERY[1], S. MCVAY[1,2], D. HOLT[1], *J. DYCHE[1];
[1]Psychology, James Madison Univ., Harrisonburg, VA; [2]St. Louis Univ., St. Louis, MO

Abstract: Cocaine intoxication is characterized by maladaptive behavioral or psychological changes including affective blunting, changes in sociability, anxiety and impaired judgment. Perhaps the most controversial and adverse side effects of long-term cocaine use are increased impulsivity which is seen in human and animal models (Moeller et al., 2001; Simon, Mendez, & Setlow, 2007). Impulsivity is behaviorally defined as picking a smaller, immediate reward (impulsive choice) over a larger, later reward (self-control choice) and is neurobiologically linked to dopamine receptors in the dorsal and ventral striatum. In animals, the spontaneously hypertensive rat (SHR) is one of the most widely used models of ADHD. The SHR exhibits the major behavioral symptoms of ADHD as well as having face validity and construct validity (Sagvolden, 2000). The literature indicates that cocaine seeking behavior is also linked to connectivity in the dorsal and ventral striatum (Belin & Everitt, 2008). Therefore, the present study examined the effects of acute cocaine administration on impulsive behavior measured by an adjusting-amount delay discounting procedure. Implementing a pre-test and post-test experimental design, baseline rates of discounting were measured. Four Sprague Dawley and

four SHR rats were sensitized to cocaine HCl for 14 days at a dosage of 30 mg/kg through intraperitoneal injections during sensitization. Following cocaine sensitization was an intermediate period for 28 days where the rats were housed in home cages. Through the use of an adjusting amount procedure used by Green et al., (2004) we calculated indifference points for each rat. An indifference point is defined as the point which the animal has the same preference for the immediate, adjusting reward and the delayed, standard reward. Results demonstrated the SHR were more impulsive than the Sprague Dawley and the animals had differential impulsivity after cocaine sensitization. This indicates that short-term use of cocaine may have effects on impulsive choice well after cocaine administration has terminated. Additionally, the plasticity of the striatum is implicated and future studies will examine the functions of metabatropic dopamine receptors in delay discounting.

Title: The role of NMDA receptors in the consolidation of habit memory

Authors: *K.-C. LEONG, M. G. PACKARD;
Psychology, Texas A&M Univ., College Station, TX

Abstract: Extensive evidence indicates that the dorsolateral striatum selectively mediates the acquisition of stimulus-response habit memory. However, relatively few studies have addressed the role of glutamate receptors within the dorsolateral striatum in consolidation of stimulus-response habits. The present experiment was designed to examine the potential role of the glutamatergic *N*-methyl-D-aspartate (NMDA) receptor in the consolidation of dorsolateral striatal-dependent habit memory. Adult male Long-Evans rats received training (6 trials per day for 4 days) in a dorsal-striatal-dependent "forced-response" water plus-maze task, in which rats were trained to swim from varying start points (north, south) and to make the same body turn response (e.g. turn right) at the choice point of the plus-maze in order to reach a hidden escape platform. Immediately following training, rats received posttraining infusions of AP5 (2 µg), an NMDA antagonist, directly into the dorsolateral striatum on days 1 to 3 of training. Posttraining administration of AP5 impaired memory consolidation in the response learning task relative to

control animals that received posttraining vehicle infusions. These results suggest that NMDA receptors within the dorsolateral striatum are critical for the consolidation of stimulus-response habit memories.

Title: The separate or concurrent effects of methylphenidate and alcohol on acquisition and retention of the Morris Water Maze in adolescent rats

Authors: M. CREECH, L. SCOTT, K. LIVESAY, *L. BAKNER;
Psychology, Linfield Col., MCMINNVILLE, OR

Abstract: Alcohol's (A) capacity to impair learning and memory has been well documented in the Morris Water Maze (MWM) but few studies have examined methylphenidate's (MPH) impact on MWM performance (Haidun et al., 2010; Zeise et al., 2007). Even fewer studies have evaluated concurrent administration of these two drugs in adolescent rats (see Markwiese, et al., 1998). This project used a rat model of adolescent drug use to examine individual effects of MPH and A, as well as polypharmacy interactions between MPH and A, on MWM spatial acquisition and retention.
32, adolescent (P30), male Long-Evans hooded rats were used. Subjects were assigned to one of 4 conditions based on drug administered prior to 6 consecutive acquisition sessions. Animals received 2 i.p. injections prior to each session. The methylphenidate group (MPH+S) received 2 mg/kg MPH and 1 ml/kg saline solution (S), the alcohol group (A+S) received 2 g/kg ethanol and S, the methylphenidate and alcohol group (MPH+A) received both MPH and A, and the saline control group (S+S) received S injections. MPH was administered 50 mins prior to each session and A administered 20 mins prior to each session. Each session consisted of 4 trials and rats swam from one of four start locations (N,E,S,W) to a submerged platform in the NE quadrant. Trial duration was 60 seconds and rats remained on the platform for 10 secs. Performances were video recorded, and latency and swim accuracy scored. Whishaw Corridors established a direct swim path from start location to platform and an error was recorded when swim paths exited the corridor. On day 7, the submerged platform was removed and a single, 60 sec retention test was conducted with no drug administered prior to test. Amount of time spent

swimming in the NE quadrant was analyzed to assess retention.
Acquisition. Both dependent measures, latency and swim accuracy, yielded similar outcomes. Factorial ANOVAs and post hoc tests showed improvement across training sessions for all groups. Importantly, the MPH+A group was impaired relative to all other conditions, and the S+S group performed better than the A group. No significant differences were observed between S+S and MPH+S groups.
Retention. A One-way ANOVA of swim time in the NE quadrant revealed longer swim times for the S+S group compared to the A+S group, and longer swim times for the MPH+S group compared to the A+S group. No other significant differences were observed.
While all groups improved performance during acquisition, methylphenidate + alcohol compromised spatial learning and alcohol alone impaired learning relative to controls. Interestingly, measures of retention indicated only alcohol diminished spatial memory in adolescent rats.

Title: Effects of intrastriatal naloxone infusion on spatial navigation performance in the rat: Implications for the treatment of obsessive compulsive disorder

Authors: J. PISCOPELLO, N. CHABAN, *B. D. DEVAN;
Psychology, Towson Univ., TOWSON, MD

Abstract: The present study investigated the possible role of mu-opiate receptors within the dorsal striatum in the spatial navigation performance of rats trained in the water maze. Intrastriatal guide cannula were stereotaxically implanted to target the anteromedial part of the caudate-putamen (CPu) complex and following a 2-3 week recovery period, subjects were trained to find a hidden platform at a fixed location in the water maze for 16 days (4 trials/day). On day 10, rats were given a passive placement test to assess checking behavior. On day 17 (retraining), subjects were infused bilaterally with the mu-opiate receptor antagonist naloxone (15 µg/side) or vehicle control (0.9% NaCl) and received four escape trials with the platform moved to a new location. A 60 sec place competition test was given the following day. Intrastriatal naloxone infusion slowed swim speed but did not alter escape performance during

retraining. The naloxone group showed shorter path lengths and entered the 'old' radial quadrant less than controls on the competition test. The present findings provide evidence for the involvement of the mu-opiate receptor-rich striatal patch compartment in the higher-order habit control of associative spatial processing (Devan, Hong & McDonald, 2011, Neurobiol Learn Mem, 96:95-120). Implications for the treatment of OCD symptoms such as compulsive checking are discussed.

Title: Motor impairment and behavior alteration tested in open field in 21 day-old male mice postnatally treated with midazolam

Authors: *A. MARQUEZ-OROZCO[1], I. JIMENEZ-ESTRADA[2], G. DE LA FUENTE-JUAREZ[1], S. SANTIAGO-LOPEZ[1], J. JOYA-VENEGAS[1], A. FORTANEL.FONSECA[1], A. FORTANEL.FONSECA[1], M. MARQUEZ-OROZCO[1];
[1]Dept Embryol, Univ. of Mexico (UNAM), Mexico 04510 DF, Mexico; [2]Physiology, Biophysics and Neurosciences, CINVESTAV-IPN, Mexico DF, Mexico

Abstract: Midazolam (MDZ) is a hypnotic benzodiazepine that rapidly induces tranquility and deep sleep during brief surgical procedures performed with local anesthetic. The drug is easily transported into the brain after intravenous infusion. MDZ induces an anterograde amnesia that creates an illusion of anesthesia in some patients. Intravenous administration of MDZ has been widely used in pediatric patients for conscious sedation in procedures such as lumbar punctures and bone marrow aspiration.
MDZ administered postnatally alters the development of both neuronal and Purkinje cells in cerebral and cerebellar cortices. The purpose of this work was investigated if 21-day-old male mice postnatally treated with MDZ develop motor impartment and behavior alterations tested in open field.
Two neonatal ICR strain male mice groups were injected daily sc from day 6 to 9 postnatal. The first group (MDZ) was treated with single daily MDZ doses (1.0 mg/kg/bw/sc) and the second group (C) with saline solution. The pups (10 MDZ and 10 C), were tested in an open field 50x50x20 cm for 5 min at 21-days of age. The open-field behavior was video-recorded. In a

screen the open field was divided in 9 equal squares and the number of squares visited by each mouse was registered during 5min. The distance (cm) and velocity (cm/s) were analyzed using a computerized digital system of the Department of Physiology, Biophysics and Neurosciences, CINVESTAV-IPN. The male mice of the MDZ group displayed a significantly higher exploratory behavior than the C mice group. The mean of distance run by MDZ male mice group, the velocity and the number of squares visited were statistically significant higher in the MDZ group mice than in the C group mice. The alterations observed may be attributed to delayed neuronal differentiation and cell neurodegeneration produced in cerebral and cerebellar cortices induced by MDZ exposition from 6 to 9 days old male mice.
Drugs that potentiate GABAA receptors such as MDZ and diazepam can trigger widespread apoptotic neurodegeneration. In the case of MDZ it has been previously shown that doses sufficient to maintain surgical anesthesia for 6 hr in 7-day-old rats cause widespread apoptotic neurodegeneration in the developing brain and persistent memory/learning impairment. We found similar results, which may be explained by the histological changes in the cerebral and cerebellar cortices induced by postnatal exposure to MDZ that we found in our trial.

Title: High-energy diet alters intrinsic excitability in young hippocampal CA1 neurons: Gender-dependent responses to insulin

Authors: *E. UNDERWOOD, L. T. THOMPSON;
The Univ. of Texas At Dallas, Richardson, TX

Abstract: Alarming increases in dietary fat intake and subsequent rises in obesity/insulin resistance/type II diabetes necessitate a focus on the effects of diet on normal physiological brain function and on cognitive performance. Rats trained in a passive-avoidance task exhibit enhanced memory retention 24 hr or more later when intrahippocampal insulin is administered immediately post-acquisition (Babri et al., 2007). Successful consolidation of many different

learning tasks (e.g. inhibitory avoidance training or trace eye-blink conditioning) reduce Ca2+ dependent afterhyperpolarizations (AHPs) of hippocampal CA1 pyramidal neurons (Farmer & Thompson, 2012). Since successful learning of a task is accompanied by a reduction of AHPs (i.e. an increase in intrinsic excitability) and insulin enhances memory retention, we investigated the effects of a chronic high-energy diet, which can alter basal insulin, on measures of CA1 hippocampal neuron intrinsic excitability which regulate information transfer to hippocampal efferents: effects of diet and of insulin on post-burst afterhyperpolarizations.
Male and female young adult Long-Evans rats (4-6 mo) were fed from weaning either a control diet (14% fat, 64.8% carbohydrate, and 21.2% protein) or a high-energy diet (57.6% fat, 26.8% carbohydrate, and 15.6% protein) prior to brain slice preparation. The experimental high-energy diet was augmented with slow-digesting casein protein and medium-chain triglyceride polyunsaturated coconut oil to achieve the desired ratios. After slice preparation, in vitro current clamp recordings were made to assess post-burst AHPs, accommodation, and passive membrane properties. After baseline recordings, brain slices were perfused with insulin (0, 6, 12.5, 25, or 50 nM) and recordings were repeated.
Young control female CA1 neurons had smaller peak AHP amplitudes (~4.0 mV), both reduced medium AHPs (mAHPs) and reduced slow AHPs (sAHPs), and reduced accommodation (fired more spikes to a sustained depolarization), while on all these measures male control neurons were less intrinsically excitable. After 2 mo on chronic high energy diet, this gender-dependent profile was not only reversed, but intrinsic excitability of CA1 neurons from both genders was significantly reduced. Neurons from females on the high-energy diet had significantly larger mAHPs and sAHPs of longer duration and area than those from males, which were still significantly enhanced by the diet compared to controls. These neurophysiological changes, occurring within a relatively short time frame, could have significant cognitive consequences, which will be assessed in the next phase of our studies.

Title: α7 nicotinic acetylcholine receptor (α7 nAChR) antagonists as potential cognition enhancers

Authors: *N. P. VAN GOETHEM[1], L. WENNOGLE[2], H. STEINBUSCH[1], J. PRICKAERTS[1]; [1]Psychiatry & Neuropsychology, Maastricht Univ., Maastricht, Netherlands; [2]Intra-Cellular Therapies, Inc., New York, NY

Abstract: α7 nicotinic acetylcholine receptors (α7 nAChRs) are ligand-gated ion channels expressed primarily in the brain. These receptors have been implicated in modulating many cognitive functions like attention, episodic memory and learning. α7 nAChRs are located both pre- and postsynaptically and modulate glutamate, GABA and dopamine. Furthermore, α7 nAChRs are directly involved in hippocampal long-term potentiation (LTP), the putative cellular mechanism underlying learning and memory. Activation of α7 nAChRs through selective, partial or full agonists and/or modulators, has been shown to improve cognitive function in both animal and human studies. The main cognitive improvement with these compounds relate to memory, in accordance with the high level of expression of α7 nAChRs in the frontal-cortex and hippocampus. Hence, α7 nAChR agonists/modulators may be attractive drug candidates to improve cognition in Alzheimer's disease (AD) and schizophrenia patients. The objective of the current study was to investigate the cognition enhancing properties of low dose administration of selective α7 nAChR antagonists in rats as low doses of MLA have sporadically been reported to improve cognition in animals. Furthermore, MLA has been shown to facilitate LTP induction in hippocampal region CA1 in rats..Memory performance was assessed with the object recognition task (ORT). The compounds used for these studies were methyllycaconitine (MLA) and Compound 7i. MLA is a norditerpenoid alkaloid produced by many species of Delphinium (larkspurs) and is often used because of its ability to potently antagonize the α7 nAChRs Compound 7i is a relatively new selective α7 nAChR antagonist.. In the current study, it was found that both Compound 7i and MLA improved memory of rats in the ORT natural forgetting (i.e. 24h retention interval) paradigm (optimal dose range: Compound 7i; 0.1-1.0 mg/kg, MLA; 0.003-0.1 mg/kg, i.p.). Moreover, it was found that a dose that was too high to improve memory in the natural forgetting paradigm (Compound 7i; 3.0 mg/kg, MLA; 1.0 mg/kg, i.p.), was also sufficient to induce a memory deficit in the 1 h retention interval ORT, an interval that normally leads to good memory performance of rats. Among other possibilities, one explanation for these findings could be that α7 nAChR antagonists promote α7 nAChR resensitization. This hypothesis is currently investigated. In summary, while the main focus of the α7 nAChR as a target for cognition enhancement lies on agonists and positive modulators, the antagonists of these receptors might also prove to be a valuable tool for cognition enhancement in AD or schizophrenia.

Title: Prenatal choline supplementation prevents behavioral and neural impairments of adult MK-801 exposure in male rats

Authors: *C. A. NICKERSON[1], A. L. BROWN[2], M. J. GLENN[2];
[2]Psychology, [1]Colby Col., Waterville, ME

Abstract: Choline is essential to the development and function of the central nervous system. Supplemental levels, especially in development, protect against a variety of neural insults. The goal of the present study was to investigate whether prenatal choline supplementation protects against behavioral deficits and neural dysfunction precipitated by dizocilpine (MK-801) given in adulthood. MK-801 is an NMDA receptor antagonist frequently used in rodent models of psychological disorders. At low doses, it impairs cognition and at high doses it impairs motor function and degenerates axons. In this study, timed-pregnant female rats were fed either a control synthetic diet (AIN67A with 1.1 g/kg choline chloride; STD) or a choline-supplemented diet (AIN67A with 5 g/kg choline chloride; SUP). At birth, pups were cross-fostered and reared in mixed litters. As adults, 39 male rats were assigned to a saline or MK-801 condition, resulting in 4 groups: STD-SAL (n=9); STD-MK (n=10); SUP-SAL (n=10); SUP-MK (n=10). To assess memory, we used the novelty preference task of object recognition. After a 5-min study phase, rats received saline or MK-801 (0.2 mg/kg i.p.) injections and memory was assessed 3 hr later. MK-801 significantly impaired memory in STD rats; this effect was prevented in SUP rats. Two weeks later, rats were given a larger MK-801 injection (3 mg/kg i.p.) and motor function was evaluated for 3 hrs post-injection. MK-801 significantly increased locomotion, stereotypy, and ataxia over the course of the observation period in STD rats; these effects were significantly attenuated in SUP rats. Three days later, rats were sacrificed under isoflurane anesthesia and decapitated. Extracted brains were post-fixed and sectioned on a vibratome. A series of 30-µm frontal sections were retained for Fluoro-Jade B staining to mark degenerating axons. STD-MK rats displayed non-significant increases in marked axons compared to all other groups--a finding consistent with protection in SUP rats. A series of 60-µm hippocampal sections were retained for doublecortin immunohistochemistry to mark new, immature neurons. In this case, STD-MK rats displayed significantly fewer new neurons compared to the other groups. Taken together, these findings provide overwhelming evidence that SUP rats were protected against the toxic effects of

MK-801 on behavior and choline may exert this protection by slowing injury to axons and declines in neural plasticity. In particular, the capacity for choline to mitigate the motor defects induced by MK-801 was a novel and compelling result. This research contributes to the growing body of evidence supporting the robust neuroprotective capacity of choline.

Title: The effect of donepezil and memantine on impaired spatial memory performances in a non-human primate, the grey mouse lemur

Authors: A. RAHMAN[1], F. PIFFERI[1], Y. LAMBERTY[2], E. SCHENKER[3], *M. SPEDDING[4], R. BORDET[5], J. C. RICHARDSON[6], F. AUJARD[1];

Abstract: Background: Clinical trials have shown the evidance of symptomatic benefits of acetylcholinesterase inhibitors such as donepezil (DPZ) and an N-methyl-D-aspartate (NMDA) receptor antagonist, memantine (MEM) in patients with Alzheimer's disease (AD). However, only 40% of patients respond positively to this treatment. The grey mouse lemur, a non-human primate, is one of the very few animals that spontaneously develop most of the AD-related neuropathologies. Here we tested the efficacy of DPZ and MEM on impaired spatial memory performance following sleep deprivation (SD) used as non pharmacological challenge to induce transient cognitive impairment. This study is part of a work performed on mouse lemur to validate this model for future drug testing programs in AD.
Methods: Thirty three adult male mouse lemurs aged between 2 to 3 years were used. Cognitive impairment was induced by 8h of SD and spatial memory performance was assessed in a radial arm maze. In a 2-day protocol, mouse lemurs underwent training and testing session on day 1. On day 2, animals were submitted to 8h SD and retested afterwards. The sleep deprived group

(SD) underwent the protocol without any intervention. The DPZ-treated group received intraperitoneal 0.1mg/kg (DPZ-0.1) and 1mg/kg (DPZ-1) and MEM-treated group 0.1mg/kg (MEM-0.1) and 1mg/kg (MEM-1) 3h before the cognitive function test. The saline treated group (Sal) received only saline. All animal studies were ethically reviewed and carried out in accordance with European Directive 2010/63/EU on the Care, Welfare and Treatment of Animals.
Results: The "SD" group showed an increase of the number of errors (NE) and of the latency to reach the goal box during testing, which were significantly higher than that of training phase (NE=3.45± 0.93 vs 6.14±1.72, p=0.045; latency 293.2±43.8 vs 465.5±49.1, p=0.042). This SD-induced deficit was not observed in the "DPZ-0.1" (p= 0.127) and "DPZ-1" (p=0.246) group. The "Sal" group showed a significantly higher NE than that of training phase (4.83± 1.10 vs 2.44± 0.36, p=0.013). The effect of MEM is yet to be completed.
Conclusion: The present results indicate that donepezil was able to prevent the cognitive impairment induced by SD in the mouse lemur. This further support the utility of this model, in particular for evaluating novel AD therapeutics.
The research leading to these results was conducted as part of the PharmaCog consortium funded by the European Community's Seventh Framework Programme for the Innovative Medicine Initiative under Grant Agreement n°115009. For further information please refer to www.pharmacog.org

Title: Posttraining peripheral administration or intra-dorsolateral striatum injection of the cannabinoid 1 (CB1) receptor agonist WIN 55, 212-2 impairs the consolidation of habit memory

Authors: *J. GOODMAN, M. G. PACKARD;
Psychology, Texas A&M Univ., College Station, TX

Abstract: Converging evidence indicates that the cannabinergic system plays a role in modulating memory processes. Previous work from our laboratory employing response learning in a water plus-maze task indicates that posttraining peripheral administration of a cannabinoid

agonist impairs the consolidation of habit memory. In the present study, we examined whether this impairing effect of peripheral cannabinoids can be replicated using a visible platform water maze task and whether posttraining infusions of a cannabinoid agonist into the dorsolateral striatum (a brain region well-known for its role in consolidation of habit memory) also produces an impairment in this habit memory task. Adult male Long-Evans rats were trained for 1 day (for 8 trials) in a cued platform water maze task in which rats were released from different start points and in order to escape had to find a cued platform which was moved to various spatial locations across trials. Immediately following training, rats received an i.p. injection of the CB1 receptor agonist WIN 55, 212-2 (1mg/kg or 3mg/kg) or a vehicle solution. In a separate study using the same water maze task, rats received posttraining bilateral infusions into the dorsolateral striatum of WIN 55, 212-2 (100ng/.5μL or 200ng/.5μL) or vehicle solution. 24 hours later rats were given two probe trials, and the latency to reach the platform on these two trials served as an index of memory. Relative to the vehicle-treated controls, peripheral WIN 55,212-2 at the 3mg/kg dose significantly impaired memory ($p < .05$). Bilateral intra-striatal infusions of WIN 55, 212-2 at 200ng/.5μL also produced a significant impairment of memory ($p< .05$). Taken together, the results indicate that peripheral or intra-striatal administration of a CB1 receptor agonist impairs consolidation of dorsolateral striatal-dependent memory. We suggest that pharmacological agents that target the cannabinergic system may prove useful in the treatment of some human psychopathologies, in particular those characterized by strong habit-like behavioral features.

Title: Methylphenidate enhances olfactory discrimination reversal learning in rats

Authors: S. E. MAGGIO[1], *J. GALIZIO[2];
[1]Psychology, [2]Univ. North Carolina, Wilmington, NC

Abstract: Recent work has shown conflicting results in the effects of methylphenidate (MPD) on reversal learning of spatial tasks, but there is little relevant research on non-spatial reversal learning. In the current study, the effects of MPD on reversal learning with olfactory stimuli in

six male Sprague-Dawley rats were examined. Using an automated olfactometer, subjects were trained in a two-odor discrimination task and its reversal. Each subject received testing on a multiple within-session discrimination reversals in baseline, and after saline, 1.0 mg/kg, 3.0 mg/kg, and 10.0 mg/kg doses of MPD. The 1.0 mg/kg dose of MPD increased the rate of reversal learning in one of the six subjects. The 3.0 mg/kg dose of MPD produced an increase in reversal learning above saline levels in five subjects. Impairments in reversal learning were observed in most rats at the 10.0 mg/kg MPD dose, but this dose also impaired accuracy on a well-learned discrimination, and seems most likely to involve a general performance deficit. In sum, the 3.0 mg/kg dose of MPD produced fairly consistent enhancement of reversal learning with olfactory stimuli using this repeated discrimination reversal procedure.

Title: Interactions of methamphetamine and HIV gp120 expression on discrimination learning in the mouse

Authors: *J. P. KESBY, A. MARKOU, S. SEMENOVA;
Psychiatry, Univ. of California San Diego, La Jolla, CA

Abstract: HIV-infected patients show deficits in learning and executive function. Methamphetamine (METH) abuse is common among HIV-infected individuals. However, whether METH abuse exacerbates learning deficits in patients with HIV remains unclear. The HIV/gp120 protein induces neuropathology in mice similar to HIV-induced pathology in humans. We investigated the separate and combined effects of METH exposure and expression of the HIV/gp120 protein on cognitive function in adult male transgenic (gp120TG) and control mice (nonTG).
Mice were exposed to an escalating METH binge regimen. Two months later, mice were tested in the attentional set-shifting task (ASST) assessing discrimination and reversal learning. The ASST included simple discrimination, compound discrimination, compound reversal, intradimensional shift and intradimensional reversal stages. Two exemplars (odor or platform

texture) were counter-balanced between test groups. The percentage of mice that failed to complete each stage (i.e. failure rate) and the number of trials to criterion (six consecutive correct responses) were analyzed.
The platform exemplar was significantly more difficult for the mice to discriminate than the odor exemplar as reflected by significantly more trials required to complete stages with platform discrimination and greater failure rates compared to odor discrimination stages. There was no effect of gp120 expression or METH exposure on the failure rate in the odor-based ASST. However, the failure rate of gp120TG mice in the platform-based ASST was significantly greater compared with nonTG mice. METH exposure exacerbated the gp120-induced failure rates in the platform-based ASST. Independent of METH exposure or the exemplar used, gp120TG mice required significantly more trials than nonTG mice to complete the discrimination, but not the reversal, stages suggesting that increased failure rates were due to impaired discrimination learning.
These results demonstrate that gp120 expression impairs discrimination learning in mice and this effect is exacerbated by METH exposure. The interaction of METH exposure and gp120 expression were only revealed under experimental conditions with increased task difficulty. Our findings in gp120TG mice suggest that learning deficits in humans with HIV infection may be partially due to the effects of the gp120 protein and deficits may be exacerbated with METH abuse. Thus, understanding the role of HIV-related proteins in HIV-induced learning deficits may allow for improved treatment of specific aspects of cognitive performance in HIV-infected patients.

Title: The benzodiazepine antagonist, flumazenil, mitigates the post-anesthesia effects of the inhaled anesthetic, isoflurane

Authors: J. A. FIDLER[1,2], B. L. RAYMOND[2], S. C. BURKE[3], S. R. BABER[1], C. KARLAPALEM[2], *P. S. GARCIA[1,2];
[1]Anesthesiol., VA Med. Ctr., Decatur, GA; [2]Anesthesiol., Emory Univ. Sch. of Med., Atlanta, GA; [3]Anesthesiol., Univ. of California San Francisco, San Francisco, CA

Abstract: Emergence from general anesthesia involves activation of several monoaminergic arousal pathways in the brain stem. Recently, pharmacologic inhibition of GABA activity using flumazenil has been shown to improve vigilance in hypersomnic subjects. In this study, the authors tested the hypothesis that flumazenil - widely considered a rescue drug for benzodiazepine toxicity - improves recovery from anesthesia. Using adult rats anesthetized for 30 minutes with isoflurane, a GABA-enhancing inhaled anesthetic, the authors tested the effect of flumazenil on time to recover the righting reflex (RR), as well as its effect on physiologic parameters, general activity, and memory in the post-anesthesia state. A histological examination of anesthetic-induced neuro-apoptosis was also performed. Flumazenil (0.4 mg/kg) decreased mean time to RR by an average of 63 seconds (mean ± sd: flumazenil, 179.2 ± 46.7 s; saline, 242.2 ± 83.3 s). Memory testing revealed an improvement in novel object recognition (NOR) with the administration of flumazenil. Flumazenil had little effect on general activity or physiologic and respiratory factors under general anesthesia. Histologic examination revealed a dose-dependent decrease in caspase-3 positive cells in the hippocampus, midbrain, and cortex in animals administered flumazenil upon cessation of isoflurane anesthesia (Figure). The authors conclude that flumazenil actively promotes emergence from isoflurane anesthesia while mitigating some of the deleterious effects of this anesthetic on memory and neuronal viability. These findings suggest that flumazenil may be a useful clinical adjunct to anesthetic practice to rapidly reverse general anesthesia and to possibly prevent cognitive problems after anesthesia.

Title: Functional coupling between non-cholinergic basal forebrain neurons and midbrain dopaminergic neurons

Authors: *I. AVILA, S.-C. LIN;
Neural Circuits and Cognition Unit, LBN, Natl. Inst. On Aging, NIH, Baltimore, MD

Abstract: Recent studies show that the brain uses two major neuromodulatory systems, the midbrain dopaminergic (DA) neurons and non-cholinergic basal forebrain (BF) neurons, to separately encode the hedonic valence and motivational salience of the stimulus. However, motivational salience and hedonic valence are strongly coupled in reward-related contexts because reward-predicting stimuli are highly motivationally salient. This underscores the importance of understanding whether DA neurons and non-cholinergic BF neurons are functionally distinct or functionally coupled in reward-related contexts. Here we investigate this issue by simultaneously recording neuronal activity in the two regions while rats perform a reward-biased simple RT task. In this task, rats were trained to respond to two distinct auditory stimuli that predicted different amounts of reward in the same port. We found that the activity profile of non-cholinergic BF neurons and putative midbrain DA neurons were highly similar throughout different epochs of this task. Both types of neurons showed similar tonic activity modulation in anticipation to stimulus onset, and robust bursting responses at similar latencies to the trial start signal, to both reward-predicting sounds as well as to reward delivery. Furthermore, both types of neurons showed robust bursting responses at similar latencies to the trial start signal, to both reward-predicting sounds as well as to reward delivery. Furthermore, both midbrain DA neurons and non-cholinergic BF neurons showed similar bursting amplitude modulation between the two stimuli that predicted large or small reward, and similar reward prediction error modulation toward reward delivery. These observations suggest that non-cholinergic BF neurons and midbrain DA neurons are not functionally distinct but highly

coupled in the reward-related contexts that we tested. The lack of functional specification between these two neuronal populations suggests a highly coordinated state early in the decision making process involving multiple subcortical neuromodulatory systems. These findings also caution against simple causal inferences based on observing BF or midbrain DA neuronal activity alone.

Title: Motivational salience signal in the basal forebrain tracks behavioral performance during learning

Authors: *H. MANZUR[1], S.-C. LIN[2];
[1]NIH, Baltimore, MD; [2]Natl. Inst. of Hlth. - Natl. Inst. on Aging, Baltimore, MD

Abstract: Recent studies show that a subset of basal forebrain (BF) neurons encodes the motivational salience of stimuli with robust bursting responses. This BF motivational salience signal does not depend on the physical salience of the stimulus and is acquired through learning because the same stimulus does not elicit bursting responses before animals learn about the stimulus-outcome association. However, how the BF motivational salience signal emerges through the learning process remains unknown. In this study, we investigated whether the emergence of the BF bursting response to a novel stimulus occurred before rats learned about the stimulus-outcome association and thus may facilitate learning, or whether the BF bursting response closely tracked behavioral performance during the learning process and therefore reflects the outcome of learning. After a novel stimulus was introduced, we found that the quick expression of the correct behavioral choice toward the novel stimulus was not driven by stimulus-outcome learning, but by a significant shift in behavioral strategy favoring exploration. This shift in behavioral strategy enabled rats to discover and learn about the new stimulus-outcome association early in the learning process and was slowly reversed after several training sessions as the new association was acquired. We found that the BF bursting response to the novel stimulus slowly emerged over several training sessions and closely tracked the reaction

time toward the novel stimulus throughout the learning process. Furthermore, we found that the gradual increase of BF bursting response to the novel stimulus over session was accompanied by a gradual decrease of BF bursting response toward the receipt of reward, resembling a reward prediction error signal. These results support that the BF motivational salience signal closely tracks behavioral performance during the learning process, and suggest that the reward prediction error modulation may serve as a learning signal in reinforcement learning. These observations also highlight the importance of shifting behavioral strategies as a key mechanism during the initial phase of learning.

Title: The topographic organization of auditory cortical projecting basal forebrain cells

Authors: *C. M. CHAVEZ, L. ZABORSZKY;
Ctr. for Mol. and Behavioral Neurosci., Rutgers, The State Univ. of New Jersey, Newark, NJ

Abstract: Learning induced plasticity in the primary auditory cortex has been a well-documented phenomenon across species and learning conditions. Learned tones gain representational area in primary auditory cortex (Weinberger, 2007). This increased representation is correlated with learned importance and memory strength and can be thought of as a cortical memory trace. The release of acetylcholine (ACh) is critical for the development of learning induced plasticity in auditory cortex. The basal forebrain cholinergic system consists of large cortically projecting cells, which provide the majority of acetylcholine to the entire cortical mantle where it plays a role in cortical activation, attention as well as plasticity. The heterogeneity and anatomical complexity of the BF has contributed to the idea that the BF is a diffuse cortically projecting system without specificity. However, research has shown that ACh may be released in a modality or area specific fashion in the cortex (Parikh et al., 2007), suggesting an architecture that is not readily expressed in the BF anatomy. Recently, we demonstrated that the BF organization reflects corticocortical connectivity patterns (Zaborszky et al., submitted). In particular, these data show that cortical areas that are interconnected share inputs from an overlapping population of BF neurons. The current experiment tests whether such

an anatomical organization exists for BF cells projecting to auditory cortex. Male Sprague-Dawley rats were anesthetized and a craniotomy was made over the auditory cortex. Auditory cortex was defined electrophysiologically or based on the cortical vasculature. Fluorogold (FG) was then deposited in the auditory cortex via ionotopheresis. A second craniotomy was made over one of several anterior cortical areas including, infralimbic, agranular insular, or auditory responsive insular cortex (defined electrophysiologically) and a small amount of Fast Blue (FB) was pressure injected into the region. The rats survived for one week, were transcardially perfused, brains removed and placed in a 30% sucrose solution. The brains were then sectioned (50 μm), immunostained for choline acetyl transferase and assessed for the presence of FG and FB retrograde labeling in the BF. Preliminary data suggests that the auditory cortex shares an overlapping pool of projection cells within the BF, specifically, with the auditory responsive granular insular cortex. These data support the hypothesis that the BF is not a diffuse system and suggests that such an organization can co-activate distinct cortical areas that are functionally linked.

Title: Cholinergic neurons excite cortically-projecting basal forebrain GABAergic/parvalbumin neurons

Authors: *C. YANG, J. T. MCKENNA, R. E. BROWN;
Psychiatry, VA Boston Healthcare Syst. and Harvard Med. Sch., Brockton, MA

Abstract: Drugs enhancing cholinergic activity are used to treat the defective cortical activation observed in disorders such as Alzheimer's disease and schizophrenia. These drugs act directly on neocortical neurons to promote fast, rhythmic, electrographic activity, mimicking cholinergic input from the basal forebrain (BF). However, whether cholinergic neurons also affect other BF

cortically projecting neurotransmitter systems is unknown. One group of BF neurons of particular interest are GABAergic neurons containing parvalbumin (PV), since they are fast-firing and have projections to cortical PV interneurons involved in generating gamma band oscillations (GBO). Furthermore, we have recently found that optogenetic stimulation of these neurons entrains cortical GBO. Here we demonstrate using immunohistochemistry in transgenic mice expresing green fluorescent protein in GABAergic neurons (GAD67-GFP knock-in mice) that BF cholinergic neurons are intermingled with GABAergic neurons and vesicular acetylcholine transporter-positive cholinergic fibers appose GABAergic neurons containing PV. Pharmacological activation of cholinergic receptors with carbachol (50 μM) increased the firing rate of cortically-projecting BF GABAergic neurons, via activation of M1/3 muscarinic receptors and sodium-permeable cation channels. Furthermore, optogenetic stimulation of cholinergic neurons caused a muscarinic receptor-mediated (atropine-sensitive) inward current in putative GABAergic neurons. Thus, the cortical activating and pro-cognitive actions of cholinergic agents may be mediated in part by activation of cortically projecting BF GABAergic neurons, a potential novel target to treat disorders of cortical activation.

Title: Visualization of basal forebrain cholinergic clusters in Cartesian coordinate system and investigation of their functional significance

Authors: *P. GOMBKÖTO, L. ZABORSZKY;
Ctr. for Mol. and Behavioral Neurosci., Rutgers Univ., Newark, NJ

Abstract: Cholinergic corticopetal neurons in the basal forebrain (BF) show inhomogeneous distribution where dense clusters of neurons are interrupted by regions of low cellular density in human as well as in rodents and monkeys (Zaborszky et al., 2008). Using a buble-clustering algorithm we have recently described that the distribution of clusters is not random, but show similar pattern across rat subjects (Nadasdy et al., 2010). A preliminary analysis of the cortical targets of the clusters suggest that cell clusters in the BF project only to a small subset of cortical areas that most likely are interconnected. The prerequisite to investigate BF cluster function, we

need to determine the location of clusters in a Cartesian coordinate system with reference to the Paxinos rat atlas (i) and design a digital large-scale recording system (ii) that would allow selective stimulation of BF clusters and record multiple cortical targets. Here we report our preliminary results in both technical directions.
We developed a Matlab program as a clustering function which can determine the existing clusters within Euclidean space where the cells positions are in Cartesian coordinates. We confirmed the inhomogeneity of the cholinergic system, defined the cell clusters, quantified and localized them with reference to the Paxinos coordinates.
For the second aim we are developing a large-scale recording system that can monitor spikes or local field potentials (LFP) with extreme high spatial and temporal resolution with the possible lowest restriction of the free movement of the animals. The digital multi-channel amplifier is using a Digital Electrophysiology Interface Chip provided by Intan Technologies. Digitalization takes place in the head stage that is directly connected to output of silicon electrodes on the head of the animal. The 32 channels are compressed/digitalized in only two cables (LVDS signals) leaving the head stage. Our new main board with a field-programmable gate array (FPGA) is able to control 32 Intan chips which allows simultaneous processing of 1024 channels by 30Khz/channel sampling rate. The main board transmits digital information to the PC through a regular Ethernet, therefore, there is no need for various digitalization cards since we utilize the PC's already existing resources. FPGA makes several solutions available, including the selection of specific channels for biofeedback, and real time spike sorting.
These new infrastructural developments could lay down the foundations for exploring new avenues in understanding the functional architecture of basalo-cortical networks.

Title: Neuromodulatory plasticity governs cortical plasticity

Authors: *A. MARTINS[1,2,3], R. C. FROEMKE[1,3];
[1]NYU Sch. of Med., New York, NY; [2]Programme in Exptl. Biol. and Biomedicine, Ctr. for

Neurosciences and Cell Biology, Univ. of Coimbra, Coimbra, Portugal; [3]Ctr. for Neural Sciences, NYU, New York, NY

Abstract: The cerebral cortex is plastic, dynamically representing the external environment. Cortical networks are part of neural circuits that include subcortical neuromodulatory systems, that contextualize incoming sensory stimuli. Neuromodulator release is required for cortical plasticity, but it is also possible that modulator systems themselves are plastic, providing differential modulatory control based on past experience.

Here we investigate how the noradrenergic locus coeruleus interacts with cortical circuits and enables plasticity. Adult rats were anesthetized, stimulation electrodes implanted in the locus coeruleus, and primary auditory cortex identified. In vivo whole-cell recordings (voltage-clamp or current-clamp) were made from auditory cortical neurons or locus coeruleus neurons, and pure tones of varying frequencies and intensities were presented to the animal to characterize auditory responses.

Pairing tones with locus coeruleus activation greatly increased synaptic and spiking responses by two- to ten-fold, elevating and flattening tuning curves across frequencies. Eventually, over tens of minutes, tuning curve structure returned, leaving the paired frequency selectively enhanced. Multiple recordings after a single episode of pairing demonstrated that tuning changes stabilized after 3-6 hours and persisted for 11+ hours.

Blocking noradrenalin receptors only during pairing temporarily blocked cortical effects, but blocking receptors after pairing prevented expression of long-term changes. This suggested that release of noradrenalin from locus coeruleus neurons was changed post-pairing, and might persist for hours. In vivo whole-cell recordings from locus coeruleus neurons showed that pairing induced long-term changes in noradrenergic circuitry, as they began to respond to paired stimuli with short latency (~30-50 msec). These changes were prevented by infusion of the NMDA receptor antagonist APV in locus coeruleus, which also reduced the duration of cortical plasticity (from 11+ hours to ~3 hours).

Furthermore, rats were implanted with locus coeruleus stimulation electrodes and trained to respond to a target 4 kHz tone, for a food reward. Locus coeruleus pairing increased detection of quiet tones at the expense of recognition of target from unrewarded foil tones. Even after a single pairing episode, improvements in detection could last for days or months in some animals.

Our results demonstrate that plasticity of subcortical neuromodulation has a major impact on the dynamics of cortical plasticity, creating persistent changes in sensory perception.

Title: Population coding of stimulus and reward in rat basal forebrain

Authors: *E. E. THOMSON[1], K. SYLVESTER[2], Â. TAKIGAMI[2], J. LOU[3], M. NICOLELIS[2];
[1]Duke Univ., DURHAM, NC; [2]Neurobio., Duke, Durham, NC; [3]Keck Sch. of Med., USC, Pasadena, CA

Abstract: The basal forebrain (BF) is known to encode stimulus salience, and it also plays important roles in neural plasticity and attention. To determine how BF activity relates to stimulus and reward parameters, we recorded from populations of single units in the nucleus basalis of Meynert of rats as they performed a whisker-dependent aperture-width discrimination task. As expected, individual neurons and populations encoded reward values with high accuracy during the task. Additionally, within 100 ms of stimulus onset, BF populations carried significant levels of information about the tactile stimulus. This is in contrast to what we observed in lightly anesthetized animals: when we delivered the same stimuli to the whiskers of lightly anesthetized animals, BF neurons transmitted significantly less information about the stimuli. Such results suggests that in the awake behaving animal, information about the stimulus is routed to BF and could be part of a mechanism for selective attention.

Title: Basal forebrain neuronal activity maps the sequences of locomotor actions associated with fluid traversal of complex paths through an environment

Authors: *S. KOLBU, A. A. CHIBA, D. A. NITZ;
Cognitive Sci., UCSD, La Jolla, CA

Abstract: Fast, fluid locomotion along complex paths through an environment demands an ongoing integration of sensory information with current and planned locomotor states. It has been suggested that the route-centered spatial firing patterns of posterior parietal cortex neurons in behaving animals could provide a temporal framework for such integration, through projections to primary and secondary sensory cortices as well as to the medial precentral sub-region of prefrontal cortex, an area having neuronal activity related to both present and future actions. The substantia innominata and ventral pallidal sub-regions of the basal forebrain, through the cortical projections of their GABAergic and cholinergic neuron populations, are also in a position to coordinate the ongoing sensorimotor integration associated with path running. Basal forebrain neurons may contribute in a variety of ways to the execution of a series of actions through environmental space. As seen in prior work, they could respond primarily to specific sensory stimuli, or to rewards associated with task performance. They could instead simply provide a tonic excitation of specific cortical regions. Alternatively, they could produce unique patterns of activity for each path position, or they could generate activity patterns associated with specific locomotor actions. In the present study, the form by which basal forebrain neurons may participate in navigation along a path was determined by examining the firing dynamics of rat basal forebrain neurons during traversal of tracks with varying degrees of path complexity and recurrence of path sub-components. Among the recorded population of basal forebrain neurons in seven animals, a sub-population was found which exhibited activity peaks closely related to specific behaviors associated with path running (e.g., left versus right turns). This result is consistent with a role for the basal forebrain in coordinating streams of sensory information with present and planned actions in the context of complex action sequences.

Title: Cell assemblies of the basal forebrain exhibit beta-frequency dynamics

Authors: *D. TINGLEY, A. ALEXANDER, S. KOLBU, A. CHIBA, D. NITZ;
UCSD, La Jolla, CA

Abstract: The basal forebrain (BF) consists of a heterogeneous population of cholinergic, GABAergic, and glutamatergic neurons having projections to many cortical regions. The importance of these projections for cognitive function has been demonstrated in behavioral studies employing lesions of BF and in examining impairments in cognitive processing in patient populations (e.g., Alzheimers disease). In recent years, such work has been complemented by single neuron recording studies demonstrating that BF cell populations: 1) form activity patterns for all phases of a selective attention task; 2) consist of neuron populations having distinct inter-spike interval (ISI) patterns; 3) are responsive to salient sensory stimuli and rewards; and 4) exhibit complex task-phase-specific firing patterns paralleling those observed in their efferent targets (e.g., parietal cortex). These functional and anatomical features of the BF allow for the possibility of complex neural assemblies that integrate information, and modulate cortex, over a distinct time frame.

BF neurons were recorded while rats performed a visual-spatial attention task. Specific groups of neurons within the recorded population had ISI histograms that represent either 'bursty' or tonic firing. These groups are most active at different phases of a behavioral task, representing temporally, and perhaps functionally, distinct cell assemblies. Such shifts in activity patterns may represent a switching mechanism between network attractor states coinciding with attentional shifts across phases of a complex behavioral task.

To further characterize interactions among BF neurons during task performance, spike firing patterns among pairs were examined in the context of the 'cell assembly' hypothesis. Using a generalized linear model, spike times of BF neurons were more accurately predicted by temporally smoothed spike time probabilities of simultaneously recorded peer neurons. Additionally, BF neurons exhibited an optimal temporal window for synchronous spike generation of 30-80 ms (12-33 Hz). This indicates that BF cell assemblies are synchronized over a beta-frequency time scale which has been proposed as an optimal global synchronization frequency.

In addition to the anatomical connections between the BF and cortex, the electrophysiological properties of the BF further suggest temporally precise integration, synchronization, and modulation of cortical targets during a task that demands visual-spatial attention. These findings suggest that the temporal dynamics of cell assemblies in the BF differ from previously explored brain regions, as does its functional and behavioral importance.

Abstract: Sensory-motor integration is key to many categories of learning, yet the mechanisms of this integration are disputed. The cholinergic basal forebrain (BF; 'nucleus basalis') is a facilitator of cortical plasticity, and its efferents differentially modulate motor, somatosensory, and visual cortical activity via topographically organized projections. During various learning tasks, sensorimotor integration occurs concurrently with BF-mediated cortical plasticity. In order to query the extent of the role of the BF in sensorimotor integration, we first identify candidate sites within the BF that might jointly modulate primary sensory and motor areas. This is achieved by depositing distinct retrograde tracers in physiologically-identified primary visual, motor, and somatosensory areas, and subsequently staining forebrain sections for choline acetyltransferase (ChAT). Although a given group of cells projecting to a particular cortical area tends to occupy several of the classical cytoarchitectural subdivisions of the BF, for a simple quantitative analysis we express the overlap and segregation of sensory-versus-motor projecting somata within each of the major BF regions, including the medial septum, diagonal band, substantia innominata, ventral pallidum, and globus pallidus / internal capsule. The resulting maps reveal locations to be targeted in future subregional and cell-type-specific manipulations of the ascending basal forebrain system during behavioral tasks, and indicate that for purposes of probing sensory-motor integration at the level of the BF, simple stimulation of the nucleus basalis is likely to be insufficient.

Title: Better late than never - the role of basal forebrain inhibition in successful and failed stopping in the stop signal task

Authors: *J. D. MAYSE[1], G. NELSON[2], I. AVILA[2], M. GALLAGHER[1], S.-C. LIN[2]; [1]Psychological and Brain Sci., Johns Hopkins Univ., Baltimore, MD; [2]Lab. of Behavioral Neurosci., Natl. Inst. on Aging, Baltimore, MD

Abstract: Cognitive inhibitory control, or the ability to suppress responses inappropriate for the context, is essential for flexible and adaptive behavior. One powerful paradigm for studying inhibitory control is the Stop-Signal Task (SST), which requires subjects to suppress a response to a go-signal when it is occasionally followed by a stop-signal. The SST is unique in that it allows for quantitative estimation of the time required to suppress the planned go-response, known as stop-signal reaction time (SSRT). We recently identified a novel subcortical neural correlate of the SSRT in the basal forebrain (BF). In rats performing a SST, we found that BF neurons with bursting responses to the go-signal (tone) were selectively inhibited by the stop-signal (light). The onset of BF neuronal inhibition was correlated with and preceded SSRT by ~30ms. In support of a causal relationship, artificially inducing BF neuronal inhibition reproduced stopping behavior even in the absence of the visual stop-signal.
In the current study, we examined whether and how BF activity was modulated between successful and failed stop trials, a comparison commonly used to identify neural mechanisms that lead to successful inhibitory control. We found that the stop signal was similarly processed on failed and successful stop trials prior to the estimated SSRT. As a result, failure to stop was not associated with absent or diminished BF inhibition, but instead with BF inhibition arriving too late after the initiation of the go response. Nevertheless, the presence of BF inhibition in failed stop trials, both in SST and in artificially induced BF inhibition, had a strong influence on behavior and resulted in corrective reentry responses especially when go responses were initiated just before SSRT. Together, our results show that successful or failed stopping is not driven by differential engagement of inhibitory control mechanism but largely determined by the variability in the go-process. The inhibitory control mechanism in the BF represents a robust and invariant process that is always engaged irrespective of behavioral outcome, which strongly modulates behavior even when it was too late to stop.

Title: Ketamine prevents neurochemical and behavioral consequence of uncontrollable stress

Authors: *K. H. KUBALA, J. P. CHRISTIANSON, J. AMAT, D. C. COOPER, L. R. WATKINS, S. F. MAIER;
Psychology, Univ. of Colorado, Boulder, CO

Abstract:
Exposure to an acute uncontrollable stressor, such as inescapable tail shock (IS), produces a variety of anxiety-like behaviors that depend on intense activation of serotonergic neurons in the dorsal raphe nucleus(DRN), which leads to exaggerated release of serotonin (5-HT) in anxiety related projection regions, such as the basolateral amygdala (BLA), this being critical to the mediation of the behavioral changes. Recent evidence suggests that ketamine, an NMDA receptor antagonist, produces rapid antidepressant-like effects in patients diagnosed with depression, and animal studies have shown that it may block some of the behavioral and physiological changes produced by stressors. The goal of the present study was to determine whether ketamine would mitigate the behavioral consequences of IS and the intense activation of the DRN produced by IS. Ketamine injected i.p. either two hours before, or immediately after IS, blocked the typical stress-induced decrease in social exploration. This behavioral deficit is dependent on serotonergic activation of the BLA, via afferents from the DRN. Ketamine also completely blocked the large serotonergic influx in the BLA produced by IS when administered 2 hours before the stressor. These results provide evidence that ketamine may block behavioral effects of IS by acting on the 5-HT system in the DRN.

Title: Controllable versus uncontrollable aversive stimuli differentially trigger ERK signaling in the dorsal striatum

Authors: *R. A. DAUT[1], J. P. CHRISTIANSON[1], J. G. N. FLYER[2], L. R. WATKINS[2], S. F. MAIER[2];
[1]Dept. of Psychology and Neurosci., [2]Univ. of Colorado, Boulder, CO

Abstract: The action-outcome learning system shapes goal-directed behavior. The medial prefrontal cortex and dorsal striatum form an action-outcome circuit that has typically been studied using positive rewards such as food. Here we attempt to extend the function of this circuit to a type of instrumental learning that involves the removal of an aversive stimulus, i.e. negative reinforcement. Rats were exposed to a series of tailshocks that could be terminated by making a wheel-turn response (controllable shock). A second group of rats was yoked to the first and received equivalent tailshocks which could not be terminated (uncontrollable shock). Rats were sacrificed immediately after 0, 25 or 100 trials, brains dissected, micro-punches taken from both the medial and lateral dorsal striatum (DMS/DLS) and prepared for Western blot analysis. Expression of phosphorylated extracellular regulated kinase 1 and 2 (pERK1/2) and phosphorylated p70S6K were quantified relative to their total isoforms. Exposure to 25 controllable shocks led to a significant elevation in DMS pERK1 levels relative to unshocked controls. In comparison, exposure to 100 uncontrollable tailshocks increased pERK2 in both DMS and DLS and increased pERK1, but only in the DMS. Phosphorylated p70S6K was increased by 100 shocks but did not appear to be sensitive to control. These results suggest that activation of the ERK mediated pathway may play a role in the behavioral consequences of uncontrollable shock, i.e. learned helplessness. Mechanistic studies aimed to test the role of ERK1/2 in the effects of controllable versus uncontrollable stress are ongoing.

Title: The long-lasting protective effects of controllable stress require ERK in the medial prefrontal cortex

Authors: J. G. N. FLYER[1], *J. P. CHRISTIANSON[2], L. R. WATKINS[1], S. F. MAIER[1]; [1]Psychology & Neurosci., Univ. of Colorado, Boulder, CO; [2]Psychology and Neurosci., Univ. of Colorado, BOULDER, CO

Abstract: Exposure to escapable tailshocks (ES) each of which can be terminated by a behavioral response is a behaviorally controllable stressor that confers protection from the neurochemical and behavioral consequences of future inescapable tailshock (IS), an uncontrollable stressor. This phenomenon, termed "behavioral immunization", requires NMDA-receptor dependent plasticity within the medial prefrontal cortex (mPFC). In the present studies we sought to test the involvement of the mitogen activated protein kinase 1/extracellular regulated kinase 1 and 2 (MAPK1/ERK1,2) and the mammalian target of rapamycin (mTOR) molecular cascades in the behavioral immunization paradigm. Using a combination of Western blot and immunohistochemistry, we identified a rapid and significant increase in phosphorylated ERK1 and ERK2 within the prelimbic cortex in rats exposed to controllable ES. Exposure to exactly equal but uncontrollable IS did not alter ERK2 phosphorylation from baseline. To determine whether ERK1/2 signaling is critical to the behavioral immunization phenomenon, the MEK1/2 inhibitor U0126 (5μg/side or vehicle) was injected into the prelimibic mPFC prior to exposure to controllable stress. One week later rats received uncontrollable stress and subsequent testing for anxiety-like behavior in a social exploration test. As previously reported, uncontrollable stress exposure significantly reduced social exploration, but prior experience with controllable stress prevented this reduction. In the critical group, U0126 blocked the behavioral immunization effect. Controllable stress exposure also increased phospho-p70S6K in prelimbic mPFC, suggesting a possible involvement of mTOR. Studies designed to test the possible contribution of mTOR in this paradigm are ongoing. However, existing data clearly implicate ERK pathway activity as critical for the stress-inoculating effect of behavioral control.

Title: The effect of hydrocortisone on emotion regulation neurocircuis in patients with PTSD

Authors: *G. OKADA, S. T. MA, S. HO, S. TAYLOR, J. L. ABELSON, I. LIBERZON; Univ. of Michigan, Ann Arbor, MI

Abstract: In the present study, we examined the effects of hydrocortisone administration on emotion regulation in individuals with and without posttraumatic stress disorder (PTSD) at a neuronal level through fMRI. Twelve patients with PTSD and 12 healthy controls were exposed to a series of compound pictures of faces (angry, fear, neutral) and places(indoor, outdoor) and cued to indicate 1) whether the face was male or female, or 2) whether the background was indoor or outdoor, or 3) whether the subject liked or disliked the feces. The experiment was of a counter-balanced, placebo-controlled, within-subject design. Two days of experiments were scheduled with a minimum interval of 3 days, and 100mg hydrocortisone (HCT) or Placebo was administered. As in our prior works, experimental manipulation robustly activated neurocircuits involved in emotional regulation by shifting attention and cognitive appraisal respectively. Furthermore, differential cortisol modulations of task related activation were observed in the hippocampus and subgenual anterior cingulate cortex between in controls and in patients with PTSD. These results suggest the altered glucocorticoid sensitivity in emotion regulation neurocircuit in PTSD.

Title: Cortisol modulation on emotion regulation neurocircuits

Authors: *S. T. MA[1], G. OKADA[3], S. HO[2], S. TAYLOR[2], J. L. ABELSON[2], I. LIBERZON[2]; [1]Dept of Psychiatry, [2]Univ. of Michigan, Ann Arbor, MI; [3]Hiroshima Univ., Hiroshima, Japan

Abstract: This study examined the effects of cortisol administration on emotion regulation at a neuronal level through fMRI. Forty individuals participated in this study and were randomly assigned to hydrocortisone (10 males, 10 females) and placebo control groups (10 males, 10 females). We used the shifted-Attention Emotion Appraisal Paradigm to investigate the neurocircuits related to emotion processing and regulation. In this task, subjects were exposed to a series of compound pictures of faces (angry, fear, neutral) and places(indoor, outdoor) and cued to indicate the (i) gender of the face (implicit emotional processing), (ii) indoor/outdoor of the place (shifted attention to places), or (iii) whether the face is liked or disliked (cognitive appraisal). As in our prior works, the experimental manipulation robustly activated neurocircuits involved in emotional processing and regulation. In addition, hydrocortisone administration significantly enhanced the medial prefrontal cortex activation ($p = 0.038$) which was increasingly activated cognitive appraisal > emotion processing > shifting attention to places. These results suggest the direct nongenomic effects of cortisol on emotion regulation neurocircuit.

Title: Opposing roles of corticotropin-releasing factor and neuropeptide Y within the dorsolateral bed nucleus of the stria terminalis in the negative affective component of pain in rats

Authors: *S. DEYAMA[1], S. IDE[1], A. OHNO[1], R. TAMANO[1], K. KOSEKI[1], T. NAKA[1], C. MARUYAMA[1], M. YOSHIOKA[2], M. MINAMI[1];

Abstract: Pain is a complex experience consisting of sensory and affective components. Although the neural systems of the sensory component of pain have been studied extensively, those of its affective component remain to be determined. In the present study, we examined the effects of corticotropin-releasing factor (CRF) and neuropeptide Y (NPY) within the dorsolateral bed nucleus of the stria terminalis (dlBNST) on pain-induced aversion and nociceptive behaviors in male Sprague-Dawley rats to elucidate the roles of these peptides in affective and sensory components of pain. In vivo microdialysis showed that intraplantar formalin-evoked pain enhanced the release of CRF in this brain region. Using a conditioned place aversion (CPA) test, we found that intra-dlBNST injection of NBI27914, a CRF1 receptor antagonist, or antisauvagine-30, a CRF2 receptor antagonist, dose-dependently suppressed formalin-induced CPA (F-CPA). These antagonists did not affect formalin-induced nociceptive behaviors. Intra-dlBNST injection of CRF dose-dependently produced CPA even in the absence of noxious stimulation. On the other hand, intra-dlBNST injection of NPY dose-dependently suppressed F-CPA without affecting nociceptive behaviors. Intra-dlBNST injection of NPY also attenuated intra-dlBNST CRF-induced CPA. This inhibitory effect of NPY was blocked by co-administration of BIBP3226, a NPY Y1 receptor antagonist, or L-152,804, a NPY Y5 receptor antagonist. Taken together, these results suggest that CRFergic neurotransmission within the dlBNST plays an important role in pain-induced aversion and that NPY may alleviate pain-induced aversion via the inhibition of CRF-mediated neurotransmission in this brain region.

Title: Opposing effects of corticotropin-releasing factor and neuropeptide Y on neuronal excitability in the dorsolateral bed nucleus of the stria terminalis

Authors: *M. MINAMI, T. HARA, S. IDE, K. KANEDA;
Dept Pharmacol, Grad Sch. Pharm Sci., Hokkaido Univ., Sapporo, Japan

Abstract: Using a conditioned place aversion (CPA) test, we found the opposing roles of corticotropin-releasing factor and neuropeptide Y within the dorsolateral bed nucleus of the stria terminalis (dlBNST) in pain-induced aversion. In the present study, to investigate the cellular mechanisms of CRF-induced CPA and counteracting effect of NPY, we examined the effects of these peptides on neuronal excitability in the dlBNST slices prepared from Sprague-Dawley rats using whole-cell patch-clamp recordings. Interestingly, we found that only type II, not type I or III, neurons responded to both CRF and NPY in the dlBNST. CRF depolarized membrane potentials in type II neurons. In contrast, NPY induced hyperpolarization in type II neurons. Furthermore, co-application of NPY extinguished the CRF-induced depolarization. Similar results were observed in firing activities of type II dlBNST neurons. Specifically, CRF increased firing activities of type II neurons, and co-application of NPY suppressed them. These counteracting effects of CRF and NPY on neuronal excitability in type II dlBNST neurons may explain the opposing roles of these peptides in pain-induced aversion. Analyses of I-V relationships demonstrated that there might be at least two classes of type II dlBNST neurons, which we designated as type IIa and type IIb. Decreased potassium conductance and increased non-selective cation current could be involved in the polarizing effect of CRF on type IIa and type IIb neurons, respectively. I-V relationship analyses revealed that NPY reduced steady-state currents, the reversal potential of which was around -60 mV, indicating suppression of cationic conductance(s). ZD7288, an Ih blocker, occluded the hyperpolarizing effect of NPY, demonstrating that NPY-induced hyperpolarization was mediated by blocking Ih channels.

Title: Postnatal refinement of OFC (area 11) projections to the striatum

Authors: *B. K. FAHRENTHOLD[1], S. N. HABER[2];
[1]Neurosci., [2]Pharmacol. and Physiol., Univ. of Rochester, Rochester, NY

Abstract: The orbital frontal cortex (OFC)-striatal circuit plays an integral role in reward-based incentive learning. Dysfunction of this circuit has been implicated in several diseases arising during adolescence, including obsessive-compulsive disorder, addiction, and attention-deficit hyperactivity disorder. In normal development there is a time-window of plasticity where cortico-striatal connection refinement continues postnatally for several months (DiFiglia et al., 1980). This period of plasticity is especially vulnerable. In adult rhesus macaques, dense and patchy terminal fields from area 11, a rostral medial part of OFC, are located ventrally and continue up the medial wall in the rostral caudate. Diffuse terminals surround and extend away from these dense terminal fields. We hypothesize that there are changes in density and distribution of terminal fields from area 11, to the striatum coupled with different developmental ages.
Anterograde tracers were placed into area 11 of rhesus macaques at ages of 3 weeks, 3 months, 6 months, and adult. Dense projection fields and diffuse terminals in the striatum (Haber et al., 2006) were charted using Neurolucida (MicroBrightfield, Colchester, VT). Preliminary observations show two types of terminal fields: dense fields that occur in patches surrounded by more diffuse terminals. Terminal field locations are similar to those seen in adult macaques. However, dense terminal fields at 3 weeks of age occupy a smaller striatal area and diffuse terminals surrounding these dense fields were less extensive compared to adults. This suggests terminations from area 11 to the striatum at early postnatal periods undergo expansion or refinement that extends both the dense and diffuse terminal field occupancy until the adult-like pattern of corticostriatal terminals is reached.
Dense projection fields from OFC converge with those from ventromedial prefrontal cortex, dorsal anterior cingulate cortex, and dorsolateral prefrontal cortex in the adult rostral striatum (Haber et al., 2006). In very young animals, smaller dense projection fields from area 11 appear to be less extensive compared to adults. This suggests convergence of these different cortical areas at early postnatal periods may be less extensive than in the adult, possibly resulting in less integration occurring between functional circuits. However, additional experiments are necessary to address the development of other prefrontal-striatal projections.

Title: The cingulum bundle contains five distinct segments: Implications for default mode network activity and psychiatric disorders

Authors: *S. R. HEILBRONNER, S. N. HABER;
Pharmacol. and Physiol., Univ. of Rochester, Rochester, NY

Abstract: For centuries, the cingulum bundle (CB) has been recognized as one of the major fiber pathways of the brain. However, its composition and function remain unclear. Diffusion imaging shows that it is abnormal in a variety of psychiatric disorders, including major depressive disorder (MDD) and obsessive-compulsive disorder (OCD). Intriguingly, the CB is also an effective target for ablative neurosurgical treatment (cingulotomy) for these two disorders. Thus, understanding the nature of the fiber projections through the CB will generate insights into OCD, MDD, and their treatments. We injected tracers into more than two dozen subcortical and cortical (both cingulate and non-cingulate) targets. We mapped the resulting efferent fiber pathways through the CB and their terminals. In doing so, we were able to segment the cingulum bundle into five distinct regions: subgenual, rostral dorsal, middle dorsal, caudal dorsal, and temporal.
We observed that all prefrontal fibers projecting to the posteromedial cortex (precuneus, retrosplenial, and posterior cingulate cortex), even those terminating in the relatively dorsal precuneal cortex, passed through the middle and caudal dorsal CB, but did not continue into the temporal CB. The posteromedial cortex is one of the two hubs of the default mode network (the other being the medial prefrontal cortex), a set of regions consistently deactivated by effective task performance. Our observations indicate that all of the direct connections between these two hubs project through the middle and caudal dorsal CB. Based on this, we mapped the projections from different regions within the prefrontal cortex to the posteromedial cortex. Finally, we discuss these results as they relate to neuroimaging data from OCD and MDD patients. These results have the potential to shed light on the relationship between default mode network activity, the cingulum bundle, and psychiatric disorders.

Title: Conditioning taste aversion after a chronic stress exposure in rats

Authors: *A. RUIZ GARCIA[1], P. TORRES-CARRILLO[2], I. ROSEMBERG-GARCIA[2], D. PAZ-TREJO[2], H. SANCHEZ-CASTILLO[2];
[1]Psychophysiology, UNAM, Mexico DF, Mexico; [2]Psychophysiology, UNAM, Mexico City, Mexico

Abstract: It has been show that chronic stress exposure causes cognitive deficits, for example, it has been observed a poor performance in memory tasks and the impairment on acquisition and extinction this probably because a decrease in the glucocorticoid receptors of the hippocampus and affectation of the cholinergic system. Those results have been related to an impairment of the prefrontal cortex. Also it has been demonstrated that the exposure to stressor before the presentation of an aversive stimuli facilitates the learning. The aim of this study was to evaluate the effect of chronic exposure to different stressors in Conditioning Taste Aversion (CTA) using a cholinergic agonist (nicotine) to observe how changes would be given in associative learning. We used 7 male Wistar rats with 4 months old at the beginning of the experiment. The subjects were exposed to 7 days of chronic stress with a variable stressors battery, this consisted of placing the rats for 12 hours (overnight) in humid sawdust for two days, five minutes of swimming in cold water (16 ° C) for three days and finally, were exposed to 12 hours (overnight) to lights on for two days, all of those were randomizing along the experiment. The animals were tested to Conditioning Taste Aversive (CTA), this consisted in exposed the rats to saccharin 30 minutes per day, after that were injected with nicotine at a dose of 1.6 mg / kg to cause the aversion for 4 days. The CTA extinguish time was recorded. The obtained results showed that the animals began to consume saccharin after 8 days, however not returned to the basal levels, and the time to acquired extinction took 8 sessions. This suggests that expose to chronic different stressors in rats demonstrated aversive learning is better consolidated, it has also been observed in people who had experience a traumatic event due to they remembered the context related to the aversive situation and they generalize it to every environment.

Title: Investigation of the neural correlates of emotion regulation with and without explicit instruction to 'reappraise'

Authors: *D. Z. BOLLING, E. KRAPOHL, N. PITSKEL, K. PELPHREY;
Yale Child Study Ctr., New Haven, CT

Abstract: Functional MRI research on emotion regulation has become increasingly common in healthy and clinical populations. Most of this work has focused on cognitive reappraisal, which involves an effortful reinterpretation of an emotion-inducing stimulus in order to modify one's response. While this work focuses on directed reappraisal, regulation in a naturalistic setting is almost always uninstructed. The current study compares directed reappraisal with an identical task that facilitates spontaneous regulation by either giving the participant information that the forthcoming picture will be negative, or leaving the valence ambiguous by telling the participant that the forthcoming picture may be negative or neutral. We hypothesize that warning subjects of the impending negative image will enable spontaneous regulation, reflected in neural responses resembling those of instructed reappraisal.

To investigate neural correlates of directed cognitive reappraisal in healthy adults, we used fMRI to measure activation to disgust images under three instruction conditions, "look", "decrease", and "increase." Neutral images were included in the "look" condition. To investigate neural correlates of spontaneous regulation in a matched group of healthy adults, we presented identical disgust images under two instruction conditions, "certain" and "ambiguous." Neutral images were included in the "ambiguous" condition. In each trial, an instruction was given, followed by an image presented for 3 seconds, concluding with an affect rating screen.

Brain responses to instructed cognitive reappraisal of negative images (decrease > look) in 20 healthy adults ($p < 0.05$) revealed increased activation during disgust image viewing following the "decrease" instruction (versus "look") in dorsolateral and ventrolateral prefrontal cortices, as well as dorsomedial prefrontal cortex, consistent with past work defining the neural correlates of reappraisal. In addition, reappraisal was associated with decreased activation in right amygdala and bilateral insula. In a second group of 12 healthy adults ($p < 0.05$), brain responses to disgust image viewing following a "certain" instruction (versus "ambiguous") revealed increased activation in dorsolateral prefrontal cortex, as well as decreased activation in insula.

Results suggest overlap in the neural correlates of instructed emotion regulation and anticipatory apprehension of disgust images, which may be indicative of spontaneous regulation in cases

when one knows of an impending negative stimulus. The relationship between spontaneous regulation and emotion regulation styles will be tested in a larger sample.

Title: Low-frequency rTMS over the ventrolateral prefrontal cortex modulates reappraisal-based down-regulation of negative affect

Authors: *J. U. KIM, S. R. LEVINE, L. R. BLAIR, D. H. ZALD;
Dept. of Psychology, Vanderbilt Univ., Nashville, TN

Abstract: Previous neuroimaging studies have demonstrated that successful reappraisal-based regulation of negative affect is associated with greater ventrolateral prefrontal cortex (vlPFC) recruitment. However, it is still unclear whether vlPFC activity plays a causal role in the reappraisal-based emotion regulation process. In the current study, we sought to investigate the effect of low-frequency repetitive transcranial magnetic stimulation (rTMS) of the vlPFC on one's ability to down-regulate negative affect using cognitive reappraisal. Based on prior correlational evidence, it was hypothesized that inhibition of the vlPFC in humans would disrupt reappraisal-based regulation of negative affect. Here, we examined healthy individuals' subjective rating of their own emotional state after viewing negatively-valenced visual stimuli while they engaged in reappraisal-based emotion regulation. Immediately prior to performing the reappraisal task, participants received a 30-minute low-frequency (1Hz) rTMS of the left vlPFC, right vlPFC, or sham stimulation (left or right vlPFC randomized). All participants received each of the three stimulation-types in a randomized and counterbalanced order in separate sessions. The TMS coil was stereotactically positioned using each participant's T1-weighted structural MRI acquired prior to the stimulation procedure. Inhibition of the left vlPFC decreased the degree to which individuals were able to down-regulate negative affect when compared to sham stimulation ($p = < .05$). By contrast, inhibition of the right vlPFC potentiated the ability to use reappraisal to down-regulate negative affect ($p = < .05$). These data suggest that the vlPFC exerts a causal influence on reappraisal-based emotion regulation, and suggests there may be laterlality-specific influences on this process.

Title: Pharmacological study on the autonomic modulation of the pupillary response during emotional processing

Authors: *S. I. BRUGUÉS SELEME, E. BRUNETTI, M. HERRERA-MARSCHITZ, P. E. MALDONADO;
Univ. De Chile, Santiago, Chile

Abstract: Susana Brugues[1], Enzo Brunetti[1], Mario Herrera-Marschitz[1] & Pedro E. Maldonado[1,2]. BNI[1] & CENEM[2] , Faculty of Medicine, University of Chile, Santiago, Chile. The pupillary response is a valuable physiological marker to study autonomic changes linked to emotional processes, because of its differential and specific responses to visual stimuli with positive or negative emotional valences. However, the particular contributions of the sympathetic and parasympathetic pathways to the dynamics of pupillary response in an emotional context are still unknown. In this study we aimed to examine the consequence of pharmacological inhibition of the sympathetic and parasympathetic components of the pupillary response to emotional stimuli. We measured the pupillary response of 23 healthy individuals after the presentation of 30 images with positive, negative and neutral emotional valences taken from the International Affective Pictures System database. We compared the responses of both pupils of each subject, after instillation of autonomic modulators in one of the eyes. We employed Brimonidine a sympathetic inhibitor (dilator muscle blocker) and Tropicamide, a parasympathetic inhibitor (sphincter muscle blocker), delivered through an ocular topical solution. Both substances evoked marked anisocoria, but the pupil was still responsive to the onset of emotional images. We found differences in pupillary responses to negative versus positive and neutral emotional stimuli early on the pupillary contraction phase of the response. These differences could not be explained by the luminance factor, which was strictly controlled. We also found that the pupillary dilation for negative emotional stimuli was considerably affected by the sympatholytic agent, thereby suggesting that pupillary response modulation to negative stimuli is mainly sympathetic. These

findings show that the processing of emotional stimuli with different valences is linked to specific patterns of autonomic changes that can be detected -with a high temporal resolution- by of dynamical measures in pupil size.

Title: Incubation of cocaine-induced habits in adolescence

Authors: L. M. DEPOY, *S. L. GOURLEY;
Pediatrics, Neurosci. Program, Emory Univ., Atlanta, GA

Abstract: Adolescence is a period of vulnerability to the development of many psychiatric disorders, including substance dependence disorders that persist across the lifespan. Incubation of certain biological factors associated with addiction may play a causal role. We explored this hypothesis in the context of cocaine-induced stimulus-response habits, which are increasingly considered a causal factor in the development and maintenance of addiction. Here, adolescent or adult mice were exposed to cocaine, and then decision-making strategies were characterized. Mice with a history of subchronic cocaine exposure in adolescence, but not adulthood, developed stimulus-response habits at the expense of engaging in goal-directed decision-making strategies, but only if behavioral characterization occurred following an incubation period. In addition to these behavioral changes, orbitofrontal prefrontal cortex (oPFC) dendritic spines were eliminated and dendrites retracted in adulthood, following adolescent cocaine exposure. The "premature" shift from response-outcome to stimulus-response decision-making strategies was replicated by site-specific infusions of an Abl-family kinase inhibitor STI-571 into the oPFC immediately following response-outcome contingency degradation. Together, these findings suggest that

adolescent cocaine exposure confers behavioral vulnerabilities in adulthood by altering cellular structure during adolescent development. We argue that cytoskeletal reorganization in adolescence is necessary for normative engagement in goal-directed response strategies, and that cocaine may impact lifelong decision-making strategies by interfering with the structural refinement of the neocortex during adolescence.

Title: Forced sedentary home cage conditions decreases cocaine-induced locomotor stimulation in rats

Authors: *M. J. WILL[1], M. MCCABE[2], K. PARKER[2], H. JOHNS[3], M. ROBERTS[3], F. BOOTH[3];
[1]Dept Psych - Life Sci. Cntr, Univ. Missouri-Columbia, COLUMBIA, MO; [2]Psychology, [3]Univ. of Missouri, Columbia, MO

Abstract: The current study examined the interaction of the locomotor response to cocaine in rats that either had 6 week access to a running wheel (voluntary running) exercise or no wheel (forced sedentary) condition. Upon arrival in the laboratory, 16 rats were given either access to a home cage environment with locked (forced sedentary) or free running wheel (voluntary exercise) access for the duration of the experiment. All rats were housed singly and had ad libitum access to home cage chow. Running distance and duration, as well as food intake and body weight, was monitored for 6 weeks. At the end of Week 6, rats were habituated to the locomotor activity apparatus (30x30x45cm) for 70 min on Day 1. All testing was conducted during the middle of the light cycle (1000-1200) and consisted of a 10 pre-injection baseline, followed by a 60 min drug response. All rats were assessed for locomotor activity in response to a low and high dose of cocaine (10mg/kg, or 20mg/kg; i.p.). All rats received alternating low vs. high dose treatments for a total of 10 sessions, including a baseline (0mg/kg) session in between each cocaine session. Each session was separated by at least 2 days. Both groups of rats (voluntary and sedentary) displayed a similar locomotor response to the initial low dose cocaine treatment. However, in response to the initial high dose treatment, the sedentary group displayed

a significantly lower locomotor response compared to the voluntary runner group. This trend continued across subsequent repeated dose sessions.

Title: Evidence of cross-sensitization between stress and alcohol in rats: Alcohol intake and locomotor behavior in rats exposed to maternal separation or social defeat stress

Authors: *B. E. CALDWELL, E. JACOBS-BRICHFORD;
Ithaca Col., Ithaca, NY

Abstract: The relationship between stress and risk for developing alcohol (ETOH) use disorders has been studied extensively in human and nonhuman animal models. The relationship between stress and ETOH drinking is likely modulated by many factors. Numerous researchers have concluded that individuals are at risk for developing maladaptive coping strategies if they are exposed to early life trauma. Although stress is known to sensitize animals to locomotor effects of stimulant drugs, the literature has not demonstrated evidence for sensitization to alcohol effects in rat populations. The present study examined the effects of maternal separation stress during the postnatal period, followed by social defeat stress in adulthood, on ETOH drinking and locomotor sensitization in male Long Evans rats. Newborn litters of Long Evans rats were culled to 6 pups per litter the day of parturition. Litters were randomly assigned to either maternal separation (MS) or animal facility rearing (AFR). MS began on post-natal day 1 (PND1), continued daily for 14 days, and pups were weaned on PND21. On PND 60, rats were assigned to either social defeat stress (DS) or non-stress groups. DS rats were exposed to 5 daily 5-minute encounters with an aggressive male conspecific. Three weeks following defeat, rats were tested for ETOH preference using a three-bottle choice protocol (10%, 5%, and 0% ETOH, all mixed with 0.5% saccharin). In addition, all animals were tested for locomotor response to an ETOH challenge in an open field apparatus at two time points, and were examined for differences relative to a saline trial and change in sensitivity to ETOH from Time 1 to Time 2. Results showed that maternally separated animals demonstrated distinctly different patterns of ethanol consumption, compared to other groups. MS rats drank less (in g/kg) ETOH during both 24-Hr

and 1-Hr access conditions, demonstrating a consistent preference for the 0% solution. In contrast, the MS/DS (both stressors) group drank the most ETOH, and drank more of the high concentration fluid than any of the other groups. Analyses of locomotor behaviors in the open field showed MS, but not AFR, rats demonstrated an increase in sensitivity to the locomotor-stimulating effects of ETOH from Time 1 to Time 2. These results suggest that neurological changes due to MS may predispose animals to an increased sensitivity to ETOH, but that adult stress is a determining factor in the transition to escalated patterns of alcohol intake.

Title: The involvement of spinal ascending pathways in acupuncture inhibition of cocaine-induced locomotor activity

Authors: *H.-Y. KIM, S. KIM, S. JANG, M. YEO, C. IM, B. LEE, C. YANG;
Col. of Oriental Med., Daegu Haany Univ., Daegu, Korea, Republic of

Abstract: We have previously demonstrated that acupuncture at Shenmen (HT7) points has powerful inhibitory effects on addictive behaviors of abused drugs including cocaine, alcohol and morphine. Our recent study suggested that HT7 inhibition of cocaine-induced locomotor activity is mediated by A-fiber activation of ulnar nerve originating from superficial and deep tissue. To investigate the possible mechanism of acupuncture on spinal ascending pathways, HT7 inhibition of cocaine-induced hyperactivity were evaluated after surgical transection of dorsal column (DC) or spinothalamic tract (STT) pathway in rats. Furthermore, to identify the involvement of secondary neurons in DC and STT pathways, the acupuncture effects were examined after chemical lesion of ventral posterior lateral nucleus (VPL). Locomotor activity

was measured in male Sprague-Dawley rats treated with lesion using a video tracking system after an intraperitoneal injection of cocaine (15 mg/kg). Acupuncture was applied at bilateral HT7 points for 20 s using a mechanical acupuncture device immediately after systemic cocaine injection. HT7 acupuncture suppressed cocaine-induced locomotor activity, which was blocked by lesion of cuneate nucleus or dorsal column, indicating requirement of DC pathways in traveling acupuncture signals. Additionally, HT7 inhibition of cocaine-induced hyperactivity was prevented by surgical transection of STT pathway or chemical lesion of VPL of both DC and STT pathways. Results suggest that both DC and STT pathways transmitting acupuncture afferent signals may mediate acupuncture's role in suppressing cocaine locomotion.

Title: Deep brain stimulation of the ventral striatum impairs extinction of morphine-induced conditioned place preference

Authors: *F. J. MARTINEZ[1], J. RODRÍGUEZ-ROMAGUERA[2], F. H. DO MONTE[2], O. A. MUÑIZ-SEDA[1], G. J. QUIRK[2], J. L. BARRETO-ESTRADA[1];
[1]Anat. and Neurobio., [2]Psychiatry, Univ. of Puerto Rico, Med. Sci. Campus, San Juan, Puerto Rico

Abstract: Deep brain stimulation (DBS) is a neurosurgical procedure used to treat refractory neurological and psychiatric disorders. Recent studies have suggested that DBS of the ventral striatum may be a potential target for treating addictive disorders (Luigjes et al., 2011). We recently showed in rats that DBS of the dorsal portion of ventral striatum (dorsal-VS) reduced fear expression and enhanced fear extinction (Rodríguez-Romaguera et al., 2012). Here, we

examined whether DBS of dorsal-VS could also reduce the expression of morphine-induced conditioned place preference (CPP), and enhance its extinction learning. Male Sprague-Dawley rats were stereotaxically implanted with bipolar electrodes aimed at dorsal-VS (−6.5 mm DV, ±2.0 mm ML, and +1.2 mm AP). Using a two-compartment CPP box, rats were conditioned across 8 days to prefer the side paired with morphine (5 mg/kg, s.c.). Subsequently, rats expressing morphine-CPP received 6 extinction sessions on 6 consecutive days, together with dorsal-VS DBS (130 Hz, 0.1 ms pulse, 100 µA, 60 min) or sham stimulation. DBS did not reduce the expression of morphine-CPP, as indicated by equivalent % time spent in the morphine paired side (Sham: 70%, DBS: 68%). Surprisingly, DBS impaired extinction of CPP, as indicated by a high % of time spent in the morphine paired side throughout extinction (Day 6 - Sham: 52%, DBS: 74%, ANOVA repeated-measures between group; $p<0.05$). Additional experiments showed that the DBS itself did not induce CPP, or alter rats' locomotion. These results suggest that ventral striatum DBS may have opposite effects on fear- vs. reward-extinction. Furthermore, it suggests that the dorsal-VS site may not be a promising target for treating addictive disorders with high-frequency DBS.

Title: Propofol pretreatment induced place preference and self-administration of the NMDA receptor antagonist-benzodiazepine combination, Zoletil®

Authors: *I. I. DELA PEÑA[1], J. DE LA PEÑA[1], A. MUHAMMAD[1], K. JUNG[1], H. KIM[1], C. SHIN[2], J. CHEONG[1];
[1]Pharm., Uimyung Res. Inst. For Neuroscience, Sahmyook Univ., Seoul, Korea, Republic of;
[2]Ctr. for Geriatric Neuroscience, Res. Inst. of Biomed. Sci. and Technology, Konkuk Univ., Seoul, Korea, Republic of

Abstract: In South Korea, there are concerns on the human use/abuse of the NMDA receptor antagonist-benzodiazepine combination, zoletil. Previously, we have shown that zoletil per se has no motivational effects. However, when administered to rats repeatedly pre-exposed to other

psychoactive drugs of abuse (ketamine, diazepam), zoletil produced significant conditioned place preference (CPP) and self-administration (SA). In the present study, we evaluated whether pre-exposure to propofol induce significant CPP and SA towards zoletil. Male Sprauge Dawley rats were repeatedly (14 days) pretreated with propofol (10, 30, or 60 mg/kg), then responses toward zoletil conditioning and self-administration were assessed. The results showed that propofol-pretreated animals spent more time on the zoletil-paired chamber, as compared to the saline-pretreated group, exhibiting significant zoletil CPP. This was supported by the findings in the SA test wherein propofol-pretreated rats facilitated and maintained significant zoletil SA. Taken together, these findings demonstrate that repeated pre-exposure to propofol may subsequently induce reward and reinforcement towards zoletil. It is possible that propofol-users may use zoletil as a substitute drug, probably because propofol is a restricted/controlled drug in South Korea while zoletil isn't. The careful use and monitoring of these psychoactive substances are highly stressed.

Title: Functional role of the N-terminal domain of deltaFosB in responses to stress and drugs of abuse

Authors: *Y. N. OHNISHI[1,2], Y. H. OHNISHI[2], V. VIALOU[2], E. MOUZON[2], Q. LAPLANT[2], A. NISHI[1], E. J. NESTLER[2];

Abstract: Previous work has implicated the transcription factor, ΔFosB, acting in the nucleus accumbens, in mediating the pro-rewarding effects of drugs of abuse such as cocaine as well as in mediating resilience to chronic social stress. However, the transgenic and viral gene transfer models used to establish these ΔFosB phenotypes express, in addition to ΔFosB, an alternative

translation product of ΔFosB mRNA, termed Δ2ΔFosB, which lacks the N-terminal 78 aa present in ΔFosB. To study the question of the possible contribution of Δ2ΔFosB to these drug and stress phenotypes, we prepared a viral vector that overexpresses a point mutant form of ΔFosB which cannot undergo alternative translation as well as a vector that overexpresses Δ2ΔFosB alone. Our results show that the mutant form of ΔFosB, when overexpressed in the nucleus accumbens, reproduces the enhancement of reward and of resilience seen with our earlier models, with no effects seen for Δ2ΔFosB. Overexpression of full length FosB, the other major product of the FosB gene, also has no effect. These findings confirm the unique role of ΔFosB in nucleus accumbens in controlling responses to drugs of abuse and stress.

Title: Signal processing in neuronal circuits mediating the reorientation from cocaine to social interaction

Authors: *J. M. PRAST, K. K. KUMMER, G. ZERNIG, A. SARIA;
Med. Univ. Innsbruck - Exp. Psychiatry Unit, Innsbruck, Austria

Abstract: A main challenge in the therapy of drug dependent individuals is to help them reactivate their interest in non-drug-associated activities. Among these activities, social interaction is doubly important because treatment adherence itself depends on it. We developed a rat animal experimental model based on the conditioned place preference (CPP) paradigm in which only four 15-min episodes of social interaction with a gender- and weight-matched male conspecific (i) reversed CPP from cocaine to social interaction despite continuing cocaine training and (ii) inhibited the reinstatement of cocaine CPP (Fritz et al. 2011, Addiction Biology 16:273-284). The reversal of CPP from cocaine to social interaction was enhanced by the sigma1 receptor antagonist BD1047 with an ED50 of 0.0036 mg/kg (i.p.) (Fritz et al. 2011, Pharmacology 87:45-48). Social interaction also reversed cocaine CPP-induced expression of the immediate-early gene zif268 in the nucleus accumbens shell, the central and basolateral amygdala and the ventral tegmental area (Fritz et al. 2011, Addiction Biology 16:273-284).

These findings suggest that social interaction, if offered in a context that is clearly distinct from the previously drug-associated ones, may profoundly decrease the incentive salience of drug-associated contextual stimuli. We propose that different neuron essembles in the nucleus accumbens core (AcbC) and the nucleus accumbens shell (AcbSh) would differentially mediate the CPP for cocaine vs. social interaction (Prast et al. 2012, Pharmacology 90:264-273). We are currently investigating which type of neurons in the AcbC is affected by this reversal.

Title: Altered reward expectancy in individuals with prior methamphetamine dependence

Authors: *A. BISCHOFF-GRETHE, C. G. CONNOLLY, S. J. JORDAN, G. G. BROWN, M. P. PAULUS, R. K. HEATON, S. P. WOODS, I. GRANT, .. THE TMARC GROUP;
UCSD, La Jolla, CA

Abstract: Despite advances in the understanding of the functional brain anatomy of reward expectancy in non-abusing adults, little is known about how these brain substrates might be altered in stimulant abusing individuals. Seventeen abstinent adults with a history of prior methamphetamine dependence (METH+) and twenty-three healthy comparison adults (METH-) performed a probabilistic feedback expectancy task during blood-oxygen level-dependent (BOLD) functional magnetic resonance imaging (fMRI). Participants were presented with visual cues that were probabilistically associated with monetary gain, loss, or neutral outcomes. Frontal systems measures associated with apathy, impulsivity/disinhibition, and sensation-seeking were acquired at a separate session. METH+ were found to have elevated apathy ($t(20.30)=6.82$, $p<0.001$, $d=2.2$) and impulsivity ($t(28.17)=5.51$, $p<0.001$, $d=1.8$) scores relative to METH-. Region of interest analyses within the left ventral striatum ($F(1,36)=5.27$, $p=0.03$, $d=0.7$) and left anterior caudate ($F(1,36)=8.66$, $p=0.006$, $d=1.0$) revealed group differences for stimuli associated with potential financial outcome. Specifically, post hoc analyses revealed that METH- exhibited a greater response than METH+ within both the ventral striatum ($z=2.3$, $p=0.02$) and the anterior caudate ($z=3.1$, $p=0.002$). In METH+, apathy scores were negatively correlated with the left anterior caudate's percent signal change response for the expectancy of financial gain

(Spearman's rho=-0.69, p=0.002), and sensation seeking was negatively correlated with the percent signal change for the expectancy of financial loss within the same region (Spearman's rho=-0.63, p=0.007). Overall, these findings suggest that the neural response to the potential for financial gains and losses is attenuated in areas associated with reward processing in the METH+ group. This is further supported by the association of greater apathy and sensation seeking scores with reduced striatal response to potential wins and losses, respectively. An impaired ability to evaluate future risks and benefits may underlie the altered decision making seen in METH+ individuals and increase the likelihood of risky behavior.

Title: Firing of lateral preoptic area during cocaine self-administration

Authors: *D. J. BARKER, B. S. STRIANO, D. H. ROOT, A. P. PAWLAK, A. T. FABBRICATORE, M. O. WEST;
Psychology, Rutgers Univ., Piscataway, NJ

Abstract: The Lateral Preoptic area is a GABAergic target of the nucleus accumbens. These projections predominantly originate in the rostral portions of the dorsal and ventral shell, as well and the caudal portions of the dorsomedial shell and core and are believed to be one route by which accumbens signaling might initiate or modulate motivated behaviors. Accordingly, it has been shown that the locomotor behaviors associated with the dopaminergic or opioidergic stimulation of the accumbens can be attenuated by injecting GABA agonists into the lateral preoptic area. Although many studies have correlated firing patterns in the accumbens with drug-seeking behaviors, few studies have focused on the role of the lateral preoptic area during drug self-administration. Importantly, recent anatomical work has shown that the lateral preoptic area sends an important neurotensin projection to the ventral tegmental area as well as GABAergic

projections to the ventral tegmental area, lateral habenula, and rostromedial tegmental nucleus. Thus, the lateral preoptic area is well positioned to influence reward circuitry. Therefore, the goal of the present study was to examine lateral preoptic neurons during cocaine self-administration and determine the neural correlates of lateral preoptic firing to drug-seeking behaviors.

Title: Neurobiological consequences of concurrent chronic stress and nicotine exposure in adult rats previously treated with nicotine during adolescence

Authors: *L. F. ALCANTARA, B. L. WARREN, E. M. PARISE, C. A. BOLAÑOS-GUZMÁN;
Psychology, Florida State Univ., Tallahassee, FL

Abstract: There is a high rate of comorbidity between mood disorders and tobacco consumption. Thus, it has been suggested that afflicted individuals may use nicotine to manage their mood. We have demonstrated that nicotine exposure during adolescence, but not adulthood, leads to a depression-like state manifested by decreased sensitivity to natural reward (sucrose preference) and enhanced sensitivity to both stress- and anxiety-eliciting situations in adulthood. Re-exposure to nicotine prior to the forced swim test (FST), a potent stressor, increases the incidence of escape-like behaviors, implying an anti-depressant-like affect. Additionally, chronic nicotine exposure during adolescence increases expression of the extracellular signal-regulated protein kinase 2 (ERK2), a signaling cascade implicated in motivation and mood regulation, and re-exposure to nicotine normalizes altered ERK2 activity within the ventral tegmental area (VTA). This suggests that nicotine exposure in adulthood could reverse the deficits caused by adolescent nicotine exposure, both at the behavioral and biochemical level. However, stress rarely occurs as a singular event and it is not known whether nicotine exposure during adulthood, in rats previously exposed to nicotine during adolescence, would buffer behavioral responses to chronic stress. To assess the possibilities, we exposed adolescent rats to saline or nicotine (0.32

mg/kg) for 15 days (postnatal day 35-49) and then left undisturbed for 4 weeks. At this time, rats were exposed to a chronic mild stress (CMS) paradigm during which half of each treatment group received concurrent saline or nicotine (0.32 mg/kg). Rats were then subjected to the elevated plus maze and the FST at various points throughout the CMS regimen to assess changes in anxiety- and depression-like behaviors, respectively. We also assessed mRNA and protein levels within the VTA, after CMS, to determine how nicotine re-exposure before acute stress differs from nicotine re-exposure during chronic stress. Our findings indicate that nicotine re-exposure in adulthood buffers the negative behavioral consequences induced by CMS exposure. Interestingly, preliminary results suggest that expression of ERK2 in the VTA is also normalized by nicotine re-exposure in adulthood. Together, this work suggests that re-exposure to nicotine in adulthood buffers the negative consequences induced by early life exposure to nicotine.

Title: Dissociating the psychoactive effects of distinct marijuana compounds in the mesocorticolimbic circuitry

Authors: *J. ZUNDER, S. R. LAVIOLETTE;
Dept. of Anat. and Cell Biol., The Univ. of Western Ontario, London, ON, Canada

Abstract: The mesocorticolimbic system, composed of the basolaetral amygdala (BLA), medial prefrontal cortex (mPFC), nucleus accumbens (NAcc) and ventral tegmental area (VTA), is responsible for processing the emotional and motivational significance of incoming sensory information. Dysfunctions in the underlying neural systems that regulate these processes may lead to aberrant salience attribution to what would normally be insignificant sensory experiences or events. In the extreme, such attribution may lead to psychotic ideation and persistent maladaptive behaviours.
The mesocorticolimbic system contains high levels of dopamine and cannabinoid CB1 receptors,

both of which have been implicated in the etiological profile of schizophrenia. A growing body of evidence supports the link between heavy marijuana exposure and an increased risk of developing schizphrenia. However, emerging clinical evidence suggests a functional dissociation between the two main pharmacological components of cannabis, cannabidiol (CBD) and Δ9-tetrahydrocannabinol (Δ9-THC). While Δ9-THC may precipitate, or even exacerbate psychotic symptoms, CBD has been shown to have antipsychotic and antianxiety properties comparable to conventional antipsychotic medications. CBD has been shown to be a weak antagonist of the CB1 receptor; in contrast, Δ9-THC acts as a partial CB1 agonist. Our previous work has shown that modulation of CB1 receptors in the mPFC-BLA pathway can mediate the emotional valence of an associative fear memory in a novel olfactory fear-conditioning paradigm. Activation of CB1 receptors in these areas results in the potentiation of an associative fear memory, while blockade of CB1 receptors prevent the formation of this memory. Our current objective is to extend these findings to other areas of the mesocorticolimbic system including the shell of the nucleus accumbens (NA Sh) and to examine the efficacy of the two major marijuana compounds (CBD and Δ9-THC) in mediating emotional learning and memory formation. Preliminary results suggest that CBD has rewarding properties and can block the formation of a fear memory to a normally highly salient footshock (0.8mA). In contrast, Δ9-THC seems to have aversive properties and potentiates the formation of a fear memory to a normally non-salient footshock (0.4mA). Ongoing studies are investigating the effects of chronic juvenile exposure to CBD and Δ9-THC on learning, memory and anxiety, and how these effects may be modulated through interactions with the serotonergic and mesolimbic dopaminergic systems respectively.

Title: Localization of ultrasonic vocalizations emitted by both male and female mouse models of Fragile X while socially interacting

Authors: *J. P. NEUNUEBEL, A. L. TAYLOR, B. J. ARTHUR, S. E. R. EGNOR;
Howard Hughes Med. Inst. - Janelia Farm Res. Campus, Ashburn, VA

Abstract: Autism is a neural developmental disorder that affects social behavior and impairs communication. Many genetically engineered mouse models of autism have shown deficits in social behavior and the production of ultrasonic vocalizations (Jamain et al., 2008; Rotschafer et al., 2012; Schmeisser et al., 2012). However, previous studies reporting vocal deficits for adult mice in social contexts have been limited by the inability to identify which mouse was vocalizing. Thus, the effect that a mouse's vocal interactions have on its behavior remains unknown. To address this issue, we simultaneously recorded vocalizations and behavior from groups (2 males and 2 females; 6-11 weeks old) of wild type (C57BL/6J; n = 7) or Fragile X (B6.129-Fmr1tm1Rbd/j; n = 7) mice over a period of five hours. Vocalizations were recorded in a large, acoustically favorable cage with an array of four ultrasonic microphones (Avisoft; CM16/CMPA). The source location of each vocalization was determined from the differences in arrival time between each pair of microphones and assigned to one of the four possible sources. Because of this method, our study is the first to identify the source of the vocalizer when multiple mice are present in the same environment. The results showed that both males and females emit ultrasonic vocalizations during social interactions regardless of their genetic background. Furthermore, provisional data suggest that each animal vocalized throughout the entire five-hour cohabitation period. Our future work will focus on quantifying the differences in vocal interaction patterns between wild type and Fragile X mice while examining the behavioral dynamics of the two groups during these periods.

Title: Female rejection and male vocal behavior may play an intimate role in the mating behavior of the house mouse

Authors: *K. SEAGRAVES, J. NEUNUEBEL, R. S. E. EGNOR;
HHMI's Janelia Farm, Ashburn, VA

Abstract: Ultrasonic vocalizations produced by adult male mice are thought to facilitate courtship behavior, either by attracting the female or by promoting her to stay close to the male

after the initial contact. Male mice produce ultrasonic vocalizations when exposed to female urine or a live female, and female mice spend more time near vocalizing males than near males who are mute. Additionally, in playback experiments females show a preference for a speaker emitting male vocalizations compared with a speaker producing background noise, and for the vocalizations of unfamiliar non-kin males over those of familiar sibling males. These results argue that females are able to use cues from the vocalizations to evaluate individual males, an ability that could be used in mate choice. However, it is not known whether male ultrasonic vocalizations affect a female's behavioral receptivity, or vice versa. We believe that the presence or absence of female rejection behavior can be used as a spontaneous measure of female receptivity, and by comparing male vocal behavior with the timing of female rejection events we can more fully understand how these two behaviors affect one another.
We simultaneously recorded audio and video data while adult male and female SWR/J mice were paired together in a 0.6 x 0.6 x 0.6 m cage for 10 minute sessions. We used MoTr (a mouse position tracking system developed in the lab [http://sourceforge.net/projects/motr/]) to identify the location of the mice in each video frame, and an automated program to extract time and frequency data for each ultrasonic vocalization in the audio recording. From these data we identified when ultrasonic vocalizations occurred relative to episodes of female rejection, and analyzed the characteristics of those vocalizations. Preliminary analyses show that significantly fewer vocalizations were recorded when the mice were less than 10 cm apart in sessions where female rejection was high, compared with sessions in which female rejection was low (t-test, $p < 0.001$). However, the number of vocalizations produced when the mice were more than 10 cm apart is not significantly different between the two session types. We will further analyze the data to answer a series of questions about how male vocal behavior and female rejection events affect one another, including: a) Does male vocalization rate change after a female rejection event? b) Is there a difference between the characteristics of ultrasonic vocalizations that occurred before and after female rejection events? c) Are there particular characteristics of male vocal behavior that affect the likelihood of female rejection?

Title: The Reelin-signaling pathway influences calling behavior: A cross-species approach

Authors: *E. FRALEY, S. A. WHITE, P. E. PHELPS;
UCLA, Los Angeles, CA

Abstract: The Reelin-signaling pathway has been implicated in autism spectrum disorders (ASD) through several lines of evidence including: genetic polymorphisms (SNPs) in *RELN*, cytogenetic abnormalities in autistic brain associated with changes on the long arm of chromosome 7 where *RELN* resides, and lower Reelin protein in the brain and blood of patients diagnosed with ASD relative to controls. New epidemiological evidence points to alterations in the primary intracellular signaling molecule Disabled-1 (Dab1) in a population that was found previously to have no ASD-associated SNPs in *RELN*. This finding underscores the importance of assessing the other components of the Reelin-signaling pathway in ASD etiology. Central features of ASD include impaired social interactions and language problems, symptoms that motivate studies in vocal-learning species such as the zebra finch songbird. We recently found that mRNA for one of the Reelin receptors, very-low density lipoprotein receptor (Vldlr), is regulated by singing behavior within the basal ganglia song control nucleus, area X of adult male zebra finches. Behavioral regulation of other components of the pathway, namely Reelin and Dab1, also were observed in area X and a subset of area X cells exhibited robust Dab1 expression. To identify these Reelin-sensitive cells, we are examining the expression of Reelin-signaling molecules in mouse basal ganglia, for which antigenic markers and mutant lines are available. We found Dab1-positive cells in mouse globus pallidus that resemble those in songbird area X. Although mice are not robust vocal learners, general mechanisms of vocal communication can be studied in this genetically modifiable species. A prior report indicated that, when separated from their dams, Reelin-deficient male mouse pups exhibited significantly fewer ultrasonic isolation calls compared to wild-type littermates at day 7. Now we ask if other components of the pathway, namely apolipoprotein receptor E2 (ApoER2), Vldlr and Dab1, also affect calling behavior by recording mouse pup ultrasonic isolation calls from wild-type, heterozygous and mutant mice of each genotype. Preliminary evidence confirms an age effect with reduced calling at day 14 compared to day 7 in all lines. Dab1-deficient male and female pups appear to call less than wild-type littermates at day 7. Call type analyses for this mutant line indicates that Dab1-deficient mice tend to have simpler, shorter call types compared to wild-type mice. This analysis is aided by our development of an automated clustering analysis for classifying call types by adapting methodology for analyzing birdsong.

Title: Assessing temporal processing in treefrogs using auditory evoked potentials

Authors: *K. M. SCHRODE[1], M. A. BEE[2];
[1]Grad. Program in Neurosci, [2]Dept. of Ecology, Evolution, and Behavior, Univ. of Minnesota, St Paul, MN

Abstract: It can be difficult to communicate acoustically in large social groups due to high noise levels, which can mask signals of interest. The human auditory system can exploit decreases or "dips" in the overall level of background noise to perceive glimpses of pertinent signals. Just as acoustic communication in social groups is not a uniquely human problem, dip listening is not a uniquely human solution. We have previously found that females of one species of treefrog, Cope's gray treefrog (Hyla chrysoscelis), are also able to exploit dips in background noise to recognize communication signals. However, a related species, the green treefrog (Hyla cinerea), appears incapable of doing so. Dip listening requires the auditory system to track fluctuations in the temporal envelope of sounds. We tested the hypothesis that differences in temporal processing between the two treefrog species can account for the apparent differences in dip listening. To test our hypothesis, we assessed temporal processing in gray and green treefrogs via two auditory evoked potential techniques. For one technique, stimuli consisted of two clicks presented with a varying inter-click interval. The shortest inter-click interval capable of eliciting two distinct responses is a measure of temporal integration time. In both species, we observed two distinct responses to clicks with inter-click intervals averaging as low as 3-4 ms. The second technique, the auditory steady-state response (ASSR), measured the ability of the auditory nerve to phase-lock to fluctuations in the envelope of amplitude-modulated tones. Modulation rate transfer functions (MRTFs) were created from the responses of the ASSR. The MRTFs were also very similar both in shape and magnitude for the two species. Our results indicate that temporal processing, at least at the level of the auditory nerve and as assessed by these two techniques, differs little between the two species. We did observe small species differences, but conclude that the differences are probably too small to be biologically relevant. We suspect that there are differences in temporal processing at higher levels of the ascending auditory system that can account for the species-difference in dip listening.

Title: The expression of foxp2 in the brain of adult green tree frogs

Authors: *D. SINKIEWICZ, W. WILCZYNSKI;
Neurosci. Inst., Georgia State Univ., Atlanta, GA

Abstract: Vocal behavior is common within the vertebrate lineage. The more primitive extant species that produce vocalizations do so without having to learn them, while some recently derived groups exhibit the ability to shape the vocalizations they produce through learning. Examining the genetic correlates of vocal communication in more primitive vertebrates provides insight into the evolution of vocal behavior and enables us to understand if there are shared genomic pathways for both learned and unlearned vocalizations. *Foxp2* is a gene that is involved in the learning of vocalizations in humans and songbirds. It has also been described developmentally in fish and amphibians, however, there is little known in regard to *foxp2* and vocalizations in these vertebrates. The green tree frog (*Hyla cinerea*) presents a powerful model for studying the genomics of primitive vocalizations because they produce calls without needing to learn them and only the males vocalize. We identified a portion of the *foxp2* transcript for the first time in *H. cinerea* and used that sequence to produce primers for quantitative PCR. In the present study we collected adult male and female green tree frogs in breeding condition. We then measured *foxp2* in brains from the collected animals following bisection into the telencephalon and the midbrain/hindbrain complex, hypothesizing that males would express higher levels when compared to females and that expression would be predominantly in the midbrain/hindbrain complex. We found that, while there is greater expression in the midbrain/hindbrain complex than in the telencephalon ($p = 0.002$), there is no effect of sex ($p = 0.550$) on expression. The regional difference is maintained when considering only males ($p = 0.05$) or only females ($p = 0.005$). These results indicate that the adult green tree frog midbrain/hindbrain expresses the majority of *foxp2* in both males and females. This region of the brain is home to several areas associated with both vocal production and auditory processing in amphibians. This suggests a strong possibility that *foxp2* is implicated in the vocal communication pathway of the green tree frog. This work was supported by a Brains & Behavior fellowship from GSU awarded to DMS.

Title: Concatenation of vocal gestures in a rodent model

Authors: *T. RIEDE;
Univ. of Utah, Dept. Biol., Salt Lake City, UT

Abstract: A small motor unit or gesture of vocal production represents an uninterrupted and unique motor pattern resulting in a specific acoustic pattern. The concept of generating and assembling vocal gestures has been demonstrated in songbirds and is well-described in humans. Nonhuman mammals can syntactically arrange calls into bouts, but the motor basis of call and bout production is little understood. Vocal production in mammals requires the fine-tuned interplay of laryngeal and respiratory movements. The simultaneous investigation of laryngeal and respiratory movements can illustrate how laryngeal and respiratory movements are integrated for sound generation. It could also show if and how flexible both movements are in generating vocal behavior. Vocal gestures were studied using laryngeal EMG and subglottal pressure recordings together with sound recordings in awake spontaneously behaving male Sprague-Dawley rats. Many call types of a rat's ultrasound vocal repertoire consisted of single motor gestures, but one call type, the 'composite call', appeared to be assembled from two or more different gestures. The rate of composite calls increased when a male interacts with a female and ranged between 0.2 and 12% in twelve male rats. Subglottal pressure pattern and laryngeal EMG activity during a gesture were not different if that gesture was produced in calls consisting of a single gesture or in composite calls. Furthermore, two different vocal gestures can be variably assembled into composite calls. Most often, the more dynamic gesture (for example, a trill component) was produced last in a composite call. The data support the hypothesis that rats use the concatenation of vocal gestures to generate more complex composite calls. The study cannot answer at which central level (brainstem or forebrain) the integration of the respective motor control is achieved, but it provides an example for this very basic requirement for the evolution of complex vocal systems.

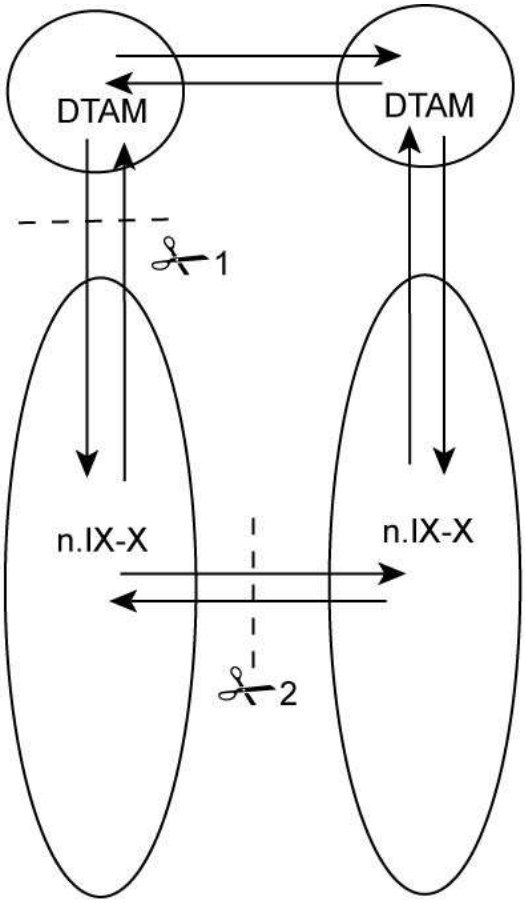
Title: Distinct neural control of vocal phases in frog calls

Authors: *A. YAMAGUCHI, J. C. BARNES;
Biol., Univ. of Utah, Salt Lake City, UT

Abstract: The behavior of animals is comprised of a variety of motions. How are the motions underlying a functional behavior generated by the nervous system? In our study, we use the vocalizations of African clawed frogs (*Xenopus laevis*) to address this question. During the breeding season, a male *Xenopus* generates advertisement calls that consist of alternating fast and slow trill phases. Previously, using a fictive preparation *in vitro*, we discovered that the advertisement call is generated by the central pattern generator (CPG) in the brainstem. The vocal CPG consists of a pair of premotor nuclei (DTAM) and a pair of laryngeal motor nuclei (n.IX-X) that are each interconnected (Fig). In this study, we examined how these nuclei contribute differently to the generation of fast and slow trill rhythms. In intact brains, application of serotonin elicits a series of compound action potentials (CAPs) that underlie fast and slow trills from left and right laryngeal motor nerves synchronously. Preliminary results indicate that when DTAM is disconnected from n.IX-X unilaterally (scissors 1), the fast trill deteriorated (in terms of rates and synchrony) while the slow trill remained intact. The results suggest that ascending projection from n.IX-X to DTAM is necessary for the proper generation of fast trill rhythms. In contrast, when connections between the n.IX-X are surgically transected (scissors 2), fast trills remained intact but the slow trills became asynchronous between the two sides, suggesting that slow trill rhythms are generated at the level of n.IX-X. Thus, fast trills seem to be generated by more complex neural mechanisms than slow trills. This may explain why a male *Xenopus* modifies its call structure by increasing the duration of fast trills when it detects a female.



The vocal nuclei that make up the central pattern generator in the brainstem of Xenopus. DTAM and n.IX-X are reciprocally connected.

Title: Intrasexual analysis of catecholaminergic cell groups and tyrosine hydroxylase fiber innervation of the vocal motor system in a teleost with alternative reproductive tactics

Authors: *Z. N. GHAHRAMANI[1,3], M. TIMOTHY[1], S. KIM[1], G. KAUR[2], P. M. FORLANO[1,3];

Abstract: The plainfin midshipman, Porichtys notatus, is a seasonal breeding marine teleost that produces vocal signals for intraspecific communication. There are two distinct reproductive male morphs: Type I males excavate and defend nests, and vocally court females by rapid contractions of the swim bladder musculature, while type II males do not court females but instead sneak-spawn and steal fertilizations from type I males. Previously established sexual polymorphisms in the hindbrain vocal circuitry of midshipman are related to divergence of male reproductive tactics, explaining the discrepancy in vocalizing ability. Catecholamines, including the neurotransmitters dopamine and noradrenaline, are known regulators of reproduction and sexually motivated behaviors across vertebrates, including vocal-acoustic communication. Therefore, we tested the hypothesis that intrasexual differences in catecholaminergic neuroanatomy may reflect intrasexual differences in vocal circuitry and behavior. Male morphs were collected from nesting sites in Tomales Bay, CA during the summer nesting season and brains were labeled by immunofluorescence for tyrosine hydroxylase (TH-ir), the rate-limiting enzyme in catecholamine synthesis. We compared numbers of catecholaminergic neurons in several nuclei including the periventricular posterior tuberculum, locus coeruleus, vagal and area postrema, known to project, in part, to vocal-acoustic centers. We also quantified catecholaminergic innervation in several nuclei within the descending vocal pathway. Preliminary results suggest no significant differences in the number of TH-ir neurons within analyzed nuclei. However, type II males have a greater density and intensity of TH-ir fibers in the dimorphic vocal motor nucleus, which directly innervates vocal musculature. Our findings support the hypothesis that TH-ir dimorphisms in vocal pathways are substrates of behavioral divergence between the two types of male midshipman, indicating possible mechanisms of neural plasticity modulating social behavior.

Center, Natl. Marine Fisheries Service, Natl. Oceanic and Atmospheric Admin., Seattle, WA

Abstract: The plainfin midshipman, Porichthys notatus, is a Pacific Northwest deep-water fish that makes seasonal migrations into the shallow intertidal zone to breed. Parental, or type I, males excavate nest sites under rocky shelters from which they produce low frequency advertisement calls (or "hums") to attract females to mate. Females detect these courtship calls using the saccule, the primary hearing organ in midshipman and most other fish species. Females undergo seasonal shifts in auditory sensitivity, particularly in the frequency range associated with the male hum. These physiological changes have been attributed to fluctuating levels of steroid hormones, including estrogen, and have been observed in the peripheral auditory system at the level of the saccular hair cells and VIIth nerve saccular afferents. Previous work has also shown a seasonal addition of hair cells in the saccule, which are thought to play a role in the increased auditory sensitivity of reproductive females. This study tests the hypothesis that elevated estrogen levels can induce an increase in saccular hair cell density. Non-reproductive female midshipman fish were gonadectomized and implanted with estrogen or control (empty) capsules. After 28-31 days fish were sacrificed and their saccular epithelia were stained with phalloidin (actin-binding hair cell marker), mounted and imaged with confocal microscopy. Hair cell counts were conducted in seven distinct regions across the saccular epithelium. Blood samples were also taken to measure circulating levels of estrogen in the control and implanted fish. Results show an estrogen-dependent increase in hair cell density consistent with our previous work in naturally occurring reproductive fish, suggesting a possible steroid-dependent mechanism for seasonal differences in hearing sensitivity and hair cell plasticity observed in this species.

Title: Immunohistochemical localization of GABA and serotonin provides an emerging picture of neuromodulator interactivity in a vocal teleost

Authors: *M. TIMOTHY, P. M. FORLANO;
Biol., Brooklyn College, City Univ. of New York (CUNY), Brooklyn, NY

Abstract: The inhibitory neurotransmitter gamma-amino-butyric acid (GABA) is essential for vertebrate neuronal signaling. Moreover, GABAergic neurons are integral components of neuromodulatory networks such as the monoamine serotonergic system. We utilized fluorescent immunohistochemistry against GABA and serotonin to map the putative interaction of these systems in the plainfin midshipman fish, a teleost model of vocal and auditory behavior. Prior anatomical research has shown the presence of monoamine immunoreactive cells and fibers in evolutionarily conserved circuitry involved in the processing and integration of audition and vocalization. Here, we identify GABA signal in cells and fibers throughout these behaviorally relevant nuclei, often in proximity to serotonin-ir signal. GABA-ir cells were found interspersed with serotonergic cells in the superior raphe nuclei. GABA-ir cells and processes were found proximal to the hindbrain-spinal cord vocal pattern generator, isthmal vocal processing areas, and the midbrain periaqueductal gray as well as in auditory nuclei in the hindbrain and torus semicircularis. 5-HT-ir fibers overlapping GABA-ir cells and processes were also identified in vocal-acoustic integration areas throughout the hypothalamus, including the anterior tuberal nucleus and preoptic area. These data suggest a crucial role for GABA as an interneuronal mediator of serotonin signaling in circuitry underlying vocal-acoustic behavior.

Title: Inferred organization of a dinosaur brain

Authors: *C.-C. CHEN[1], K. WADA[3], M. V. RIVAS[4], E. JARVIS[2], D. SOARES[5], D. FRIEDEBERG[2], T. GLENN[6], E. D. JARVIS[2];

Abstract: Because dinosaurs are extinct, no known viable brain material exists. The closest living relatives are crocodiles, which pre-date many dinosaurs, and birds, which post-date them. Therefore, the similarities between the brains of crocodiles and birds would suggest shared organization with dinosaur brains. Here, we used thirteen genes [PPAPDC1A, SEMA6A, FOXP1, FOXP2, SLIT1, COUP-TF2, ER81, LHX9, GRIN2D, GRIN2A, ROR-β, DLX6, LHX8] that we found define seven major cerebral subdivisions of the avian brain, consistent with a new understanding of avian brain organization (Jarvis et al., 2013; Chen et al., 2013), to decipher whether some or most of these regions exists in crocodilian brain. We found six regions in the alligator brain with a similar, but not identical organization as the avian brain. Two of these, the striatum and pallidum, make up the basal ganglia, which we know to be conserved among amniotes. The others include the pallial regions that in birds were recently redefined as the arcopallium, nidopallium, mesopallium, hyperpallium and associated primary sensory pallial fields. These regions in birds contain pathways for vocal learning behavior and other complex behaviors, and like in birds show hearing-induced gene expression when hearing alligator vocalizations. The more highly developed subdivision in birds was the hyperpallium, at the dorsal surface of the brain, which contains one of two visual pathways and somatosensory processing areas. Overall, the molecular topographic organization of the crocodilian cerebrum is about 90% similar to that of birds, including the presence of a relatively large pallium, an analogue of the mammalian cortex. These findings suggest that the brains of dinosaurs must have included a cerebrum with these six subdivisions that have the capacity to process complex, cognitive behaviors.

Title: Defining a new terminology for non-avian reptile brains

Authors: *D. FRIEDEBERG, C.-C. CHEN, E. JARVIS, M. LEAL;
Duke, Durham, NC

Abstract: In 2004 the Avian Brain Nomenclature Consortium published a new avian brain terminology that better reflects our current understanding of the homologies between mammals and birds. This revision was based on neural connectivity, developmental, neurobehavioral, and particularly comparative gene expression profile studies. The consortium concluded that the avian telencephalon is organized into pallial, striatal and pallidal regions that are homologous in all vertebrates. The new nomenclature has replaced the classic system in all contemporary avian neurobiology studies. Though this modern avian nomenclature should by extension include all reptiles, non-avian reptilian studies continue to use a partly obsolete system. This is due in part to the lack of a systematic comparative identification of the telenchepalic regions between birds and non-avian reptiles. In our companion abstract, we discovered that most telencephalic cell populations identified with gene expression markers in the avian brain are also present in their closest living relatives, crocodiles. Here, we used multiple gene expression patterns to delineate the telencephalic subdivisions in two other reptile lineages, lizards and turtles. We found that these markers labeled in the classically defined lizard and turtle dorsal ventricular ridge (DVR) a mesopallium-like region, a nidoplallium-like region, and an arcopallium-like region. These regions had continuous domains that wrapped dorsal to the lateral ventrical, where the hyperpallium and dorsal mesopallium are located in birds. However the relative shapes of these regions were more divergent than the alligator was to birds. We are currently examining additional markers, including those of the primary sensory populations of the pallium. Overall, putative homologues of the revised cell population can be found in non-avian reptiles, but there is divergence on the overall topology of the populations.

Title: Reconceptualizing the auditory dorsal stream within a unified neurobiological model of audition and language

Authors: *I. BORNKESSEL-SCHLESEWSKY[1], J. P. RAUSCHECKER[2], M. SCHLESEWSKY[3], S. L. SMALL[4];
[1]Dept. of Germanic Linguistics, Univ. of Marburg, Marburg, Germany; [2]Georgetown Univ., Washington, DC; [3]Johannes Gutenberg-University, Mainz, Germany; [4]Univ. of California Irvine, Irvine, CA

Abstract: Successful models of human brain systems are typically based on detailed animal models. However, this approach was long deemed impossible for higher cognitive functions such as language since these, almost by definition, are not shared across species. Within the now generally accepted framework of dual (i.e. dorsal and ventral) auditory pathways, this issue has been debated particularly for the dorsal stream, with several influential dual-stream models of speech and language based on the assumption of a dissociation from the auditory dorsal stream in non-human primates [1,2].
Here, we present a reconceptualization of the auditory dorsal stream as the basis for a new, unified, cross-species model of auditory cognition. Specifically, we posit that the dorsal stream shows a parallel organization to the ventral stream in that it is structured hierarchically and subserves the processing of auditory input from primary auditory regions to posterior temporal, inferior parietal and frontal regions. The crucial difference between the two streams lies in the nature of the computations performed: in contrast to the ventral stream's identification and encoding of successively more complex auditory objects (via experience-based statistical associations) [3], the dorsal stream performs time-dependent computations predicting future outcomes that are subsequently matched against the actual input in the sense of a forward model. This computational characterization applies to auditory spatial information in both monkeys and humans, as well as to speech and other human cognitive tasks that require complex sequence processing (e.g. understanding sentences) [4]. A characterization of the dorsal stream along these lines paves the way for the assumption that both streams operate in monkeys as well as humans and, most importantly, that they process all types of auditory stimuli - from simple sounds to higher-level sequences (e.g. language, music).
In addition to presenting the basic assumptions of this new model, we review recent evidence in its favor, including findings on sentence processing in normal and patient populations as well as the observation of a cortical hierarchy of temporal receptive windows [5].

Title: Generation of unique vocalizations via laryngeal filtering and premotor patterning

Authors: *C. L. BARKAN[1], D. B. KELLEY[2];
[1]Neurobio. & Behavior, [2]Biol. Sci., Columbia Univ., New York, NY

Abstract: Xenopus males produce temporally distinct calls that attract female mates and silence male rivals. The X. laevis clade includes 6 geographically distinct populations. Two of these, X. laevis South Africa (SA) and X. laevis Congo (Cg), produce a call composed of two distinct click rate segments. However, in X. laevis SA the segments are fast and slow trills, while in X. laevis Cg the segments are slow trills and single clicks. Segment durations in X. laevis Cg are shorter than in SA. We are using these two populations to determine vocal circuit properties that underlie generation of temporally distinct motor patterns.

Sound production in X. laevis relies on contractions of a single set of muscles in the larynx. Activity recorded from the motor nerve innervating the laryngeal muscles matches the temporal pattern of the click trains comprising vocalizations. The simplicity of this sound production mechanism led to development of two experimentally reduced preparations: an isolated brain that facilitates analysis of the hindbrain vocal central pattern generator (CPG) and an isolated larynx that assesses how CPG output is translated to vocal clicks. An isolated X. laevis SA brain bathed in serotonin produces compound action potentials (CAPs) on the laryngeal nerve that precisely match the temporal pattern of clicks comprising vocalizations. Cells in the pre-motor dorsal tegmental area of the medulla (DTAM) drive the vocal motor neurons that synchronously produce the CAPs and set CAP rate and segment duration. In the isolated X. laevis SA larynx, each stimulus applied to the laryngeal nerves elicits a vocal click.

In X. laevis Cg, we find that CAPs recorded from the laryngeal nerve in response to serotonin match the vocal patterns only during the slow segment, not the single click segment. During the portion of fictive calling corresponding to the single click segment, the nerve produces bursts of fast rate CAPs. Recordings of laryngeal muscle EMG, tension transients and sound production suggest that the larynx transforms trains of fast rate CAPs on the nerve into single vocal clicks,

but faithfully reproduces CAPs at a slow rate. Extracellular recordings indicate that DTAM activity precedes CAP patterns on the nerve and sets the shorter duration of the segments. These findings suggest that similar CPG mechanisms set distinct call segment durations in X. laevis SA and Cg, but that click number is regulated at fast rates by a laryngeal filter in X. laevis Cg and not X. laevis SA. Further investigation of how vocal patterns are created by hindbrain circuitry and filtered by the larynx will provide insight into how each Xenopus population produces a unique call.

Title: Anterior lateral line nerve encoding to tones and play back vocalisations in free swimming oyster toadfish, Opsanus tau

Authors: C. A. RADFORD[1,2], *A. F. MENSINGER[3,2];
[1]Univ. of Aukland, Aukland, New Zealand; [2]Marine Biol. Lab., Woods Hole, MA; [3]Univ. of Minnesota Duluth, DULUTH, MN

Abstract: In the underwater environment, sound propagates both as a pressure wave and as particle motion, with particle motions dominating close to the source. At the receptor level, both the fish ear and the neuromast hair cells act as displacement detectors and both are potentially stimulated by the particle motion component of sound sources. Here we examined the encoding of the anterior lateral line nerve to sound stimuli in a freely behaving oyster toadfish, Opsanus tau, using the chronic recording technique. Nerve sensitivity and directional responses were constructed using spike rate and vector strength analysis, a measure of phase-locking of spike times to the stimulus waveform. All units showed greatest sensitivity to 100 Hz. While sensitivity did not change with orientation to the stimulus their ability to phase-lock did. Three different types of units were classified, Type 1 (tonic), Type 2 (phasic) and Type 3 (inhibitory).

The Type 1 fibers could be classified further into two sub-types based on their frequency response (Type 1-1 and Type 1-2), which was hypothesised to be related to canal (Type 1-1) and superficial (Type 1-2) neuromast innervation. Oyster toadfish also exhibited sensitivity and phase locked to boatwhistle vocalisations, with greatest spike rates exhibited at the onset of the call. These results provide the first direct evidence that oyster toadfish can use their lateral line to detect behaviourally relevant sound stimuli, which could provide a second sensory pathway to aid in sound source localisation.

Title: Evidence of voluntary vocal control by the common marmosets (Callithrix jacchus)

Authors: *L. ZHAO, S. ROY, X. WANG;
Dept. of Biomed. Engin., The Johns Hopkins Univ. Sch. of Med., Baltimore, MD

Abstract: Humans are capable of exquisite voluntary vocal control in such behaviors as speaking and singing. When presented with altered auditory feedback, human subjects quickly adjust parameters of vocal production to compensate for feedback perturbations. However, it has long been believed that non-human primates are incapable of voluntary vocal control. Instead their vocalizations are stereotyped and do not exhibit compensations when presented with feedback perturbations. Recent experiments in our laboratory in the common marmoset (Callithrix jacchus), a highly vocal New World primate, showed that they exhibited the Lombard effect in noisy background and were capable of adjusting the timing of calls during vocal exchanges in the presence of interfering noise. In the present study, we investigated whether marmosets are capable of altering acoustic structures of their vocalizations when presented with interrupting noises. Marmosets produce long duration calls known as phee calls and are often engaged in antiphonal calling when visual contact is occluded. Our study was based on phee calls and the antiphonal calling behavior paradigm. We introduced acoustic perturbations by playing interfering noises during a vocalization while a marmoset was producing spontaneous phees or engaged in antiphonal calling. The acoustic perturbations led to vocal alterations not only in call timing but also in its spectral characteristics. Our results showed that: (1) with

acoustic perturbations, marmosets produced phee calls with fewer phrases than observed during vocal exchanges in normal conditions; (2) the perturbations resulted in changes in the fine structure of calls (e.g., change in frequency slope was found to be higher in calls with perturbation compared to calls in silent background); (3) when presented with band-pass noise at frequency either below or above the fundamental frequency (F0) of vocalization, marmosets tended to shift their vocalization F0 away from the noise spectrum. Collectively, these results suggest that marmosets rely on auditory feedback to maintain their vocalizations and exhibit voluntary control of the acoustic structures of their vocalizations. Title: Characterizing human ion channels in induced pluripotent stem cell derived neurons

Authors: *S. STOELZLE, A. HAYTHORNTHWAITE;
Nanion Technologies, Munich, Germany

Abstract: Neurons derived from human induced pluripotent stem cells were characterized using manual and automated patch clamp recordings. These cells expressed voltage-gated Na, Ca and K channels as expected from excitable cells. The Na current was TTX sensitive. About 50% of the Ca current was blocked by 10 μM of the L-type channel blocker nifedipine. Two populations of K channel were present in different proportions: an inactivating (A-type) and a non-inactivating type. The A-type current was sensitive to 4-AP and TEA. Application of γ-aminobutyric acid (GABA) activated a current sensitive to the GABAA receptor antagonist bicuculline. In both devices, comparable action potentials were generated in current clamp. With unbiased, automated patch clamp, about 40% of the cells expressed Na currents, while visual guidance in manual patch clamp provides almost 100% success rate of patching 'excitable cells'. These results show high potential for pluripotent stem cell-derived neurons as a useful model for drug discovery, in combination with automated patch clamp recordings for high throughput and high quality drug assessments at human neuronal ion channels in their correct cellular background.

Title: Development of an impedance measurement system to detect temperature changes in single ionic channels using Patch-Clamp technique

Authors: *J. AGUILAR[1], L. ISLAS[2], D. ELIAS-VIÑAS[1];
[1]Bioelectronics seccion, CINVESTAV-IPN, Mexico City, Mexico; [2]Fisiologia, Univ. Nacional Autónoma de México, Facultad de Medicina, Mexico city, Mexico

Abstract: Temperature gating studies of ion channels by patch clamp recording methods have been made difficult by a lack of methods for rapid alteration and detection of temperature in live cells. To address this issue, we developed a closed-loop temperature control system with infrared diode lasers (as heat generator), a cooling system based on peltier cells (thermoelectric cells) controlled by a pulse width modulator (PWM), a digital ohmmeter and a containment chamber. The aim of this system was to obtain a controlled temperature pulse and to detect cell responses induced by temperature changes. The digital ohmmeter measures the bath´s impedance near a cell or membrane path (as a temperature indicator) through electrodes, digitally selects the corresponding gain for the value interval that will be measured in the cell, therefore obtaining a corresponding value to that measurement in ohms. The impedance measurement system has been evaluated through electric simulators and our results corroborate system functionality. The cooling system rapidly diminishes the temperature near a cell, does not interfere with patch clamp recordings and does not heat the containment chamber. Our system has the advantage of been a low cost device and to be a useful tool for recording electrical signals from channels of living cells with an adequate temporal resolution through patch clamp techniques and under precise temperature control.

Title: Transforming the TRP channel drug discovery using medium throughput electrophysiological assays

Authors: J.-M. CHAMBARD, E. TAGAT, P. BOUDEAU, *M. PARTISETI;
Lead Identification Technologies, Sanofi R&D, Vitry sur Seine, France

Abstract: Since the cloning of its first member in 1998, transient receptor potential (TRP) cation channels have become one of the most studied ion channel families in drug discovery. These channels, almost all calcium permeant, have been involved in many different (patho)-physiological and therapeutic areas as diverse as pain, neurodegenerative, cardiovascular, inflammatory diseases and cancer.
At the same time, implementation of automated electrophysiology screening platforms has significantly increased the tractability of ion channels, mainly voltage-gated, as drug targets. The work presented in this poster shows the design and validation of TRP screening assays using the IonWorks Quattro platform (Molecular Devices) allowing a significant increase in throughput to support drug discovery programs. This new player has a direct impact on resources and timelines by prioritizing potential candidates and reducing the number of molecules requiring final testing by manual patch-clamp which is still today the gold standard technology for this challenging drug target class.

Title: A method for patch-clamp recordings of fast-acting ion channels in rat dorsal root ganglion cells

Authors: *J. SVENSSON DALÉN, A. KARLSSON, M. KARLSSON, S. ASPENGREN, P. KARILA;
Cellectricon AB, Mölndal, Sweden

Abstract: We have developed a patch clamp based assay for characterization of fast-acting ion channels in primary dorsal root ganglion (DRG) neurons. This assay is based on the use of primary DRG neurons in culture as a cell model for chronic pain. These neurons retain their sensory functionality and remain responsive to thermal, mechanical and functional stimuli, and when supplemented with nerve growth factor (NGF) they can be used to mimic peripheral sensitization.
The assay utilizes a microfluidic perfusion system, Dynaflow Resolve, to facilitate a stable recording situation and fast and programmable solution exchange. At the start of the experiment, compounds and buffer are loaded in the 16 wells of the Dynaflow Resolve chip. Micro-channels connect each well to a recording chamber where the cells are added. To be able to provide fast solution exchange the DRG neuron is lifted using the patch pipette and positioned in front of the micro-channel outlets. Then, the cell is scanned through the discrete flow zones formed outside the channels.
Data will be presented on the characterization on P2X receptor-mediated ionic currents in dorsal root ganglion neurons.

Title: Achieving Quality and Throughput in human nAChR α7 Screening: A Cross-platform comparison study using a recombinant cell model

Authors: *H. WEI, C. W. BENJAMIN, D. H. WERTH;
EMD Millipore Corporation, Discovery & Develop. Solutions, Saint Charles, MO

Abstract: The α7 subtype of nicotinic acetylcholine receptors (nAChRs) is a ligand gated ion channel of broad distribution whose activity can be modulated by endogenous neurotransmitters as well as synthetic ligands. There is a growing body of evidence that nAChR α7 is an important target for Alzheimer's disease, Schizophrenia and other psychiatric disorders. Selective nAChR

α7 agonists, as well as allosteric modulators and pharmaceutically relevant antagonists are in development for the treatment of these diseases. However, the screening efforts for compounds targeting nAChR α7 are constrained due to the unique properties of nAChR α7 such as the low probability of channel opening and rapid desensitization. In addition, the challenges in recording nAChR α7 ion flux are complicated by the need for higher throughput platforms. In this study, we compared the activation profile of the PrecisION™ hnAChR α7/ric3-HEK recombinant cell line (EMD Millipore, Cat. No.: CYL3097) to the endogenous ligand acetylcholine (ACh), reference agonists, antagonists and positive allosteric modulators (PAMs), using three unique recording platforms with a range of throughput capacity: OctaFlow ^{TM} fast perfusion manual electrophysiology system, PatchXpress 7000A and FLIPR$^{TETRA\ TM}$ system. These methods produced consistent pharmacology data within instrumentation, suggesting that the recombinant cell model provides robust data in both low and high-throughput platforms. This study provides validation of the recombinant cell model using different platforms and supports their use for screening nAChR α7 compounds for agonist, antagonist and modulator activity.

Title: Lab-on-a-chip microfluidic device for kinetically resolved electrochemical detection of adrenal catecholamine secretion

Authors: *K. P. CURRIE[1], I. GES[2], R. L. BRINDLEY[1], F. J. BAUDENBACHER[2];
[1]Anesthesiol & Pharmacol, Vanderbilt Univ. Sch. of Med., NASHVILLE, TN; [2]Biomed. Engin., Vanderbilt Univ., Nashville, TN

Abstract: Release of neurotransmitters and hormones by calcium-regulated exocytosis is a fundamental cellular/molecular process that is disrupted in a variety of psychiatric, neurological, and endocrine disorders. Therefore, this area represents a relevant target for drug and therapeutic development, efforts that will be aided by novel analytical tools and devices that provide mechanistically rich data with increased throughput. Here we outline a microfluidic platform designed to analyze catecholamine secretion from small populations of adrenal chromaffin cells, an important neuroendocrine component of the sympathetic nervous system and versatile

neurosecretory model. Our goal was to develop a modular platform that will: 1) enable rapid and reliable assessment of drug candidates or other manipulations on neuroendocrine secretion (e.g. use cells isolated from transgenic mice, or other rodent models of disease); 2) maintain and enable spatiotemporal analyses of autocrine/paracrine communication within small clusters of chromaffin cells; 3) develop a "sympathoadrenal module" for future "on-chip" integrative analyses of physiological systems.
The devices were fabricated by replica molding using a patterned photoresist on a silicon wafer as the master, and polydimethylsiloxane (PDMS) as the biocompatible polymer. Three microfluidic inlet channels lead to an array of "cell traps", each capable of immobilizing single or small clusters of chromaffin cells. This is assembled onto a glass coverslip with patterned thin film platinum electrodes for electrochemical detection of catecholamines. The response of the platinum electrodes to perfusion of the device with epinephrine / norepinephrine (no cells present) was stable and linearly related to catecholamine concentration. We optimized the cell isolation procedure to enable reliable loading of the device with small populations of bovine chromaffin cells. Robust catecholamine secretion was evoked by perfusion with physiologically relevant secretagogues (direct depolarization with KCl, the cholinergic agonist carbachol, or the neuropeptide PACAP). The response to carbachol was concentration-dependent, and abolished in the absence of extracellular calcium. We also show that the kinetics of catecholamine secretion can be followed with high temporal resolution, and remain stable during multiple rounds of stimulation. Overall, the data we present demonstrate the utility of this microfluidic device for quantitative analyses of the amount and time-course of catecholamine secretion from neuroendocrine chromaffin cells.

Title: Enhancement of neurite outgrowth and neuronal differentiation by using β-NGF conjugated to maghemite nanoparticles

Authors: M. MARCUS[1], H. SKAAT[2], S. MARGEL[2], *O. SHEFI[1];
[1]Fac. of Engin. and Inst. of Nanotechnologies and Advanced Materials, Ramat Gan, Israel;
[2]Dept. of Chem. and Inst. of Nanotechnologies and Advanced Materials, Bar Ilan Univ., Ramat Gan, Israel

Abstract: The ability to increase neuronal differentiation and neuronal growth has great implications in the tissue engineering field. In the present study, we describe a new approach to promote neuronal differentiation and growth, by using a NGF-nano-based tool. Growth factors are critical components in nerve tissue development and repair. The nerve growth factor (β-NGF), a prototypical growth factor, functions as a signaling molecule and stimulates the growth, maintenance and survival of certain target neurons. We found that covalent conjugation of β-NGF to maghemite (γ-Fe2O3) nanoparticles enhances neuronal differentiation in PC12 cells. PC12 cells, a common model for primary neuronal cells, undergo cellular changes when exposed to β-NGF in vitro, i.e., cease proliferation, grow long neurites, and show changes in cellular composition associated with neuronal differentiation. In our study, PC12 cells were exposed to β-NGF, conjugated to maghemite nanoparticles or as a free factor, and the effect on cell-differentiation properties was observed. We found that the stabilization of β-NGF by covalent conjugation to the maghemite nanoparticles significantly enhances PC12 neurites outgrowth, compared to free β-NGF at the same concentration. We also found an increase in the complexity of the branching tree and in the clustering behavior. In addition, neuronal differentiation markers were upregulated in PC12 cells when treated with the conjugated factor. Several concentrations of nanoparticles were tested indicating the effect to be more significant at lower concentrations. Single cell imaging revealed particles accumulation in the soma (but not in the nucleus), in the growth cones and at branching points. We suggest that by covalently binding β-NGF to nanoparticles, β-NGF's half-life is extended and therefore leads to an increase in PC12 differentiation. Our study opens new directions in neuronal repair.

Title: Use of stem cell-derived human neurons to screen a chemical library for potential neurotoxicity

Authors: *M. ROACH[1], R. MALAVARCA[2], K. GOMES[2];
[1]PhoenixSongs Biologicals, Inc., Branford, CT; [2]PhoenixSongs Biologicals, Branford, CT

Abstract:
Human neural stem cells (NSCs) offer advantages over established cell lines and primary rodent neurons in that they are genetically stable, scalable for molecular and chemical screening and they can be reliably differentiated into excitatory and inhibitory neurons with mature functional synapses for use in cellular assays for drug efficacy and chemical safety screens.
Here we will present how we have used human neurons produced from the robust and scalable differentiation of neural stem cells in a high throughput format to screen a chemical library to identify compounds that have potential neurotoxicity. The NSCs were expanded and differentiated in defined media containing stage specific growth factors and signaling molecules and then following 28 days of differentiation and maturation were exposed to the compounds for 24-48 hours.
The results from these studies will be presented.

Title: Establishment of a single cell assay to screen individual cell types for efficacy of putative small molecule drugs for lowering Aß

Authors: *M.-C. LIAO[1], J. LOVE[2], T. YOUNG-PEARSE[1];
[1]Harvard Med. School/Brigham and Women'S Hosp., Boston, MA; [2]Dept. of Chem. Engin., MIT, Boston, MA

Abstract: Progressive accumulation of amyloid beta (Aß) in senile plaques in the brain is a hallmark of Alzheimer's disease (AD). Aß is generated from sequential processing of amyloid precursor protein (APP) by ß-secretase followed by γ-secretase. Aß species of varying amino acid lengths are generated due to imprecise cleavage by γ-secretase within the transmembrance

domain of APP. In familial AD, mutations in APP or Presenillin1 lead to a general increase in Aß production, or more commonly to an increase in the ratio of Aß42 to Aß40. Several classes of γ-secretase inhibitors have been developed that target Aß production. Because γ-secretase cleaves a multitude of substrates in addition to APP, it is important to identify γ-secretase modulators having selective effects on the generation of Aß, but only minimal effects on other γ-secretase substrates. While Aß is generated throughout the body, neuronal cells generate high levels relative to other cell types. Very little is known about which neuronal subtypes secrete the most toxic forms of Aß. Therefore, high throughput examination of which cell types generate the highest levels of Aß, and the response of these cells to γ -secretase inhibitors would be valuable. In order to investigate Aß production from single neuronal cells, we adopted the method of microengraving, which was originally developed in the immunology field by Dr. Love's lab at MIT. First, we optimized the capture and detection antibody pairs that are specific for total Aß, Aß40 or Aß42. These antibody pairs allowed us to detect Aß production from single human APP overexpressed cell over the course of 2-4 hours in culture. Second, through comparison of the Aß level from single cells before and after treatment with different γ-secretase inhibitors (DAPT, L685,458, 31C and compound E), we observed that there are different profiles of responsiveness from single cells with different inhibitors. In addition, we evaluated Aß40 and Aß42 levels from single cells before and after treatment of different γ-secretase modulators including R-flurbiprofen and sulindac sulfate. Treatment with these modulators showed that the correlation slope of Aß42 to Aß40 was reduced after treatment suggesting that these γ-secretase modulators lowered the production of Aß42 to a greater degree than Aß40 when examined at the single cell level. Ongoing studies are examining total Aß detected from individual neuronal cells derived from human induced pluripotent stem cells. From the single cell analysis platform, we could evaluate what subtypes of neurons secrete the highest levels of Aß, and further evaluate the response of each single cell to different γ-secretase inhibitors and modulators.

Title: Characterization of human fetal hippocampus-derived neural stem/progenitor cells and its application to drug discovery

Authors: *K. FUKUSHIMA, Y. IMAIZUMI, Y. TABATA, N. KOHMURA, K. YAMAZAKI, M. SUGAWARA, K. SAWADA, M. ITO;
Eisai Co., Ltd., Tsukuba-Shi / Ibaraki, Japan

Abstract: To improve the success rate of drug development, it is important to predict clinical efficacy and toxicity of candidate compounds in its upper stream with high probability. Human cells are a promising tool to be used for this purpose, but it has been difficult to utilize human cells in the neuroscience field, because of limited accessibility to human primary neurons. However, recent progress in human stem cell availability has provided solutions for this problem, such as using human iPS cells-derived and human neural stem cells-derived neurons. In this study, we characterized HIP009 cells (PhoenixSongs Biologicals, Inc.) which are human fetal hippocampus-derived neural stem/progenitor cells. HIP009 cells can be differentiated into neural cells by the cultivation in differentiation medium for ≥ 4 weeks. After the differentiation, population analysis by immunocytochemistry showed that about fifty percent of differentiated HIP009 cells were neurons and the remaining were astrocytes. mRNA expression analysis by RT-qPCR revealed that MAP2 expression was upregulated in the differentiated HIP009 cells, indicating differentiation into neurons. The analysis also demonstrated upregulation of *GRIN1* encoding NMDA receptor subunit 1, and *GRIA2* encoding AMPA receptor subunit 2. To confirm these glutamate receptor function, Ca^{2+} mobilization assay of differentiated HIP009 cells was conducted using a Ca^{2+} sensitive fluorescent dye. Fluorescent signals were increased by NMDA treatment, and NMDA-induced signals were decreased by MK-801 in a concentration-dependent manner. These results indicated that differentiated HIP009 cells expressed functional NMDA receptors. In addition, function of AMPA receptors was confirmed by AMPA and NBQX. AMPA also increased frequency of spontaneous action potential in electrophysiological recordings. These data suggest that differentiated HIP009 cells are a unique tool derived from human neural stem/progenitor cells to assess effects of compounds on human NMDA and AMPA receptors. Moreover, differentiated HIP009 cells can be more applicable to the drug screening than human primary neurons, because undifferentiated HIP009 cells can be proliferative.

Title: Fast-scan cyclic voltammetric measurements of tonic and phasic dopaminergic neurotransmission

Authors: C. W. ATCHERLEY[1], K. M. WOOD[2], E. B. MONROE[1], N. D. LAUDE[1], K. L. PARENT[1], P. HASHEMI[2], *M. L. HEIEN[1];
[1]Chem. and Biochem., Univ. of Arizona, Tucson, AZ; [2]Wayne State Univ., Detroit, MI

Abstract: Fast-scan cyclic voltammetry (FSCV) at carbon fiber microelectrodes (CFMs) is a well-established technique used to correlate phasic (rapid) chemical changes to electrical, pharmacological, and behavioral stimulations. A large, non-Faradaic background current generated from high scan rates necessitates background subtraction, which makes FSCV unable to measure tonic (slow) changes. This limitation means that flow injection analysis (FIA), where a sample bolus is introduced onto the CFM, is needed for in vitro calibrations. In this work, we show that calibration using FIA underestimates neurotransmitter concentration and overestimates their duration. We describe the development of a novel method, delayed-timing voltammetry (DTV), which exploits adsorption phenomena at CFMs. We use DTV to report absolute dopamine concentrations in vivo. With FSCV, electrically stimulated, phasic dopamine changes were determined to be 560 + 60 (± SEM, n = 15 animals) and with DTV, the tonic levels of dopamine in vivo were measured as 210 ± 25 nM (± SEM, n = 15 animals). These measurements were validated with pharmacological agents. Furthermore, DTV was to develop a kinetic calibration for in vivo measurements. Because the response of carbon-fiber microelectrodes is on the same temporal order as biological events, pharmacokinetic studies have been difficult. By using a kinetic calibration the electrode response can be deconvolved from the analytical signal, thereby improving the fidelity of fast-scan cyclic voltammetry. The kinetic calibration was used to study the kinetic effects of GBR 12909, a DAT inhibitor, in mice. Whereas with traditional analysis post-GBR changes were found to be insignificant we found, using the method, it was found that the drug significantly increased Km from 0.2 to 1.0, We thereby present two novel applications for DTV; obtaining absolute neurotransmitter concentrations and for creating a more 'true' calibration profile for FSCV data.

Title: Biomechanical issues in autonomous positioning of microelectrodes in brain tissue

Authors: *S. ANAND, S. SAMPATH KUMAR, J. MUTHUSWAMY;
Sch. of Biol. and Hlth. Systems Engin., Arizona State Univ., Tempe, AZ

Abstract: Advances in implantable MEMS technology has made possible adaptive microscale robotic implants that can track and record from single neurons in the brain. An adaptive micro-robotic system can enhance quality and reliability of neural recordings by automated tracking of single neurons in brain tissue in chronic experiments.
The research presented here is motivated by the need to (a) precisely position microelectrodes close to a single neuron(s) of interest in the brain so that signal to noise ratio (SNR) of the neural signal recorded is maximized and (b) to maintain the relative distance between the neuron and the microelectrode to achieve stability in the recorded signal. However, due to the viscoelastic properties of the brain tissue that has a complex non-linear time dependent response to a step displacement, moving the microelectrode by a known distance does not always directly translate to an equivalent displacement in brain tissue. The challenges to achieve precise positioning of microelectrode near a neuron include - i) no direct visual feedback of the position of the electrode ii) absence of reliable constituitve model that can fully model the inhomogeniety and variability in the mechanical properties of brain tissue at the micro-scale.
A force-feedback strategy is used in this study where the microelectrode is mounted on a force sensor and data is recorded while positioning the microelectrode in brain tissue. A quasi-steady state is defined where the forces on the microelectrode from the brain tissue reach a constant value. Constant force values indicate a steady-state relative displacement between neuron and microelectrode. Two microelectrode movement parameters were varied - i) step size of movement (3 μm - 120 μm) and ii) inter-movement interval (IMI) (30 s - 20 min). Unidirectional movement of microelectrode with the above step sizes and IMIs did not yield steady state force values after the microelectrode was positioned at the desired location. A stress relaxation model for viscoelastic materials was fit to this data. Careful analysis of the different step-sizes and IMIs showed that an inchworm type movement methodology with a forward movement of 60 μm immediately followed by a backward movement of 30 μm within a span of 1 min resulted in quasi steady-state forces. Results of testing the above optimal microelectrode movement strategy in an open-loop micro-robotic control system in short and long-term rodent experiments will be presented. The autonomous positioning system includes a ‘search’ mode for seeking neural recordings of interest and a ‘maintain’ mode for maintaining stable units once desired target neural recording has been achieved.

Title: Two-photon targeted robotic patch-clamp electrophysiological recording *In vivo*

Authors: L. A. ANNECCHINO, A. MORRIS, O. AGABI, P. CHADDERTON, *S. R. SCHULTZ;
Dept of Bioengineering, Imperial Col., London, United Kingdom

Abstract: Understanding the functional principles of the mammalian cortical circuit is one of the major projects of modern neuroscience. To make progress on this problem, we need to be able to observe the behavior of the individual neuronal elements of this circuit. The whole cell patch clamp technique has been the gold standard method for this, as it allows both subthreshold and suprathreshold signals to be recorded, perturbations to be applied through current injection, and delivery of DNA vectors directly into single cells. However, it has largely been limited to investigating a single neuron at a time in vivo. Considerable advantages could be gained by (i) automation and (ii) visual targeting. Recently, Kodandaramaiah et al (Nature Methods 9:585-7, 2012) developed an automated approach for performing blind, in vivo patch clamping. However, this method does not allow individual elements of the cortical circuit to be addressed. By targeting the technique to specifically labeled individual cells or cell classes (Margrie et al, Neuron 39:911-8, 2003), it may be possible to test a wide range of hypotheses concerning information processing operations performed by the cortical circuit. To make this possible, we have developed a strategy for two-photon targeting of an automated whole cell patch clamping algorithm. Our robotic patch clamp implementation was motivated by the system described by Kodandaramaiah, but has a number of key differences, including Labview implementation of a finite state machine software architecture, a closed loop pressure regulation system, and a more accurate suction procedure. The pressure regulator is controlled by the computer through a routine implementing a PID controller. In order to perform the suction task a parametric algorithm was implemented which dynamically changes the pressure set point of the PID controller, allowing greater reliability in the seal formation and break-in processes. Since pipette pull-off following single neuron targeting plays a critical role in success of transfection

procedures, our improved procedure offers the prospect of more accurate and reproducible pull-off dynamics, and thus higher hit rates in comparison to manual approaches. Our patch clamping robot is coupled to a two-photon microscope, which is used to drive neuronal target acquisition via a point-and-click graphical user interface. 3D stacks of labeled tissue are acquired, targets are selected, optical coordinates converted into the micromanipulator coordinate system, and then a suitable path calculated to feed to the patching system. Our system naturally scales to the selection of multiple identified neurons.

Abstract: How individual neurons are linked to each other to form circuitries within the nervous system and how their activity leads to complex functions, such as sensory and motor processes as well as learning and cognition, are fundamental questions in neuroscience. In order to make a direct link between the morphological and functional study of the nervous system, it is necessary to label the electrophysiologically identified neuron during behavior. Previously, we have

succeeded in labeling individual neurons persistently without microscopic guidance by injecting a plasmid encoding fluorescent protein electroporatively after recording their activity extracellularly. The purpose of this study was to optimize the injection protocol for in vivo blind single-neuron electroporation for labeling. Using a glass pipette filled with electrolyte solution containing a plasmid encoding green fluorescent protein (GFP), single-neuron recording and electroporation were performed on anesthetized rats. When performing the electroporation at the completion of recording, the degree of contact between the target neuron and the electrode tip was adjusted by monitoring the change of the trace of recorded action potentials and the increase of electrode resistance. We tested two parameters of voltage pulse train (50 pulses at 50 Hz or 200 pulses at 200 Hz) and five degrees of contact (increase rate of electrode resistance from the normal baseline level; 0, 15, 30, 60, or 120%). The optimum condition for labeling was a 30% increase of the electrode resistance with voltage pulse train of 50 pulses at 50 Hz, and the labeling success rate evaluated 3 days after labeling was 40%. The rate evaluated one month after labeling using this optimum condition was only slightly lower (33%). We also confirmed experimentally that this recording and labeling procedure can be similarly successful in head-fixed behaving rats. This new experimental protocol will be a breakthrough in systems neuroscience because it makes a direct link between the morphology and behavior-related activity of single neurons.

Title: Sensing exocytosis using an electrochemical glutamate sensor at the calyx of Held

Authors: *A. KISNER[1], S. CLARKE[2], K. G. PARADISO[2];
[2]Cell Biol. and Neurosci., [1]Rutgers Univ., New Brunswick, NJ

Abstract: A key component of neuronal communication is the ability to release neurotransmitter from presynaptic terminals. This process is mediated by the exocytosis of neurotransmitter filled vesicles from the presynaptic terminal. Current analysis of the exocytotic events from neurons in

brain slices are often made by postsynaptic electrical recordings. Fast cyclic voltammetry, or patch-capacitance at presynaptic terminals, and/or fluorescence based techniques are also frequently used. However, these techniques have some limitations. For instance, voltammetry is limited to detection of dopamine and serotonin release, while presynaptic capacitance recordings can only measure exocytosis in a limited number of large presynaptic terminals. Fluorescence techniques can have difficulties due to the need for transgenic animals, or due to low signal-to-noise ratio, and in slices they can lack spatiotemporal resolution to best analyze exocytosis. In this work, we describe an alternative approach employing a tip electrode that allows electrochemical based measurements to probe for changes in glutamate levels at physiologically relevant concentrations. Our initial experiments detecting various known glutamate concentrations in solution are encouraging for detection at concentrations from a few to hundreds of micromolar up to millimolar levels. We are now in the process of minimizing the size of the probe's tip while maintaining sensitivity for glutamate detection in an effort to optimize both parameters which is important for detection of glutamate at synapses. We are also testing the temporal sensitivity of this sensor, and its ability to detect multiple brief applications of neurotransmitter by using a fast perfusion system. In addition, we are testing other neurotransmitters, such as GABA and glycine, to determine the probes ability to selectively detect glutamate. In parallel, we are determining the ability of this probe to measure release of glutamate from calyx of Held synapses. This large presynaptic terminal allows an ideal system to investigate the ability of this electrochemical sensor to measure glutamate release from neurons in brain slices. This type of sensor would be a valuable and sensitive tool for studying glutamate release and can provide new insights into exocytotic events at excitatory glutamatergic synapses.

Title: A novel sealant for FSCV electrodes that is cheap, fast, easy, and reliable

Authors: *E. RAMSSON;
Biomed. Sci., Grand Valley State Univ., Allendale, MI

Abstract: Fast-scan cyclic voltammetry (FSCV) is a powerful technique for measuring sub-second changes in neurotransmitter levels. One of the greatest limiting factors in the use of

FSCV is the production of high quality recording electrodes; the most common recording electrode consists of cylindrical carbon-fiber encased in borosilicate glass. When the borosilicate is heated and pulled, the molten glass ideally forms a tight seal around the carbon-fiber cylinder. It is often difficult, however, to guarantee a perfect seal between the glass and carbon. Indeed, much of the time spent creating electrodes is in an effort to find a good seal. To that end, many labs will utilize epoxy resins to generate a seal between the surrounding glass and carbon. While this can be effective, it is irreversible (seals cannot be adjusted), wasteful (it cannot be reused once hardener is added), hazardous (hardeners are toxic), and requires extensive curing times and/or conditions. Herein I describe the use of paraffin as a novel electrode sealant for FSCV borosilicate cylinder electrodes. Paraffin boasts the advantages of immediate curing times, resealing capability, and lack of toxicity. It is reusable, cheap, simple, and provides stable waterproof seals capable of withstanding normal mammalian body temperatures. Electrode tips were left as-is or broken and resealed with paraffin embedding wax, store-bought household paraffin wax, or epoxy resin. Excess wax was removed from the carbon surface by repeated cycling at an extended waveform (-0.4 to 1.4V, 400 V/s, 60 Hz) until the electrode size stabilized, at which point it was switched to a more standard waveform (-0.4 to 1.3V, 400 V/s, 10 Hz) and cycled until stable. Excess epoxy was removed with xylene prior to hardening and electrodes cycled at the 1.3V waveform until stable. Paraffin-sealed electrodes were just as effective at detecting dopamine as glass or epoxy-sealed electrodes, were stable, and caused a dramatic increase in the throughput of electrode production. From this it is clear that paraffin wax is an effective sealant for FSCV electrodes that not only decreases electrode production times, but provides a convenient substitute to epoxy sealants.

Abstract: Neuronal firing and field oscillations are major readouts of brain function *in vivo*. Numerous devices have been designed to record single units and field potentials, on the surface of the brain (e.g. grids) or *in situ* (e.g.
silicon probes), including in human for diagnosis purposes. These electrodes have enabled major scientific and clinical advances. However, a technological jump is now needed to allow micro scale multimodal recordings.
We now present such devices.
We developed new microelectrodes which record neuronal activities in vivo and which can be functionalize for glucose sensing. Those electrodes use OECT (organic electrochemical transistor) as recording site. Those electrodes show a more sensitive and powerful glucose sensing than the catalytic electrode. We present two models of glucose sensors based an OECT including the first use of PGMA nanobrushes attached to organic materials here demonstrated allowing a local covalent docking of the glucose oxidase without altering the conductivity of the transistor.
These new probes may constitute the basis for future local multimodal in vivo recording.

Title: Experimental procedure for electrophysiological investigation of nervous conduction in murine spinal cord *In vivo*

Authors: *P. DIBAJ[1], H. STEFFENS[2], K.-A. NAVE[3], E. D. SCHOMBURG[4];
[1]Neurogenetics, Max-planck-Institute For Exptl. Med., Göttingen, Germany; [2]NanoBiophotonik,

Max-Planck-Institute for biophysical chemistry, Göttingen, Germany; [3]Neurogenetics, [4]Max-Planck-Institute for Exptl. Med., Göttingen, Germany

Abstract: Excitability and conduction of peripheral and central nerve fibers in mice gained increasing interest, since transgenic mice have been generated with alterations of neuronal and glial properties, partly resembling the clinic of human diseases. After we had investigated the conduction velocity of different nerve fiber groups in different nerves of the PNS in vivo (Steffens et al. Physiol Res 2012; 61:203-14), we now investigated characteristics of nervous conduction of peripheral and central nerve fibers from the ischiadic nerve over the dorsal root L4 to fasciculus gracilis of the spinal dorsal column. The Experiments were performed in fully anesthetized mice (initially pentobarbital i. p., continuance with methohexital i. v.). A tracheotomy was performed for artificial ventilation and electrocardiogram was recorded throughout the experiment. After paralyzation (pancuronium i. p.), changes of the heart rate and core body temperature were used to control the anesthetic state.
In the first type of experiments, we stimulated the sciatic nerve and recorded the incoming volley and dorsal column potentials at dorsal root L4 and fasciculus gracilis, respectively. Hereby, we were able to investigate simultaneously peripheral and central nerve fibers. In a second approach, in which central fibers were only investigated, stimulation was carried out at dorsal root L4 and recording was performed 7 to 10 mm cranially at the dorsal column.
In both type of experiment, the recorded compound action potentials (CAP) showed interindividually different amplitudes but comparable conduction velocities. During a period of high frequency tetanic stimulation a reliable decay of the amplitude of CAP was observed. With the stimulus frequency of 100 Hz decay of the CAP amplitude of up to 40% was observed within 10 min of tetanic stimulation. This experimental approach is of particular interest for the functional characterization of nerve fibers, not only for those with structural abnormalities but also for those with metabolic deficits due to alterations of axon-glia interaction without structural abnormalities.

Title: Open-ended MEMS probe for single unit recording

Authors: *S. OH, J. CHO;
Hwarangno 14-gil 5, Seongbuk-gu, KIST, Seoul, Korea, Republic of

Abstract: Behavioral single unit recording is the most advanced method for identifying neuronal functions in relation with a specific behavior. Especially, a tetrode, a bundle of four electrodes that are positioned in the form of square array, has been known to be the most efficient tool for measuring signals from individual neurons. The stereotrode or tetrode has been prepared by mechanically twisting two or four micro-sized electrodes. In addition, proper heat or adhesives should be applied to stick electrodes together. Disadvantage of this conventional method is the variation of shape and size of electrode tips due to insulation damage during heating and the extent of twisting, which can possibly reduce the efficiency of signal separation. The present study attempts to provide a most standardized way to fabricate uniform stereotrode or tetrode in terms of tip size and gap size between each electrode, which could enhance the capability of signal separation. We have applied a variety of MEMS (Micro Electro Mechanical Systems) processes including LASER technique to fabricate stereotrode. Moreover, polymers have also been used for insulation, which provides excellent biocompatibility and electrical stability. We were able to design the uniform open-ended streotrode or tetrode that can be obtained by combining two stereotrodes. Confirmations are made on the shape of open-ended MEMS probes under SEM (Scanning Electron Microscope) image and also on electrical properties of the probe.

Title: Pattern and guide - getting control over a developing neuron network

Authors: *H. DERMUTZ, R. GRÜTER, A. TRUONG, L. DEMKO, T. ZAMBELLI, J. VÖRÖS;
IBT, ETH Zurich, Zürich, Switzerland

Abstract: Neuron cultures in neuroscience are a powerful and essential tool when it comes to basic questions about network behavior and learning. In vivo, the tremendous complexity of the brain topology results in too many variable parameters influencing the basic network of interest. Many groups have started to use chemically patterned surfaces to create defined networks. These small networks are a useful tool for investigating the basic functionalities and parameters of neuron networks. We developed a method to control the location and the time of neurite outgrowth by locally switching the surface from repulsive to adhesive.
We use an AFM-cantilever with a microchannel to locally dispense an adhesion promoter onto a polymer coated glass substrate. The Poly-L-Lysine grafted Polyethyleneglycol (PLL-g-PEG, SuSoS, Switzerland) monolayer is known to be non-fouling and prevents cells from adhering to the substrate. The non-adhesive PLL-g-PEG is locally exchanged with adhesion promoting Poly-L-Lysine (PLL) when later the PLL is dispensed onto the PLL-g-PEG monolayer with the FluidFM (Cytosurge, Switzerland). After depositing PLL spots into the non-fouling PLL-g-PEG background, primary hippocampal neurons from E17 Wistar rats are dispensed over the whole substrate. The non-adherent cells are later rinsed off resulting in patterned cell spots.
Furthermore it is possible to write adhesive cues into the non-adhesive substrate with micrometer precision. This results in neurite outgrowth only in the defined direction. Control over polarity of the patterned network can be achieved with correct timing of writing the connection path between two cell spots. We have shown that the patterned network has spontaneous activity after 15 days in culture.
The system presented has flexible control over the topology of a neuron network. The possibility to change the surface from non-adhesive to attractive even when the cells are already present, makes it a very powerful tool for investigating network development and network plasticity. In addition, we have started to adapt the system to write on a standard micro-electrode array (MEA, Multichannel Systems, Germany). This will allow to overcome the limited time and spatial resolution of the calcium indicators which are used right now to investigate the network activity.

Abstract: Several neurological disorders, such as autism and intellectual disability (ID), are linked to genetic mutations that result in changes in neuronal morphology and synaptic strength. Whereas on single neuron level genetically induced synaptic deficits have been intensively investigated, it is not known how these changes can affect neural network formation and maturation. We developed a system in which small neural networks of dissociated cortical neurons of embryonic rats are compartmentalized. The compartments connected by topographically guided axon projections through polydimethylsiloxaan (PDMS) microtunnels. By culturing the neurons on planar multi electrode arrays (MEAs), we tracked the formation of the topographically connected neural networks over time by (a) recording the spatiotemporal aspects of their spontaneous action potential firing, which took the form of network bursts and silent periods. (b) Recording the stimulus evoked synaptic signal propagation to a neural network in a neighboring compartment. In our setting, electrical activation of one neural network resulted in propagation of activity to the connected neural networks. Synaptic recruitment of network activity is delayed by 50 millisecond for a compartment directly connected to the stimulated compartment. Synaptic recruitment for networks connected through a relay neural compartment, a delay of 100 millisecond is recorded. The compartments are electrically stimulated as well as optically stimulated by using the light-gated channelrhodopsin ionchannels. We also tracked the network maturation and the role of single ID-linked genes by recording the same neural networks from day-in-vitro (DIV) 7 up to DIV 32 and show how the spontaneous network bursts develop as the network matures.

Abstract: In order to study the memory process and neuronal network activity in a less modified environment *in vivo* experiments are required. Although several electrophysiological methodologies and imaging techniques have been developed for 3 dimension network measurements none of them provided the high spatial and temporal resolution that can be realized with 3D two-photon acousto optical imaging.
We used a high-resolution, acousto-optic two-photon random-access scanning microscope that reaches near-cubic-millimeter scan range (up to 700 × 700 × 1,400 μm^3), with a high scanning speed, with 470 × 490 × 2,490 nm^3 resolution in the center core, and less than 1.9 x 1.9 x 7.9 μm^3 resolution throughout the whole scanning volume, which is still sufficient to measure activity from the cell somatas in the whole scanning volume. With these tools we measured the neuronal activity of hundred of cells in the visual cortex in 3D with millisecond temporal resolution.
We show volumetric random-access scanning calcium imaging of visual stimulation-evoked activity in hundreds of neurons of the mouse visual cortex in *in vivo* head restrained mice.

Title: Development of a functional assay for investigating human neural network plasticity *In vitro* toward the integration with a “body-on-a-chip” device

Authors: *B. J. BERRY, M. T. SCHNEPPER, N. AKANDA, X. GUO, J. J. HICKMAN; Nanoscience Technol. Ctr., Orlando, FL

Abstract: The pre-clinical research and drug development process of bench to bedside to public is an expensive and slow process. Furthermore, the translation of drug effects from animal trials to clinical research is often poor, with clinical trials failing in humans after promising results were obtained in animal models. This gap in the translation of results in animal studies to human clinical trials could be closed with the use of robust human-based in vitro test beds. To this end, we are working to construct a human-on-a-chip in vitro system which models human tissue from multiple organs for measuring drug effects. One component of this large-scale system will model the central nervous system's in vivo structure by recapitulating layered neural networks. Previous work has characterized the initial establishment of this system, and validated the methodology employed to achieve a functional in vitro analogue of the layered neural networks observed in the in vivo central nervous system using rat cells (Natarajan et al. 2013). Human stem cell-derived pyramidal neurons are now being investigated for their ability to reach functional maturity, as measured using standard electrophysiological techniques. Cells were capable of producing substantial inward Na+ currents and outward rectifying K+ currents following 21 days in vitro when maintained in a defined, serum-free environment on a controlled, self-assembled monolayer (SAM) surface. Chemical patterning of cytophilic and cytophobic SAMs facilitated the establishment of patterned surfaces for the control of cell attachment and neuritic outgrowth. Using this technology, surfaces were patterned to produce neural populations arranged into layers feeding forward to subsequent layers, thereby mimicking the cellular architecture of the in vivo tissue. Microelectrode arrays were used to monitor these layered networks for evidence of network connectivity over time. Such cultures were stimulated using defined electrical protocols in order to induce changes in synaptic strength and thereby produce in vitro analogues of phenomena such as long-term potentiation (LTP). Dynamic changes in synaptic strength are continuously occurring in vivo with neurodegeneration occurring when this process breaks down. Inhibition of LTP is an indicator of serious neurodegenerative diseases, such as Alzheimer's. This study focuses on the development of a system whereby LTP can be induced, maintained and altered, with and without drug treatment, as an indicator of network health and viability. With the development of an in vitro system which can predict clinical drug effects, we hope to improve future medical research and drug development.

Title: Oxygen polarography and electrophysiology in the default-mode and dorsal-attention networks during rest and stimulation: Bridging BOLD fMRI and electrophysiology

Authors: *W. J. BENTLEY[1], J. LI[1], A. SNYDER[2], M. RAICHLE[2], L. SNYDER[1];
[1]Anat. and Neurobio., [2]Radiology, Washington Univ., Saint Louis, MO

Abstract: Blood oxygen level dependent (BOLD) fMRI is our primary window into the functioning human brain. Unfortunately, the neural activity underlying BOLD remains unclear. We developed a microelectrode-based oxygen polarographic system capable of recording tissue oxygen simultaneously at 4 sites in awake macaques with 30-100 micron spatial specificity and 20 Hz sampling. Tissue oxygen is in equilibrium with blood oxygen. Thus this system can be considered a high resolution alternative to BOLD (Thompson 2003, Lowry 2010). This tool can be implemented in awake monkeys alongside standard electrophysiology and provides an unprecedented platform for high resolution study of BOLD and the neural-BOLD link. We recorded neural activity and oxygen from posterior cingulate (PC) and area V3 in awake macaques during both resting state and 15 s of 1 Hz wide-field textured stroboscopic illumination. These regions, in the default and dorsal attention networks, respectively, behave very differently. In PC, a transient increase in oxygen at the start of visual stimulation was followed by a sustained drop to a level below baseline. In V3, a large initial oxygen transient was followed by a sustained level above baseline, ending with a second smaller transient at the cessation of stimulation. In the resting state both areas show oxygen fluctuations with a 1/f power spectrum, similar to resting state BOLD. These fluctuations were correlated among all recording sites, but more strongly between bilateral within-network pairs (r=.6) than between out-of-network pairs (r=.4). Correlation strength was frequency dependent (peak at .05 Hz) suggesting that correlation involves a subset of the mechanisms driving the local fluctuations. In PC, local field potentials (LFP) and multi-unit activity show a very brief (compared to oxygen) initial peak followed by a sustained suppression. In V3, LFP and MUA track each stroboscopic flash. The response to the first flash is greater than that to subsequent flashes, consistent with the oxygen response, but there is no obvious response to the cessation of stimulation. The magnitude of the LFP response is on average 3-4 times greater in V3. In contrast, the absolute value of the oxygen response is similar in both regions (~±2%). Analysis of the average transfer function from LFP to oxygen shows different latencies, magnitudes, and waveforms in the two regions as well as different LFP frequency contributions. Together these observations argue for substantially different neural-bold links in these two regions.

Title: Precise control of neural network structural connectivity in neural cultures

Authors: *J. R. GAMBLE[1], J. A. MAURER[2], D. L. BARBOUR[1];
[1]Biomed. Engin., [2]Chem., Washington Univ. In St. Louis, Saint Louis, MO

Abstract: Neuronal interactions occur in the context of non-random structural connectivity and distributed network activity, but these dynamic interactions are challenging to study in vivo due to the overall complexity of the system. Although neuronal cultures have been utilized as a reduced system for the probing of neuronal function, the random structures inherent in these traditional cultures limit the investigation of network structure/function relationships. For example, cultured random neural networks can be trained without specific synaptic constraints to perform experimenter-defined tasks; conversely, specific synapses can be potentiated through spike-timing dependent plasticity (STDP). In order to elucidate the neural network architecture bridging these two phenomena, experimenters must be able to reliably and precisely control the structure of the cultured networks. Photolithography and microcontact printing (μCP) have been used recently in conjunction with surface chemistry to pattern neural networks of arbitrary geometries in vitro. More specifically, these techniques have been used to create low-density functional neuronal circuits, but the directionality of the axons within the networks could not be controlled. Single isolated neurons have been patterned with controlled directionality for axon differentiation by stamping self-assembling alkanethiols onto gold. However, the small feature sizes necessary to develop high-fidelity control are difficult to reproduce with traditional microstamping techniques due to problems associated with high feature aspect ratios. We have extended this latter work in combination with other μCP techniques such as submerged μCP and composite polydimethylsiloxane (PDMS)/h-PDMS stamps, which have both been shown to increase reproducibility of high aspect ratio features. This modification increases pattern feature fidelity at the single micron level and enables creation of neural networks of predetermined structural connectivity. Our current results indicate that the precise shapes of the individual

neuronal patterns are critical for neuronal compliance to the desired configuration. The starburst shaped pattern previously used for axon differentiation encourages the correct placement of somas compared to a unipolar pattern, in which somas tend to adhere to regions intended for axons. The success of this project will enable the ability to culture neural circuits of predefined geometry and directionality, providing precise control of the context of connectivity during the study of cell-cell interactions such as synaptic plasticity.

Title: High frequency blocking of central pathways in the primate motor system

Authors: *K. M. FISHER[1], N. JILLANI[2], S. N. BAKER[1];
[1]Inst. of Neurosci., Newcastle Univ., Newcastle-upon-Tyne, United Kingdom; [2]Inst. of Primate Res., Nairobi, Kenya

Abstract: Transient blocking of nerves using a high frequency electrical stimulus has previously been demonstrated in the peripheral nervous system. Such reversible block of peripheral nerves has enormous clinical potential for blocking pain, muscle spasticity and unwanted bladder sphincter activity in spinal cord injury patients. Successful blocking of central pathways could have similar potential, both in the experimental field (to induce specific, transient and reversible lesions) and also in the attempt to block the unwanted signals associated with some neurological diseases.
Here, we demonstrate the first successful application of a high frequency blocking stimulus to the central nervous system using a sharp metal electrode. Experiments were performed in 3 healthy adult male olive baboons (*Papio Anubis*; 22.5-25.8kg) maintained under terminal general anaesthesia.
A laminectomy was performed to expose spinal segments T1-C5 and the underlying dura was removed to allow access to the spinal cord. Stainless steel macroelectrodes were fixed in a caudal section of the exposed spinal cord (~C6 level, dorsolateral funiculus) targeted to produce a maximal antidromic response in motor cortex via corticospinal pathways. A stainless steel movable electrode was then inserted into a more rostral region of the spinal cord (~C5 level) to

serve as the blocking electrode. This was mounted in a micromanipulator to enable slow advancement into the cord to test the blocking stimulus at multiple depths.
Stimulation was delivered through the caudal electrode as the movable 'blocking' electrode was advanced into the spinal cord. At each depth, high frequency sinusoidal blocking stimuli were delivered at a range of intensities (200-1000µA) and frequencies (2-10kHz). An epidural recording over M1 was observed throughout to determine the proportion of the antidromic field which was blocked.
Results in all 3 animals showed a frequency and intensity specific effect of blocking. High intensity, low frequency (2kHz) sinusoidal stimuli were most effective at blocking the antidromic field and were capable of near-complete blockade at the optimal depth.
In conclusion, we have demonstrated transient, reversible blocking of central motor pathways using a high frequency sinusoidal stimulus. This technique could be a valuable tool for experimenters wishing to induce reversible lesions in central nervous pathways.

Title: An improved M-Sorter for automatic and robust spike sorting

Authors: *S. WANG, Y. YUAN, W. MA, J. SI;
Arizona State Univ., Tempe, AZ

Abstract: Neural spike detection and classification, or spike sorting, is the first and a critical step prior to any single unit based neuroscientific studies and applications. A good spike sorter is usually characterized by high detection and classification accuracy, robustness to changes in signal-to-noise (SNR) ratio, objectivity in results or less user dependency, and real-time applicability. The M-Sorter is an automatic and robust spike detection and classification system, based on the multiple correlation of wavelet coefficients (MCWC) detection algorithm in conjunction with k-Means and template matching for classification. Extensive tests have been performed using the M-Sorter and compared with several popular algorithms, the thresholding

detection and T-distribution EM classification of the Offline Sorter by Plexon and the open source code of Wave Clus. Note that the sorters we compared were under the automatic modes since our aim was to perform automatic spike sorting. Therefore we did not compare manual spike sorting with Offline Sorter or any other sorter. The sorters under consideration were comparable under high SNRs conditions while the M-Sorter showed advantage in low SNRs. Also, the M-Sorter results appeared more consistent and less sensitive to parameter changes.
Two improvements were made to the improved version of the M-Sorter for enhanced user experience. First, time efficiency is greatly improved by utilizing parallel computation toolbox in the Matlab. This toolbox is available for computers equipped with multi-core processors. Tests were made using Dell Optiplex 7010 with Intel Core i7-3770 and 16GB ram. As a result, running time is reduced to 50% of the previous version. For example, for a single channel dataset of 1 hour long, it takes 97 seconds to sort with resulted firing rate of 71 spikes/s.
Second, a user-friendly interface is developed and implemented. This allows the user to view the clustering results from the automatic mode of the M-Sorter, merge clusters, and save results. In addition, the principal components, averaged waveforms, inter-spike intervals (ISIs) are also available as guidance to the user when choosing clusters.
This M-Sorter is available online for free download.

Title: Coupling between spiking activity and beta band spatio-temporal patterns in the macaque PFC

Authors: S. SAFAVI[1], *F. PANAGIOTAROPOULOS[2], V. KAPOOR[1], N. LOGOTHETIS[1], M. BESSERVE[1];
[1]Max Planck Inst. for Biol. Cybernetics, Tuebingen, Germany; [2]Max Planck Inst., Tuebingen, Germany

Abstract: Previous analysis of Local Field Potentials (LFPs) recorded from the inferior convexity of the macaque prefrontal cortex (PFC) revealed a dominant travelling wave pattern in the beta band (15-30 Hz) propagating along the ventral-dorsal plane. We hypothesized that

propagating rhythmic activity reflects the intrinsic dynamics of the underlying neural populations which might be instrumental to information processing and sensory integration. Here, we investigated the relationship between multi-unit spiking activities (MUA) and LFPs in the same area of the PFC.
We first computed spike-field coherence for each channel of the array. Many recording sites (typical example in Fig 1A) exhibited a distinctive peak in the beta frequency range both for resting state (spontaneous activity) and during visual stimulation with dynamic movie stimuli. We extracted the instantaneous phases in the beta band using Hilbert transform. We then computed the phase locking of spikes in each channel to a common LFP reference channel. The results exemplified on Fig 1 B, showed that many recording sites exhibited locking of spikes to the same phase of remote beta band LFP. This result was observed for many LFP reference channels, suggesting action potentials in all channels are synchronized to a common phenomenon.
We used complex Singular Value Decomposition (SVD) of the spike-phase locking matrix to capture the dominant underlying spatio-temporal pattern of beta oscillations associated to spiking activity across the array. The dominant pattern estimated from the first eigen-mode of SVD exhibits a phase gradient along the ventral-dorsal plane (Fig 1 C), suggesting that MUA across the array are synchronized to the global travelling wave pattern previously observed along this direction in the LFP signal.
This new result suggests MUA is synchronized to large scale ongoing travelling wave patterns in the beta band both during stimulation and spontaneous activity. Further information theoretic analysis will address how this mechanism serves distributed sensory encoding and processing in this area.

Title: Online detection of ripple events and theta waves in the hippocampus *In vivo*

Authors: *N. GRAVEL[1,1], J. HURTADO[1], P. FUENTEALBA[1,2];
[1]Dept. de Psiquiatría, Facultad de Medicina y Ctr. Interdisciplinario de Neurociencia, Pontificia Univ. Católica de Chile, Santiago, Chile; [2]Fundacio Sant Joan de Deu, Spain, Spain

Abstract: Fast online detection of LFP activity patterns has become an essential tool to understand the neural correlates of a variety of cognitive processes. In the hippocampus, high frequency (100-300 Hz) sharp wave ripples, an activity pattern that has been associated with memory formation and recall, can be disrupted by early pattern detection followed by feedback stimulation. Being highly localized in time and frequency, early ripple detection pushes the limits of reliability and sensitivity. In contrast, lower frequency signals, such as theta activity (5-9 Hz), are less localized in time, allowing for a long observation period before a more reliable and accurate detection can be made. In both cases, most detection methods used so far depend on parameters that are tuned heuristically by the investigator, after inspecting a large sample of the time series. However, the parameter space for automatic detection systems is large, and an exhaustive search is hard to achieve. We present online and offline detection methods especially devised for ripple events and theta oscillatory activity. We used signal detection theory to quantitatively compare the performance of online versus offline detection algorithm using human experts as "gold standard". Receiver operating characteristics and precision-recall curves were constructed to evaluate the performance of the detectors and a systematic search of parameter space was undertaken to find regions of optimal performance. Our results reveal that false hits pose a major methodological issue in many online detection algorithms and that a quantitative approach to parameter selection can largely improve the design of precise, high recall detection systems.

Title: The effect of temporal stimulus waveform on the cortical steady-state visual evoked potential (SSVEP)

Authors: *T. J. GAWNE[1], T. DICKERHOFF[1], W. J. KRAFT[2], K. Q. CHANG[1];
[1]Dept Vision Sci., Univ. Alabama Birmingham, BIRMINGHAM, AL; [2]Auburn Univ., Auburn, AL

Abstract: The cortical steady-state visual evoked potential (SSVEP) is simply flickering or flashing a visual stimulus and recording the electrical response from visual cortex. The SSVEP has been used for decades, but it is still an active area of research. However, there is little data on the effects of temporal stimulus waveform on the SSVEP. Researchers typically just use whatever stimulus is available: brief flashes for strobe lights, single brief pulses or trains of brief pulses for CRT displays, and LCD displays can exhibit a variety of temporal waveforms. In particular, with conventional paradigms it is difficult to change stimulus waveform or frequency without also changing mean luminance. Here we constructed an LED-based visual stimulator that, by using pulse-width modulation at 5 kHz, could generate visual displays with different frequencies and temporal waveforms but the same mean luminance. The display was a diffuse white disk divided into four quadrants, and subtending 20 degrees in visual angle. Subjects fixated the center of the disk. The conditions were two seconds each of null control, square wave at 10 and 20 Hz, and 10% duty cycle pulse at 10 and 20 Hz. The conditions were presented in random shuffled order with a variable inter-trial interval. Signals were recorded from a novel three-electrode array centered over the occiput. Preliminary results from four subjects indicate that the effects of changing stimulus waveform while keeping the mean luminance constant is idiosyncratic between subjects and frequencies. Sometimes there was no difference in the SSVEP using square wave or pulsatile stimuli, and sometimes the differences were marked. Nonetheless, there was a trend for the pulsatile stimulus waveform to generate stronger phase-locked responses especially at higher frequencies. Using another protocol where mean-luminance matched pulses of 1,2,4, and 8 msec durations were presented at 15 Hz indicates that small changes in the shape of a pulsatile stimulus have negligible effects on the SSVEP, except for a small increase in response phase with increasing pulse width. These results suggest that it may be difficult to compare the results of different SSVEP studies that use high- or low- duty

cycle stimulation, but that small differences in the waveforms of a pulsatile visual stimulus likely have little effect.

Title: Optimizing EEG/EMG signal/noise ratio

Authors: R. KOZMA[1], *W. J. FREEMAN, III[2], C. T. LIN[3], L.-D. LIAO[3];
[1]Mathematics, Memphis Univ., Memphis, TN; [2]Dept Molec & Cell Biol, Univ. California, BERKELEY, CA; [3]Natl. Chiao Tung Univ., Hsinchu, Taiwan

Abstract: Aim: Our goal is to extract information on higher cognitive functions from the noninvasive scalp electroencephalogram (EEG).
Introduction: The human scalp EEG contains massive information that is correlated with higher cognitive functions. Samples taken from arrays of electrodes show that the information is in the form of spatiotemporal patterns of briefly stationary bursts of electric potential differences (1). The bursts are generated by masses of cortical neurons located 10-30 mm below the scalp surface. They are signals that are contaminated by electrical noise from scalp muscles located 2-5 mm beneath the scalp surface.
Methods: We oversample the mix of EEG signals and electromyographic (EMG) noise, calculate temporal and spatial power spectral densities (PSDt and PSDx), calculate temporal and spatial Nyquist sampling frequencies, and write temporal and spatial filters in software to optimize the temporal and spatial pass bands to extract neural correlates of cognition (1).
Results: We designed and constructed an electrode array to oversample EEG+EMG by 48 closely spaced electrodes in a flexible curvilinear array that was quickly fixed on the scalp in any orientation (2). The spacing was based on preliminary analyses of the spatial frequencies imposed on the scalp EEG by the gyri and sulci of the cortex (3); the typical width and length of gyri are on the order of 10 and 30 cm, giving a spatial Nyquist frequency of 0.2 cycles/mm. The temporal Nyquist frequency of 2000 Hz was based on the need for temporal precision in measurements of the phase of signals in the high gamma and epsilon ranges, respectively 30-80 Hz and 80-200 Hz.
Conclusions: Previous studies (4) have shown that the PSDt of the EEG is 1/fA, where the

exponent is 2<A<4 (5), while on average the EMG PSDt conforms to 1/fB, where B = 0. Therefore the EMG imposes a plateau onto the combined PSDt, with an inflection at a high frequency, fH, on transit from 1/fA to 1/ fB above fH. Subjects can be trained by biofeedback, on seeing the PSDt, to minimize EMG and reveal the signals in the upper gamma and epsilon ranges.
A low pass spatial filter can attenuate the EMG. The cut-off spatial frequency is calculated by the spatial autocorrelation function (6), which has a spike at zero lag, which is attenuated by spatial averaging.

Title: A small-volume recirculating bath using a modified airlift pump provides both oxygenation and flow for *In vitro* electrophysiological studies

Authors: *M. L. MCKINNON, S. HOCHMAN;
Emory Univ., Decatur, GA

Abstract: In vitro electrophysiological studies allow for bath application of drugs at known concentrations without impediment of the blood-brain barrier. Oxygenation is provided via perfusion systems to maintain tissue viability. This typically involves tubing and external reservoirs with relatively large volumes of fluid. Many pharmacological studies require the use of expensive drugs so minimization of recirculation volume becomes important.
We have designed a small-volume self-contained recirculating perfusion chamber utilizing the action of a modified airlift pump. Physiological saline solutions are simultaneously oxygenated and pumped through the chamber at very high flow rates (60 mL/min). The device may be

quickly fabricated using acrylic sheets cut with an automated laser cutter, allowing for rapid production. Pieces are subsequently bonded with dichloromethane for assembly. The current design allows for a minimum of 8 mL of fluid, but may be scaled up to larger volumes to suit the individual application. There are no mechanical or electrical components and an internal design minimizes bath level fluctuations, thereby reducing noise.
A previous study used the airlift pump for low volume recirculation (Wilson et al 1999; J Neurosci Methods. 87:175-184). Our design additionally allows for incorporation of a simple external mechanism for rapid solution exchanges (< 1 min). Solution exchange is performed by inserting a flow bypass circuit into the bath outlet to decouple recirculation. Using this chamber we have been able to demonstrate increased activity in rat spinal cord following bath application of serotonin, and a subsequent decrease in activity following drug washout after 2 hours in vitro. We anticipate use of this chamber in studies where high flow rates and expensive pharmacology are required.

Title: Toward a self-wired active reconstruction of the hippocampal trisynaptic loop: DG-CA3

Authors: *B. C. WHEELER[1], M. D. BOEHLER[2], S. LEONDOPULOS[1], L. PAN[1], S. ALAGAPAN[1], T. B. DEMARSE[1], G. J. BREWER[2];

Abstract: The mammalian hippocampus functions to encode and retrieve memories by transiently changing synaptic strengths, yet encoding in individual subregions for transmission between regions remains poorly understood. Toward the goal of better understanding the coding in the trisynaptic pathway from the dentate gyrus (DG) to the CA3 and CA1, we report a novel microfabricated device that divides a micro-electrode array into two compartments of separate hippocampal network subregions connected by axons that grow through 3x10x400 um tunnels. Gene expression by qPCR demonstrated selective enrichment of separate DG, CA3 and CA1 subregions. Reconnection of DG to CA3 altered burst dynamics associated with marked

enrichment of GAD67 in DG and GFAP in CA3. Surprisingly, DG axon spike propagation was preferentially unidirectional to the CA3 region at 0.5 m/s with little reverse transmission. Therefore, select hippocampal subregions intrinsically self-wire in anatomically appropriate patterns and maintain their distinct subregion phenotype without external inputs.

Title: Accurate and automatic spike classification based on robust EM algorithm

Authors: *W. MA, H. MARKLEY, J. SI;
Arizona State Univ., Tempe, AZ

Abstract: Spike classification is an essential step in the analysis of single unit neural activities recorded using multi-channel electrodes. In this study we propose an accurate and automatic spike classification method named the accurate robust expectation-maximization (AREM) algorithm. It is a novel interleaving two-step approach. The AREM is initialized by the K-means. Then the following two steps are performed recursively in time. The first step is to compute the optimal clustering results once the number of clusters is given using the conventional robust EM algorithm. The other step, which is also our innovation, is to eliminate an unnecessary cluster per iteration until an optimal number of clusters is reached. This step is important for obtaining robust and improved clustering.
For eliminating unnecessary clusters, a pair of the most similar clusters is first identified, which corresponds to the largest overlapping area of two clusters that are above a certain threshold. The smaller cluster of the pair is then eliminated. The final optimal number of clusters is considered to be the one that corresponds with when the negative change in the log-likelihood performance measure is above a threshold.
The AREM and some popular sorters are compared for performance evaluation. The EM sorting

and the valley-seeking methods in Plexon's Offline sorter (Plexon Inc.) are considered, as well as the Superparamagnetic Clustering in Wave Clus (Quiroga et al., 2004). These specific algorithms are chosen for comparisons because they are all in the automatic spike sorting category.
First, two artificial spike data sets were used. All three sorters have comparable total accuracy and misclassification rates for data with high signal-to-noise (SNR) ratios and low similarities among clusters. But the AREM outperformed others on both false positive and false negative rates for difficult data sets with low SNR, high similarity among clusters, and occasional overlapping spikes.
Additionally, the AREM was used in conjunction with the M-Sorter (Yuan et al., 2012) to replace the semi-automatic K-means clustering method. Two real neural data sets recorded from rat's motor cortex were used for performance testing. Comparisons among the updated M-Sorter with AREM classifier, the Plexon's Offline sorter, and the Wave Clus reveal that the updated M-Sorter with AREM not only maintains its overall accuracy, but also has less required design parameters, resulting in a high performance automatic sorter.

Title: A novel method to assess event-related brain potentials (ERP) in clinical domains using frontal epidermal electronics (EES) sensors

Authors: *R. GIL-DA-COSTA[1], R. FUNG[1], S. KIM[2], D. MESA[2], R. MA[2], D. KANG[2], M. BAJEMA[2], T. D. ALBRIGHT[1], T. P. COLEMAN[2];
[1]Salk Inst. For Biol. Studies, LA JOLLA, CA; [2]Bionengineering, UCSD, San Diego, CA

Abstract: We have previously reported the development of an epidermal electronics system (EES), and its use to capture event-related brain potentials (ERP). The EES is no thicker than a human hair, flexible, stretchable, and mechanically matched to the skin. We further investigated the use of EES together with advanced signal processing techniques, to detect and measure the mismatch negativity (MMN), an ERP modulation widely correlated with neuropsychiatric

disorders. The MMN is thought to reflect pre-attentive detection of a deviant stimulus and can be calculated as the difference wave between the responses to deviants (infrequent) and to standard (frequent) stimuli in an oddball paradigm. Neuropsychiatric patients suffering from a variety of disorders, such as schizophrenia, Alzheimer's disease or autism spectrum disorder, appear less able to detect novel stimuli than healthy controls. Consistent with this behavioral deficit, the amplitude of MMN has been found to be reduced. This has led to the proposal that a reduced MMN is a marker of progressive pathology or vulnerability for these disorders. Currently, there is a two-fold limitation for a wider and successful application of these findings in neuropsychiatric research and therapy, arising from: i) the difficulty of testing using a traditional electroencephalography (EEG) cap and ii) the analytical limitations associated with lower signal-to-noise ratios when attempting to obtain successful evaluations at the individual level.
Here, we show the development of a novel minimally obtrusive forehead sensing technology, using EES, together with a novel analytical approach, a "neuroscience-guided test", for MMN detection in healthy subjects. A group of 14 subjects were tested with both: (a) a traditional EEG full cap and typical statistical analysis and (b) our novel EES frontal sensors and methodology. Our results show that while a traditional approach, selecting an optimal electrode (Cz), can detect a significant MMN ($p < 0.01$) in only 9 subjects, our novel non-obtrusive, easy to apply methodology can detect a MMN ($p < 0.01$) in 11 subjects. As such, our proposed novel method combining forehead EES sensors with a "neuroscience-guided test" brings a striking advance at both i) ease of testing and ii) increased individual detection. We believe that these methodology developments can open new avenues for clinical research and therapeutic intervention opportunities across a myriad of neuropsychiatric and neurological disorders. Future studies should assess the efficacy of this methodology on detection and quantification of modulations of the MMN, as well as other ERPs of interest, in different patient populations.

Title: The development and characterisation of new software that integrates behavioral tracking with real time oxygen monitoring using a wireless implantable telemetry system in freely moving rats

Authors: *E. M. GARRY[1], C. LLOYD[2], R. BENNETT[3], J. KEALY[4], J. LOWRY[4], R. GEOGHEGAN[3];
[1]Blue Box Sensors Limited, Dublin, Ireland; [2]ANY-maze, Stoelting Co., Chicago, IL; [3]Blue Box Sensors, Dublin, Ireland; [4]NUI Maynooth, Kildare, Ireland

Abstract: We have developed new software that allows simultaneous monitoring of data from an implanted oxygen sensor in the brain which is directly integrated into ANY-maze behavioral tracking software to create a new and powerful data collection tool.
This system involves the selective detection of dissolved oxygen (O2) in vivo by amperometry using a pre-calibrated carbon paste electrode (CPE, diameter 200 µM) that responds within O2 physiological concentrations (50-80 µM). The O2 sensor is implanted in the hippocampus and is connected to a wireless telemetry transmitter which is implanted in the abdomen. This system is fully implanted subcutaneously and can remain in the animal with continuous data collection possible for >6weeks.
This is therefore ideal for behavioral and social interaction experiments but no software that could integrate tracking and physiological data from the same source was available. Data from the implanted telemeter is received from a charging pad which allows telemeter recharging while implanted. This charging pad is connected to a data acquisition system that contains the software for acquisition of the oxygen signal. Behavioral tracking data was monitored with separate ANY-Maze software making synchronisation of both data sets difficult. We designed software that integrated the oxygen signal directly into ANY-maze behavioral tracking software to allow complete synchronisation of both signals as well as data analysis.
To validate the system, we have tracked the behaviour of implanted rats in different behavioral mazes and simultaneously monitored oxygen. We show that this integrated tracking and telemetry system is a valid way to examine real-time changes in brain tissue oxygen during spatial and information processing tasks.
This system supersedes existing telemetry systems with a fully integrated behavioral tracking and data analysis package making this a powerful tool for long term in vivo monitoring of tissue oxygen in rat brain.

Title: Quantification of brain complexity to assess the level of consciousness

Authors: *O. GOSSERIES[1,2], A. CASALI[3], M. ROSANOVA[3], M. BOLY[4,2], S. SARASSO[3], K. CASALI[5], S. CASAROTTO[3], M.-A. BRUNO[2], S. LAUREYS[2], G. TONONI[4], M. MASSIMINI[3];
[1]Postle Lab. & Ctr. For Sleep and Consciousness, Dept. of Psychiatry, Madison, WI; [2]Coma Sci. Group, Cyclotron Res. Center, Univ. of Liege, Liege, Belgium; [3]Dept. of Biomed. and Clin. Sci. "Luigi Sacco", Univ. of Milan, Milan, Italy; [4]Ctr. For Sleep and Consciousness, Dept. of Psychiatry, Univ. of Wisconsin, Madison, WI; [5]Federal Univ. of Rio Grande do Sul, Porto Alegre, Brazil

Abstract: ***Objectives***: A fundamental shortcoming of current clinical practice is the lack of a reliable method to objectively assess the level of consciousness. Theoretical considerations suggest that consciousness depends on the ability of neural elements to engage in complex activity patterns that are, at once, distributed within a system of interacting cortical areas (integrated) and differentiated in space and time (information-rich). The aim of the study is to test a novel measure of complexity, the Perturbational Complexity Index (PCI), based on transcranial magnetic stimulation combined with electroencephalography (TMS/EEG) measurements to assess the level of consciousness in single individuals across different conditions.
Methods: We used TMS-EEG in healthy subjects during wakefulness, dreaming, NREM sleep,

different levels of sedation induced by different anesthetic agents (midazolam, xenon and propofol), as well as in severely brain-injured patients (vegetative/unresponsive, minimally conscious, and conscious states including locked-in syndrome). In total, 208 sessions were performed in 52 subjects. PCI was used to calculate the amount of information contained in the integrated response of the corticothalamic system to a direct perturbation using algorithmic complexity measures, such as the Lempel-Ziv complexity index.
Results: PCI allowed discriminating between consciousness and unconsciousness in single individuals across the different physiological, pharmacological and pathological conditions. PCI was sensitive to graded changes in the level of consciousness, and was stable across stimulation parameters such as intensity or site. Regarding the patients with brain injury, we stimulated preserved brain regions as the stimulation of brain-damaged areas induced no response.
Conclusions: This theoretically motivated quantification of brain complexity allows establishing an objective, graded measurement scale along the consciousness/unconsciousness spectrum and provides a principled approach for estimating objectively the level of consciousness at the bedside. The use of a neuronavigation system is strongly advised to assess the level of consciousness in patients recovering from coma.

Title: Quantifying signal degradation caused by different spike removal techniques: Examples from human micro-electrode recordings

Authors: *M. BAYRAKTAR[1], V. A. COENEN[2], C. E. ELGER[1], F. MORMANN[1];
[1]Dept. of Epileptology, [2]Stereotaxy and MR based OR Techniques, Dept. of Neurosurg., Univ. of Bonn, Bonn, Germany

Abstract: Single neurons interact with the neuronal network they are embedded in. Thus, the firing behavior of a single neuron can be modulated by the oscillatory activity of the Local Field Potential (LFP) of the surrounding neuronal network, a phenomenon described as phase locking. Methodological approaches to detect and quantify phase locking of a neuron's action potentials (spikes) to the raw or filtered LFP can yield false positive results due to the spectral properties of spikes extracted from the same LFP signal. Several recent studies have implemented preprocessing techniques to remove spikes before examination of spike-LFP synchronization in order to avoid false positive results induced by action potentials. In this study, we show that common techniques for removal of action potentials can have spurious effects on the detection of phase locking.

We studied the effects of four spike removal techniques: linear interpolation, mean spike removal, cubic spline interpolation and Bayesian spike removal. We applied each technique to extracellular microwire recordings obtained from epilepsy patients undergoing seizure monitoring prior to resective surgery. To test for false positive detections of phase locking we created phase-randomized surrogate signals from the original LFPs and used these in combination with the original spike trains. To scan for false negative effects, we used the surrogate LFP signals in combination with artificial spike trains designed to show a predefined amount of phase locking. Phase locking detection was implemented using phase extraction by Hilbert transformation and subsequent statistical testing by the Kuiper's test. We studied effects of spike removal on raw LFP signals as well as from different frequency ranges from the delta to the fast ripple band.

We analyzed recordings from four microwires in the human medial temporal lobe. Our results show that even for analyses in low frequency ranges, spike removal by both linear and cubic spline interpolation causes significantly high false positive and false negative effects on the phase locking detection, whereas mean spike and Bayesian spike removal have significant impact only on frequency ranges above 100 Hz.

Judging from our preliminary findings, we reason that spike removal can lead to wrong interpretation of phase-related metrics, particularly for high frequency bands such as ripple and fast ripple activity. Mean spike removal and Bayesian spike removal techniqes appear far more reliable than linear and cubic spline interpolation.

Title: Eye fixation-related potentials for natural event processing in a computer interaction

Authors: *F. COURTEMANCHE, P.-M. LÉGER, S. SÉNÉCAL, A. ORTIZ DE GUINEA, R. TITAH, M. FREDETTE, É. L. LEMOYNE;
HEC Montreal, Montreal, QC, Canada

Abstract: The eye-fixation related potential (EFRP) method allows the synchronization of eye tracking with electroencephalographic (EEG) recording to precisely capture individuals' neural activity at the exact time at which they start to cognitively process a natural stimulus while interacting with a computer (e.g., event on the screen). This method is well suited to register neural activity while individuals use a computer device in a multitasking environment. This method complements and addresses some of the shortcomings of the traditional Event Related Potential (ERP) method. For example, the traditional ERP can only stamp the time at which a stimulus is presented to an individual, not the time at which the individual cognitively processes it. An experiment was conducted with twenty-four healthy university students to demonstrate that the processing of the stimulus is phase-locked to the fixation rather than its presentation. During the experiment, participants were asked to read a business report with a computer screen while email pop-up notifications arrived on their screen. The participants then had to open (or not) the emails if they thought they were relevant for their report reading task.. EEG was measured during the task with 32-electrode array geodesic sensor net using Netstation acquisition software and EGI amplifiers. A Tobii X-60 eye tracker was used to record participants' eye movement patterns during the experiment. The Noldus Observer XT was used to synchronize the EEG and eye-tracking data by sending a TTL signal to the EGI amplifier and a keystroke signal to the Tobii Studio v 3.2. The results showed three distinct neural processes associated with a) the cognitive reaction to email pop-up notification (a P300 component), b) the cognitive processing of the email pop-up notification (a N400 component identified with the EFRP method), and c) the motor planning activity involved in opening or not the email (a BP component). Furthermore, post-hoc analyses showed the criticality of the EFRP method to isolate the neural activity associated with stimulus processing by illustrating that such activity cannot be obtained with the ERP method alone. The original and distinctive characteristic of this technique is that it allows, by using eye-tracking in conjunction with EEG, to stamp the exact time at which a particular natural stimulus is processed by an individual, rather than the time at which the stimulus is presented to this individual.

Title: Change in functional connectivity by continuous whisker stimulation correlates with decrease in LFP power correlation in the delta band

Authors: *H. LU[1], L. WANG[2], W. REA[2], E. A. STEIN[2], Y. YANG[2];
[1]Natl. Inst. On Drug Abuse, Baltimore, MD; [2]Natl. Inst. on Drug Abuse, Baltimore, MD

Abstract: Spontaneous fluctuations in the resting state fMRI time course exhibit structured spatial and temporal patterns. However, the underlying mechanisms of the fluctuations are still poorly understood. The goal of this study is to investigate how tasks modulate ongoing spontaneous fluctuations in resting state fMRI and electrophysiological signals. SD Rats (n=6) were scanned at a 9.4T scanner under two conditions: 1) continuous whisker stimulation (sinusoidal waveform; frequency: 2, 4 or 6 Hz; peak-to-peak amplitude: 4 mm); 2) resting state (no stimulation). fMRI time courses were low-pass filtered (< 0.1 Hz). Functional connectivity between bilateral whisker barrel cortex (WBC) was analyzed using cross-correlation. In comparison to the resting condition, continuous whisker stimulation decreased bilateral WBC functional connectivity only at 2Hz, but not at 4 or 6 Hz. In a separate experiment, epidural EEG recordings were performed from bilateral WBC, with visual cortex (VC) serving as a control site (n=10). Time-frequency analysis was conducted using Morlet wavelet transformation. Power time course correlations between recording sites were calculated. Whisker stimulation significantly augmented EEG power from alpha to gamma frequency range, but decreased power only in the delta band. Furthermore, for all frequencies (2, 4 or 6Hz) examined, whisker stimulation significantly decreased power correlations between bilateral WBC from beta to low gamma ranges. Notably, only with the stimulation frequency of 2 Hz did we observe a decrease in delta band power correlation between bilateral WBC. Finally, there was no significant change in any of the frequency bands between either side of WB and VC.
In summary, stimulating whiskers at 4 and 6 Hz changed bilateral WBC power correlation in high frequency LFP (beta to low gamma), but did not change WBC functional connectivity; however, stimulating whiskers at 2 Hz changed both low (<4 Hz) and high frequency LFP power correlations, and WBC functional connectivity was reduced. Our data support the hypothesis that ongoing spontaneous activity and task-evoked activity may reflect two at least partially separable processes which can be differentially registered by both the fMRI and the electrophysiological signals. More specifically, ongoing spontaneous activity seems to be registered in low frequency LFP (<4 Hz), stimulations that modulate LFP within this frequency window could modulate functional activity as revealed by fMRI; but modulating high frequency LFP signal has minimal effect on fMRI functional connectivity.

Title: P300- like event related potentials in rat brain have a latency between 650 and 850 msec

Authors: *W. D. KLIPEC[1], J. BOWDEN[2], L. PHILLIPS[2], R. LEWIS[2], T. GRAY[2], A. PAJSER[2];
[2]Psychology, [1]Drake Univ., Des Moines, IA

Abstract: The human P300 event-related potential (ERP) is a time-locked response to rare, response-relevant stimuli. Alterations in amplitude, latency and lateralization have been shown in early onset Alzheimer's disease and schizophrenia. Since rat models of these diseases have been developed, a reliable rat P300-like model would be a useful tool in studying both the etiology of these conditions and efficacy of treatment models. In our laboratory, we have reported robust P300-like ERPs to task relevant stimuli in freely behaving rats, but the latency and amplitude of these ERPs has been highly variable. With closely spaced events, the ERPs for the events may merge forming a compound ERP that makes reliable identification of the peak voltage difficult. Here, within a standard operant lever-pressing paradigm for food reinforcement, we have systematically manipulated the inter-event intervals both for a tone that predicts the click of a food delivery mechanism, and a different tone that predicts the insertion of the lever. By tracking the latency shifts in the ERP to the predictive stimulus and the ERP to the predicted event, we have been able to separate what appears to be late auditory ERPs at about 240-340 msec from much larger ERPs that are P300-like but reliably occur at latencies between 650-850 msec. The amplitude of these events is consistent with our earlier research that suggested these ERPs represent correlates of conditioned reinforcement. This rat P300-like model has significant potential as a research tool for investigating both Alzheimer's and schizophrenia using a rat model.

Title: Validation of a real-world multi-aspect integrated neuroimaging system

Authors: W. D. HAIRSTON[1], *T. J. DOTY[1], B. KELLIHAN[2], J. CANADY[2], K. W. WHITAKER[1], K. S. OIE[1], K. MCDOWELL[1];
[1]Translational Neurosci. Br., Army Res. Lab., Aberdeen Proving Ground, MD; [2]Intelligent Systems Dept., DCS Corp., Alexandria, VA

Abstract: The multi-aspect integrated neuroimaging system described here is a brand new, first-of-its-kind system designed to monitor changes in neurological, physiological, behavioral, and subjective experience in real-world environments. This project is the first attempt at simultaneous long-term monitoring and integration of all four aspects of human function outlined above, and includes four different devices that must work in concert to collect data in real-time. The system consists of a high density, wireless, dry electrode EEG cap to measure neurological output throughout a normal day; a bioharness worn around the chest for measuring heart rate variability and movement; a sensor worn on the wrist that measures skin conductance; and an Android-based portable electronic device (PED) carried by the participant which integrates wireless data from the other devices, displays scheduled inventories, and provides the participant with an
interaction panel to log relevant events throughout the day. By having all components synchronized with a PED, we are afforded the unique opportunity to integrate contextual information about real-world daily activities which is often lacking from previous studies. Namely, context is created 1) objectively from integrated physiological sensors (e.g. measuring cardiac and skin conductance fluctuations) and 2) subjectively from an event monitoring panel on the PED which the user interacts with at intervals throughout the data collection period. This robust collection of data comes, however, with the necessity of precise synchronization of equipment, and verification that the approach is not only comfortable but also non-intrusive for use within daily life.
Here we discuss the methods developed to validate the performance of the system and its ability

to be used within a standard office environment over the course of several complete work days. This is a critical step because, given the novelty of this approach within the neuroimaging field, no current guidelines exist for system evaluation. Examples include use of phantom devices for quantifying integration, analytical methods for evaluating system performance and stability of the components over time, and metrics for general comfort and usability, such as the Comfort Visual Analog Scale (VAS) and assessments of burden (from the Burden VAS). Taken together, we aim to establish feasibility of real-world neuroimaging through the approaches described here, which employ synchronized context monitoring while minimizing discomfort and burden on the user.

Title: Portable EEG device and mobile application for mTBI assessment

Authors: *K. S. HALE, M. JOHNSTON, B. D. WINSLOW;
Design Interactive, Inc., Oviedo, FL

Abstract: Electroencephalography (EEG) is a well-established non-invasive technique for neurological monitoring with high temporal resolution and relatively low cost. As such, EEG has proven to be a critical monitoring and diagnostic tool in the clinic. EEG is also a popular research tool among psychologists and neuroscientists for evaluating somatosensory responses to stimuli, error detection, and sleep monitoring, among other uses. An emerging role for EEG is a first-line measure or triage tool for brain injury or stroke in situations where access to high spatial resolution imaging technologies is not readily available. In the immediate post-injury phase several abnormal electrophysiological signatures are apparent in the EEG, including decreased delta and theta amplitudes, low coherence, and reduced asymmetry in eyes-closed recordings. Current approaches to treat sports or blast-related injuries consist of care center-based imaging and neurosurgical procedures when necessary. However, there are no devices available to support field triage of affected individuals and assess severity immediately following injury. Here we present miniaturized, wireless, high-performance EEG, which consists of the

integration of recording and transmission hardware within a small, lightweight form factor, with low power consumption. The device streams data to a mobile device, which allows for immediate, non-expert data visualization and interpretation. To aid users without significant EEG experience, software applications were developed to support placement, data interpretation and visualization. The montage application also features augmented reality sensor placement and an anatomical landmarking support tool to aid users without significant EEG experience. Following 5 minutes of eyes-closed recordings, the software detects the presence or absence and type of mTBI.

Title: Enhancements to a non-invasive system for high-throughput monitoring of mouse sleep and other behaviors

Authors: M. STRIZ[1], M. SETHI[1], T. ZHANG[2], H. L. CANTER[1], J. BRIGHAM[1], S. JOSHI[1], R. GOOCH[3], M. GOPALAIAHGARI[1], F. YAGHOUBI[4], K. D. DONOHUE[3], S. SUNDERAM[4], *B. F. O'HARA[2];
[1]Biol., [3]Electrical and Computer Engin., [4]Biomed. Engin., [2]Univ. of Kentucky, Lexington, KY

Abstract: Traditional methods of characterizing sleep and wake in rodents suffer from substantial limitations. EEG/EMG is invasive and time consuming, while wheel-running and other activity monitors do not distinguish sleep from low activity periods. We developed a noninvasive, high-throughput piezoelectric system that distinguishes sleep and wake in mice with high accuracy. A piezoelectric pad placed at the bottom of the mouse cage records gross body movements, while a computer classifier analyzes features of the signal and differentiates sleep from wake. Sleep signals are characterized by regular 3 Hz rhythms, as well as several other features, while wake signals exhibit variable amplitude and frequency. The classifier correlates 90-95% with EEG and human observation. This system has been used in a variety of studies, including genetic studies of sleep-related traits, and characterizing sleep in mouse models of traumatic brain injury, Alzheimer's disease and Parkinson's disease.
We are expanding the system to identify other mouse behaviors. We performed human

observation, as well as EEG and piezoelectric recordings, of C57BL/6J mice, the most common inbred strain used in biomedical research, and CFW mice, a common outbred strain. High correlation between all three methods in identifying sleep serves as a control to validate the effectiveness of human observation in identifying other behaviors. We then use human observation as a basis for identifying quiet wake, grooming, rearing, feeding, drinking, and locomotion. When these behaviors are identified, we isolate the piezoelectric signals from those time points and train the classifier to find features that reliably distinguish each behavioral domain.
Distinguishing these behaviors through the piezoelectric system would improve our phenotyping and behavioral assessments in a wide variety of projects where our system is being used_including the analysis of mouse models of traumatic brain injury, Alzheimer's Disease, Parkinson's Disease, and genetic studies designed to find genes and alleles that influence these behavioral traits.

Title: Validation of automated pruritus sensing in mice and rats

Authors: ***J. C. SKAHEN**, M. MARINO, S. MALKMUS, Y. SHTAERMAN, T. L. YAKSH; Anesthesia Res. Lab., UCSD Anesthesia Res. Lab., La Jolla, CA

Abstract: Pruritus, the sensation that leads to the desire to or act of scratching, is present in a diverse number of clinical settings. Currently, pruritus is addressed by a limited number of treatments and further elucidation of its mechanisms will have great clinical significance. This

work characterizes and validates a paw motion detector (PMD) automated system for mice and rats. By detection of the movement of a removable metal band affixed to the hind paw inside an electromagnetic (EM) field, the PMD allows for the rapid automated analysis of animal motion. An important issue relates to the validation of the automated scratch detection algorithm with the counting determined by the trained observer. Male C57 Bl6 mice and male Holtzman Sprague Dawley rats were fitted with a small metal hind paw band and adapted individually to an EM producing and detecting chamber. In mice and rats, ID (intradermal) injection of 48/80 in the dorsolateral aspect of the upper shoulder induced high frequency scratching at the injection site with the ipsilateral (banded) hind paw. This motion was recorded via the PMD system and video camera for analysis. Animal motion was analyzed for scratch counts using various machine detection algorithms that varied over the following parameters: Signal Smoothing, Amplitude, and Frequency of motion. Based on this process, algorithms which proved optimal for accurate signal detection from the machine were noted. In mice, the scratch counts after ID saline and 48-80 were 39 ± 3.59 and 258.8± 26.7, respectively (mean ± SEM). In rats the counts after ID saline and 48-80 were 55.7± 13.45 and 298.6 ± 77.61, respectively (mean ± SEM). Linear regression between the optimal algorithm for rat and mouse scratching and trained human observation were then produced. Following ID injection of 48/80, slopes of the regression relating human observer versus machine counts using the optimal algorithm were 1.022± 0.024 in the mouse and 1.009 ± 0.069 in the rat (mean ± SEM). In additional studies various pharmacology was characterized showing that 48/80 response was blocked by diphenhydramine whereas chloroquine was not. These results show the PMD permits an accurate automated assessment of pruritus.

Title: Development of an evaluation method that analyzed the motor performance among elderly people using handwriting features

Authors: *T. ISHIZAKI[1], K. TOKUTAKE[2], T. WATANABE[2], S. ARIOKA[2], E. TANAKA[2], T. ANME[2], H. KAWAGUCHI[3];

[1]TOYO UNIVERSITY, Oura-Gun Gunma, Japan; [2]Univ. of Tsukuba, Ibaraki, Japan; [3]Toyo Univ., Gunnma, Japan

Abstract: Elderly people show a gradual decrease in motor performance caused by the progressive loss of skeletal muscle strength and mass. Control of motor performance is important for the maintenance of physical and social health, namely, quality of life (QOL), in elderly people. Therefore, we aimed to establish an easy quantitative method to evaluate the motor performance of elderly people by analyzing their handwriting features through the use of a "digital pen." This device, which digitizes handwriting at a rate of 13 ms and has a spatial resolution of 0.3 mm, can be advantageously used in our evaluation method because it can acquire data from many users easily and simultaneously. In addition, we used surface electromyography (sEMG) to measure muscle activity. sEMG of the arm was performed similar to a blood pressure manometer. A total of approximately 300 elderly people from the Joso Project (Elderly People Health Empowerment Project in Joso City), which was performed in cooperation with Joso City, University of Tsukuba and Toyo University, participated in our study. The participants were required to use digital pens to complete a questionnaire on lifestyle, memory recall and drawing a wood. We analyzed several handwriting features, including writing speed and pressure. The handwriting data were compared with their physical and motor performance. As a preliminary study, four participants (two men, 55 and 83 years of age; two women, 55 and 87 years of age) completed the questionnaire using digital pens. We measured skeletal muscle mass and handgrip strength and conducted the chair-stand test in four participants. sEMG data obtained from each participant's dominant arm were based on the weight of water-filled PET bottles (0-2 L). We determined the correlations between handgrip strength and average writing speed, as well as the correlations between the chair-stand test results, average writing speed, and stroke rate. sEMG data revealed that the muscle activity of healthy individuals differed from that of individuals with sarcopenia syndrome. Thereafter, we will continue to analyze the data acquired from the Joso Project.
The protocols used in this study were approved by the Ethics Committee of University of Tsukuba. This study was partially supported by Inoue Enryo Memorial Foundation for Promoting Sciences of Toyo University.

Title: Assessment of central sensitization in chronic pain patients: The influence of crosstalk on reflex receptive field mapping

Authors: *M. B. JENSEN, J. BIURRUN MANRESA, O. K. ANDERSEN;
Aalborg Univ., Aalborg Ø, Denmark

Abstract: Recent studies indicate that evaluation of the human withdrawal reflex is useful for assessing central sensitization. Enlarged reflex receptive fields (RRF) have been detected in groups of chronic pain patients compared to control groups, most likely reflecting expansion of spinal neuronal receptive fields. The RRF of muscles in the lower extremities can be quantified by randomised, distributed electrical stimulation, typically on the sole of the foot. Each muscle or group of synergistic muscles has a unique cutaneous RRF where noxious stimulation may elicit a reflex in that specific muscle. Interestingly, the RRFs of the two antagonistic muscles tibialis anterior (TA) and soleus (SOL) exhibit substantial overlap, in contrast to what is predicted by the modular organization theory. Most likely, this observation reflects limited specificity of the single differential (SD) EMG recordings used to quantify the reflexes, meaning that crosstalk from relatively strong reflexes in TA dominates the EMG recorded over SOL.
To evaluate this assertion, this study mapped RRFs for both TA and SOL using three different approaches to detect reflexes; evaluation of SD EMG, evaluation of double differential (DD) EMG and a novel conduction velocity analysis (CVA) specifically developed to reject crosstalk during reflex detection (Jensen et al. 2013). Reflexes were elicited by five sweeps of noxious electrical stimulation of 10 sites on the sole of the foot of 17 chronic pain patients lying in supine position, a position rendering genuine reflex activity in SOL unlikely. The area of the RRF was quantified as the fraction of the foot where a reflex was elicited by at least 25% of the stimulations. Results are expressed as median (quartiles).
In 15 of the 17 subjects, reflexes were identified from the SD EMG recorded over SOL. Moreover, the RRF mappings for SOL based on evaluation of SD EMG resemble to a great extent the corresponding mappings for TA. The RRF area for SOL was 0.17(0.00,0.51) when derived from SD EMG, whereas DD EMG (0.00(0.00,0.06)) and CVA (0.00(0.00,0.00)) entailed significantly smaller and nearly non-existing RRF areas. A markedly smaller but significant reduction in RRF area was observed for TA when reflex detection was based on CVA, from 0.34(0.17,0.53) for SD EMG and 0.37(0.20,0.53) for DD EMG to 0.28(0.17,0.45) for CVA.
These results support the notion that crosstalk may significantly influence mappings of RRFs based on evaluation of SD EMG. However, this issue can readily be reduced by the use of DD EMG or CVA, both of which constitute valuable measures to deal with crosstalk and enable improved mapping of RRFs for specific muscles.

Title: Predicting mental health disorders based on the time intervals between strokes while writing numbers

Authors: *H. KAWAGUCHI, S. TAKISE;
Toyo Univ., Gunma, Japan

Abstract: The number of patients with mental health disorders has recently increased. Because the recurrence of mental health disorders in such patients is high, there is a social need for a method that predicts the onset of mental health disorders. Therefore, we investigated whether the Uchida-Kraepelin test, one of the tests to examine the character in stressful situations, could provide a method for predicting mental health disorders using the handwriting features of participants. We analyzed the participants' handwriting using a "digital pen," which can digitize handwriting at a rate of 13 ms and has a spatial resolution of 0.3 mm. During this test, participants were asked to perform two sets of single-digit additions for 15 min each (with a 5-min rest period between each set). A total of 201 students (who were initially aged 18-19 years) were recruited for a follow-up cohort study conducted over 3 years (once per year, in early April) and who voluntarily underwent the Uchida-Kraepelin test and answered a mental health questionnaire, General Health Questionnaire, 30 items (GHQ30). We analyzed the time intervals between the first and second stroke of a number (4, 5, and 7; mean time interval: t_1) and the time intervals between finishing the writing of a number and starting the writing of the next number (mean time interval: t_2). The ratio of the mean time interval (t_2/t_1) for people with mental health disorders was significantly higher than that of healthy individuals. In addition, a correlation was observed between the t_2/t_1 indicator and the anxiety and tension scores on GHQ30 ($p < 0.001$ for the first year, $p < 0.05$ for the second year). Furthermore, the dropout rate of the high-risk group (the group with $t_2/t_1 > 11$) was much higher than that of low-risk group (the group with $t_2/t_1 \leqq 11$; $p < 0.01$). These results suggest that it may be possible to predict mental health disorders using the t_2/t_1 indicator.
The protocols used in this study were approved by the Ethics Committee of Toyo University.

Title: A novel test of motor and other neurological dysfunctions in mice

Authors: ***A. M. BARTH**, I. MODY;
Neurol., UCLA Sch. of Med., Los Angeles, CA

Abstract: Like most human neurological disorders, corresponding mouse models present multiple deficiencies. Therefore, estimating disease progression or potential treatment effectiveness in such models necessitates the use of multiple time-consuming tests that usually require a large number of scarcely available genetically modified animals. To overcome this shortcoming, we wanted to develop a single, multipurpose test for functional evaluation of motor and other neurological deficits in mice.
Our approach extracts complex, 3-dimensional data from video recordings by a single camera. We investigated 3 groups of mice with various neurological deficits: 1) mice with unilateral stroke in the forelimb motor cortex; 2) mice injected with a moderate dose of ethanol (1.6 g/kg, i.p.); and 3) old (96-99 weeks of age) mice.
We show that post stroke recovery can be divided into separate stages based on strikingly different characteristics of motor function deficits deriving from compensatory mechanisms. We distinguished motor impairments with early-onset transient as well as gradually developing and persistent characteristics. We also identified motor impairments after stroke, which resemble the human motor neglect syndrome. Mice treated with a moderate dose of ethanol and old mice also showed characteristic motor and exploratory deficits.
Our novel experimental approach provides qualitatively sophisticated and complex information

about motor impairments and locomotor/exploratory activity. It should be useful for the detailed characterization of a broad range of human neurological disease models in mice, the more accurate assessment of disease progression, and treatment effectiveness.

Title: Biocompatibility analysis by histological techniques of nanostructured materials in the central nervous system

Authors: *P. R. ARTEAGA-LOPEZ[1], A. MORA LAZARINI[3], I. SANCHEZ-JERONIMO[2]; [1]Biol. of Reproduction, [2]Biol. Sci. and Hlth., Univ. Autonoma Metropolitana Iztapalapa, Mexico city, Mexico; [3]Nanomaterials, CINVESTAV, Mexico city, Mexico

Abstract: The innovation in the area of pharmacology are focusing the attention at novel innovative delivery systems and treatments based on nanotechnology devices that will improve the chemotherapeutics results and diminish the secondary effects. With the aim to improve this nanotechnology we evaluated the biocompatibility of the new devices in brain. We used rats as a model of study.
Adult intact male intact rats were used, then microinjected with nanostructured materials, as titanium dioxide bilaterally in the brain by stereotaxic method. There was no mortality in any rat during the treatment. Then the rat was perfused with PFA 4% and the brain extracted in cold conditions and stored in glucose/thymerosal solution 1% at 4oC for one week. The brain slices were obtained using a cryostat at -17oC, with a grossor thick of 8 um, then the brain were mounted in a microscope slide coated with poli-l-lisine (0.1%) and dehydrated with an alcohol series, followed by a specific stain process (nissl, hematoxiline-eosine and trypan blue). The microphotographies were taken with a light microscope (Olympus IX81) accopled with a digital camera. The biocompatibility analysis shown that the material microinjected in the brain, has not negative effects over the tissue and cell integrity because the histological analysis demonstrates that the membrane and nucleus are normal, the neurons and the membrane are intact. Those results confirm those reported previously in our laboratory. In conclusion the nanostructured titaniium dioxide used as a vector for the drug delivery is biocompatible with brain tissue and it suggest that this kind of nanomaterials are secure because it has no effect over the system.

Abstract: The electric properties of the extracellular medium are still subject to a controversy because of contradictory measurements. One possibility is that the use of metal electrodes as current sources in previous studies provides non-physiological results. We tested this possibility by performing impedance measurements in conditions as close as possible to physiological conditions. We generated single-cell local field potentials (LFP) by injecting subthreshold inputs in single neurons using patch-clamp recordings, combined with extracellular recordings with micropipettes. Various measurement configurations, such as current-source or voltage-source, provided contradictory results, either low-pass or high-pass filters. Although these results never showed resistive extracellular properties, their apparent contradictory character could prevent any conclusion about the exact nature of the extracellular and intracellular impedances. To clarify this, we developed a theoretical model based on Maxwell equations, which shows that all measurements can be explained if the extracellular medium is of diffusive type (Warburg impedance). This model predicts that the phase difference between intracellular and extracellular signals should provide a signature of the physical nature of the impedance, with 45 degrees phase

difference for diffusive type. Preliminary experiments show that indeed, the phase is centered around 45 degrees, therefore confirming the diffusive nature of the extracellular impedance. In a companion poster, we provide evidence for diffusive media from EEG and MEG measurements (Dehghani et al. - this conference). These findings have potentially important consequences for interpreting LFP measurements and source estimation such as CSD analysis.

Title: Computational model of a charge steering DBS electrode

Authors: *A. WILLSIE, A. D. DORVAL;
Biomed. Engin., Univ. of Utah, Salt Lake City, UT

Abstract: Deep Brain Stimulation (DBS) is used to alleviate some of the symptoms associated with neurodegenerative disorders. Targets for DBS are located deep in the brain, are typically small, making targeting difficult, and have unique 3D geometries. Clinical electrodes used for DBS are limited by their geometry, cylindrical with four ring contacts, to produce roughly spherical areas of activation. Targeting and target shape can limit the ability of the clinical electrode to deliver adequate stimulation while controlling the effects of charge spread outside targets, which may drive side effects. We introduce a computational model of a new electrode geometry with thousands of contacts, capable of charge steering. Modeling shows that the new electrode can deliver stimulation to the unique geometries of deep brain targets more completely than the clinical electrode. Additionally, displacements from optimal target placement, which directly impact the utility of the clinical device, are mediated by the charge steering ability of the new electrode geometry.

Title: The effects of realistic conductivity distribution and slice geometry on simulations of local field potentials and in Current Source Density analysis

Authors: *D. K. WOJCIK[1], T. B. NESS[3], C. H. CHINTALURI[2], J. POTWOROWSKI[2], H. GLABSKA[2], S. LESKI[2], G. T. EINEVOLL[3];
[2]Dept. of Neurophysiol., [1]Nencki Inst. of Exptl. Biol., Warszawa, Poland; [3]Dept. of Mathematical Sci. and Technol., Norwegian Univ. of Life Sci., Aas, Norway

Abstract: Multielectrode recordings of local field potentials (LFP) from brain slices are a standard research technique. To test different methods of LFP analysis we need to have realistic ground truth data which demands plausible models of neural activity and taking into account physical properties of the setup, tissue, and the electrodes. To decorrelate the electrode signals it is often useful to reconstruct the Current Source Density from the measured potentials (CSD). In CSD analysis one often assumes field propagation in isotropic and homogeneous tissue, which is not true in slice recordings.
We studied the effect of realistic conductivity profiles and the slice geometry on i) computation of LFP generated by cell populations embedded in slice, as would be measured on MEA, and ii) CSD reconstruction in the slice from such potentials.
First, we investigated how the use of increasingly detailed physical models of slice tissue affects the resulting model LFPs. We simulated Traub's model of thalamo-cortical loop (Traub et al. (2005)) in NEURON and the extracellular potentials in uniform, homogeneous medium were computed post-hoc from tracked trans-membrane currents. To verify the need for inclusion of experimental setup context we modeled the field in the tissue and saline using finite-element approach (FEM). The slice was placed in a saline solution, the cortical column was put inside the slice, and we computed the extracellular potentials it generated at the electrode plane underneath. We saw that the inclusion of slice setup noticeably modifies the observed activity as both the amplitude and shape of the potential profile were changed. However, inclusion of inhomogeneity

and anisotropy in the computations does not lead to substantial changes of the profile and amplitude. Indeed, inaccurate estimation of conductivity will in general introduce bigger errors than assuming homogeneous and isotropic tissue.
We also obtained an approximation to the potential computed at the electrode grid from the slice using the method of images (MOI). In computation of the LFP for the cases studied, the MOI approximation gives results very close to FEM model while being much more efficient computationally. To improve CSD estimation in the slice we included MOI model in the kernel CSD method. Testing the new kCSD variant on FEM model data we found that i) the reconstructed error is smaller when the correct slice thickness and the difference in conductivities (slice/saline) are taken into account, but the improvement is relatively minor, ii) the first two extra terms from the method of images are enough.

Title: Fornix deep brain stimulation induces functional activation in hippocampal circuitry

Authors: *E. K. ROSS[1,2], J. KIM[2], S. HAN[2], P. MIN[2], K. LEE[2,3];
[1]Neurosci., Mayo Clin. Col. of Med., Rochester, MN; [2]Neurosurg., [3]Physiol. and Biomed. Engin., Mayo Clin., Rochester, MN

Abstract: Deep brain stimulation (DBS) has emerged as a treatment for various neurologic and neuropsychiatric disorders, including Parkinson's disease, dystonia, depression, and obsessive-compulsive disorder (Lang et al., 1998). Though the mechanisms behind therapeutic benefit of stimulation-induced neuromodulation are not completely understood, it has been established that modification of brain function by DBS depends on targeting specific sites in the complex underlying neuronal circuitry (Lee et al., 2009). Alzheimer's Disease (AD), among many other forms of dementia, is characterized by progressive deterioration of memory and other cognitive functions (Querfurth et al., 2010). Recently, DBS has been applied to the Papez circuit to address the memory function associated with dementia (Laxton et al., 2010; Suthana et al., 2012). As part of the Papez circuit, the fornix is thought to play an integral role in declarative memory. DBS within the medial temporal lobe at the level of the fornix is a promising approach to addressing

memory deterioration associated with dimentia. In this study, we address functional connectivity of fornix stimulation, as measured by fMRI before and after chronic stimulation, in a DBS large animal model (pig) using the same stimulation parameters and electrode configuration currently applied in human patients. We conducted a preliminary study of DBS of the fornix and found activation in the hippocampus, entorhinal cortex, parahippocampal gyrus, substantia nigra, nucleus accumbens, and prefrontal cortex. In this study, we show that this activation is voltage-dependent. Finally, using FSCV we show that fornix DBS results in dopamine release in the nucleus accumbens (NAc), which implicates this circuitry in hippocampal-based declarative memory. In previous studies, structural MRI, and PET scan in early AD revealed hippocampal atrophy and cingulum bundle disruption was highly correlated with posterior hypometabolism, which is hallmark in AD (Villain et al., 2008). Sexton et al. reported that episodic memory was associated with hippocampal volume and mean diffusivity of cingulum and fornix (Sexton et al., 2010). Additionally, it has been reported that age-related decline in recall was specifically associated with degradation of fornix microstructure, consistent with the view that this tract is important for episodic memory (Metzler-Baddely et al., 2011). Taken together, these data support the idea that DBS within the medial temporal lobe at the level of the Papez circuit shows promise for memory enhancement.

Title: Simulation analysis of conduction block in unmyelinated axon after high-frequency electrical stimulation

Authors: *G. YANG[1,3], J. WANG[1], J. R. ROPPOLO[2], W. C. DE GROAT[2], C. TAI[1]; [2]Dept. of Pharmacol. and Chem. Biol., [1]Univ. of Pittsburgh, Pittsburgh, PA; [3]Dept. of Biomed. Engin., Beijing Jiaotong Univ., Beijing, China

Abstract: Nerve conduction block induced by high frequency (>5 kHz) electrical stimulation have many potential clinical applications. Although the original Hodgkin-Huxley model can successfully simulate the conduction block in unmyelinated axon during the stimulation, it failed

to simulate the conduction block during the period after the stimulation. In this study, the Hodgkin-Huxley model was modified to include an electrogenic sodium-potassium pump and successfully simulated the post-stimulation conduction block. Simulation analysis indicates that high frequency electrical stimulation causes continuous sodium influx and increases intra-axonal sodium concentration that can only recover slowly after the stimulation, causing conduction block during the post-stimulation period. The duration of the post-stimulation block is proportional to the duration and intensity of high frequency electrical stimulation. Understanding the mechanisms underlying high frequency block is important to further promote its clinical applications.

Title: Frequency scaling properties of EEG and MEG signals at high frequencies are consistent with diffusive electric properties of intracellular and extracellular media

Authors: *N. DEHGHANI[1,2], C. BEDARD[2], S. CASH[3], E. HALGREN[4], A. DESTEXHE[2]; [1]Wyss Inst., Harvard Univ., Boston, MA; [2]Lab. for Computat. Neuroscience. Unité de Neurosciences, Information & Complexité (UNIC), Ctr. Natl. de la Recherche Scientifique (CNRS), Gif-sur-yvette, France; [3]Dept. of Neurology, MGH, Harvard Med. School., Boston, MA; [4]Multimodal Imaging Lab, Dept. Radiology and Neurosciences, Univ. of Californica, San Diego (UCSD), La Jolla, CA

Abstract: Electro-encephalogram (EEG) and magneto-encephalogram (EEG) signals can be recorded simultaneously and provide two complementary signals of neuronal activity. It was shown previously that EEG and MEG signals display different frequency-scaling properties for low frequencies (Dehghani et al., JCNS 2010). Theoretical models show that if the extracellular medium is resistive, then the scaling exponent at low frequencies should be the same for EEG and MEG signals. Therefore, the different exponents observed constitute an indirect evidence for non-resistive extracellular properties. Here, we complement this study by providing a frequency-scaling analysis for high frequencies. We show theoretically that if the extracellular and intracellular media have diffusive electrical properties, then EEG and MEG signals should scale identically for high-frequencies (>20 Hz).Analysis of simultaneous EEG and MEG signals for 4 different subjects show that this is indeed the case, suggesting that diffusive properties are important. Diffusive extracellular media are also consistent with other measurements such as the frequency scaling of local-field potential (LFP) signals, or the transfer function between intracellular and extracellular potentials. In a companion poster (Bedard et al., this conference) we show that extracellular impedance measurements are indeed compatible with the paricipation of diffusive properties. We conclude that the diffusive properties of intracellular and extracellular media provide a framework that explains a large body of direct and indirect experimental measurements.

Title: Impact of surface charges on cellular mechanics in a uniform DC electric field - A model study

Authors: *H. YE;
Dept. of Biol., Chicago, IL

Abstract: Cells deform and migrate under electric field, partially mediated by the interactions between the field and the electric charges on the cell membrane. Two kinds of charges present on the cell membrane: the intrinsic charges carried by the charged proteins, and the free charges induced by the electric field. How do these surface charges involve in the biomechanics of the cells that contribute to the membrane deformation and migration of the cell? Using a simple spherical cell model, we computed the distribution of the electric fields, the induced surface charges, the forces and torques exerted on the cell. We found that the biomechanical roles of the two charge groups are different -while the induced charges could be involved in membrane deformation in the DC field, the intrinsic charges could contribute to cell migration. Shape deformation depends on the ratio between the conductivities of the medium and the cytoplasm (Figure 1). Translational force generated on the cell is proportional to the net intrinsic charges carried by the cell membrane (Figure 2). The calculated forces for deformation and migration are both quantitatively comparable to those reported in the literature. It is therefore possible to control cell mobility and deformation by manipulating different charge groups.

Title: EEG cortical patch sources and equivalent dipole source localization

Authors: *Z. AKALIN ACAR[1], S. MAKEIG[2];
[1]Inst. for Neural Computation, Univ. of California San Diego, LA JOLLA, CA; [2]Univ. of California San Diego, La Jolla, CA

Abstract: Accurate of EEG source localization requires a realistic electrical forward model of the subject's head based on a structural head model, and a realistic source model when solving the inverse problem. In linear source localization of EEG, the most commonly used anatomical constraint on source distribution is to restrict the dipoles to the cortical surface with fixed orientations perpendicular to the surface. The magnitudes are then allowed to change during a given experiment. This is based on the fact that the neuronal electric activity that can be measured outside the skull by EEG and MEG originates primarily from groups of neurons organized in macro-columns perpendicular to the surface of the cortex [1]. Taking this a step further, a physiologically relevant assumption is to construct the source space using “patches” that are tangential to the surface, based on the observation that metabolically active areas are closely related to active neuron groups. We have shown the use of patch-based electro-cortical source localization in our previous studies [2]. In this work, we present a comparison of dipolar and patch-based source models and investigate source localization errors when a simulated recording of a patch-based source is localized using a dipolar source.
We used a subject-specific four-layer realistic head model and simulated EEG for 8,000 locations on the subject’s cortical surface. The EEG scalp maps were calculated for three Gaussian-tapered patches with geodesic radii of 10 mm, 6 mm, and 3 mm. For each patch activity equivalent dipole source localization was performed using the same head model, a four-layer template MNI head model, and a spherical head model.
When the patch size was small the source can be better modeled as a point source, so the error magnitudes were lowest for 3 mm radius patches. For larger patches, the dipole was localized farther away, below the patch, so the localization errors increased. However, with the realistic head model, the maximum error was 2 mm. The maximum error for the MNI model was 8 mm, and the errors increased up to 2 cm for the spherical model. The mean orientation errors obtained

by 10 mm patches were 0.7 degrees using the realistic model and 6.7 degrees using the other head models. The errors for the equivalent dipoles fitted using the realistic model is below 2 mm, which suggests that a dipole source model is suitable for most purposes.

Title: Spatial and polarity precision of high-definition transcranial direct current stimulation (HD-tDCS)

Authors: M. ALAM, *M. BIKSON, D. TRUONG;
Dept of Biomed. Engin., City Col. of New York, NEW YORK, NY

Abstract: Transcranial Direct Current Stimulation (tDCS) is a non-invasive neuromodulation technique that applies low amplitude current via electrodes placed on the scalp. Rather than directly eliciting a neuronal response, tDCS is believed to modulate excitability - encouraging or suppressing activity in regions of the brain depending on the polarity of stimulation. Studies have explored a wide range of clinical applications including neuropathic pain, motor rehabilitation, speech rehabilitation, working memory as well as others. In these cases, the particular application of tDCS is determined by the electrode configuration and intensity of stimulation. Relatively large (5x7 cm) conventional sponge pads in a 1 anode and 1 cathode (1x1) montage have been the standard configuration used in past studies. In recent years the 4x1 High-Definition (HD) tDCS ring configuration has been explored as an alternative montage with improved spatial control. The extent of this control was explored through MRI-derived Finite Element (FE) models.

Finite element models were created to analyze the cortical electric field generated during tDCS. High resolution MRIs were segmented into seven tissue/material masks of varying conductivities through a combination of automated and manual tools. Computer generated models of electrodes, gel, and/or sponge pads were incorporated into the segmentation. Volume meshes were generated, boundary conditions were applied, and the Laplace equation ($\nabla\cdot(\sigma\nabla V)= 0$) was solved. The resulting cortical electric field was interpreted as a correlate for stimulation and modulation.
In comparison to conventional sponge pads 4x1 HD-tDCS has a number of advantages, the most pronounced being focality. Studies with a mechanistic, anatomical, emphasis could be better served by this more precise method of stimulation that could avoid potentially confounding brain regions. Still, conventional pad stimulation has an extensive history of use. Clinicians may feel comfortable relying on the established safety record of conventional pads, but modeling results suggest much more spatial and polarity control utilizing the 4x1 configuration. This degree of control can be leveraged in cases where an additional safety factor would be warranted, particularly in susceptible populations (e.g. implants or skull defects). As more is understood about the brain and how different regions may affect clinical outcomes, 4x1 HD-tDCS can provide both the spatial and polarity precision needed to target these regions.

Title: Fast and reliable estimation of non-Gaussian stimulus receptive fields using large-margin classification

Authors: *A. F. MEYER[1], J.-P. DIEPENBROCK[2], F. OHL[2], J. ANEMÜLLER[1];
[1]Physics, Carl Von Ossietzky Univ. Oldenburg, Oldenburg, Germany; [2]Leibniz Inst. for Neurobio., Magdeburg, Germany

Abstract: The receptive field (RF) represents a classic approach to the characterization of sensory neurons through a linear filter. The underlying neuronal model consists of a linear non-linear cascade model that drives a spike-generating Poisson process [Chichilnisky 2001]. When computed with stimuli that are non-white or non-Gaussian, in particular natural stimuli, standard

RF estimation methods like the spike-triggered average (STA) and variations thereof have been shown to result in biased estimates of the true receptive field.
Recently developed RF estimation methods include semi-parametric information theoretic approaches that in theory allow for unbiased RF estimates independent of stimulus statistics and neural response nonlinearity [Sharpee et al. 2004]. However, numerical optimization of the underlying non-convex objective functions is non-trivial in practice. It results in comparably high variance of obtained RF estimates, in particular when available data is of limited length.
The approach pursued here assumes the well-known neuron model of a weighted linear integrator with a noisy threshold operation, which together determine the spike/non-spike response. In stimulus input space, a hyperplane defined by linear filter and threshold value optimally separates spike-eliciting stimulus examples from non-spike-eliciting ones.
We propose to estimate this optimal hyperplane using a modified largin-margin classifier and show that this is equivalent to estimating the neuron's linear receptive field. In contrast to STA-based estimators, the approach does not make any assumptions regarding multivariate stimulus distribution or correlation structure of the stimulus ensemble. In contrast to information theoretic approaches, optimization is performed on a well-behaved convex goal function. The resulting method bears qualitative similarities to maximization of mutual information between stimulus and response while maintaining the advantage of convex optimization.
Using simulated responses, we demonstrate that the proposed approach is robust to highly non-Gaussian stimulus ensembles. Findings are verified by estimation of spectro-temporal receptive fields (STRFs) for the inferior colliculus of mongolian gerbils, recorded in response to auditory stimuli. In the large data regime, the presented approach performs equal to unbiased information-theoretic estimators. With limited amounts of data, it exhibits significantly smaller variance of the obtained RF estimates. The method may permit more accurate investigation of neural effects such as adaptation that occur on smaller time scales than common RF estimators require to converge.

Abstract: One of the simplest nervous systems in nature - that of the hermaphrodite of the nematode *Caenorhabditis elegans* - still evades our complete understanding. Despite being one of the five best characterized model organisms with all of its 302 neurons and almost its entire connectome precisely mapped, there is only sparse knowledge on how its nervous system codes for its rich behavioral repertoire. The European ***Si elegans*** project aims at unravelling *C. elegans*‘ nervous system function by emulating it with 302 parallelly interconnected field-programmable gate array (FPGA) neurons and by embodying this hardware nervous system with a biophysically accurate soft-body representation in a virtual behavioral arena. In a closed-feedback loop, any sensory experience of the virtual nematode in its virtual environment will be processed by sensory and subsequently interconnected neurons to result in motor commands at neuromuscular junctions at the hardware-software interface to actuate virtual muscles of the virtual nematode. The postural change in the virtual world will lead to a new sensory experience, thereby altering the set of virtual stimuli to be processed by the hardware nervous system and thus closing the loop. We will present the overall concepts, first implementation steps and our envisioned reach-out strategies to involve the neuroscience community at large in an open-source and peer-contribution spirit. For further information and recent news please visit www.si-elegans.eu.

Title: Analytical conditions for the entrainment of basal ganglia structures by their exogenous inputs

Authors: *A. CHAILLET;
L2S - Supélec, Gif Sur Yvette, France

Abstract: Due to the nonlinear nature of the dynamics involved, the oscillations generated in a neuronal population may occur at a different frequency from the stimulus that generated it. An illustrative example of this fact is the Wilson & Cowan model, consisting of the coupling between two neuronal populations involving inhibitory and excitatory neuron models: depending on its parameters, this model may for instance exhibit sustained oscillations in response to a constant stimulus.
A tool developed in the control theory community offers a systematic way to guarantee that a nonlinear dynamical system can be entrained by its periodic input, meaning that it eventually tends to a rhythmic behavior at the input's frequency. This tool is known as contraction, convergence, or incremental stability and constitutes a noteworthy way to check whether a

network of neuronal populations will be entrained by its input, or rather exhibit endogenous frequencies. Several techniques can be used to establish this feature in practice; in particular, we have recently introduced a Ratzumikhin-type condition to ensure incremental stability in presence of delays (Chaillet et al. 2013).
Here, we show how this theoretical framework can help in analyzing the basal ganglia oscillations in Parkinson's disease (PD). Several works have studied the possible pacemaker role played by the interaction between the subthalamic nucleus (STN) and the global pallidus pars externa (GPe) in the generation of the beta-band oscillations characterizing PD. Some of these works rely on a delayed version of the Wilson & Cowan model (Nevado-Holgado et al. 2010, Pasillas-Lépine 2012, Pavlides et al. 2012, Haidar et al. 2013). An alternative hypothesis suggests that these pathological beta-oscillations may be endogenously generated by the striatum and then propagate to the basal ganglia network by an entrainment mechanism (McCarthy et al. 2011). The analysis we conduct here provides easily checkable conditions on the interconnection weights between the individual populations and the slope of their activation functions for the STN-GPe network to be incrementally stable, in which case it may indeed be entrained by a striatum endogenous beta-oscillation.

Title: A neural coding scheme to allow global workspace functionality

Authors: *K. J. HAYWORTH;
Howard Hughes Med. Inst., Ashburn, VA

Abstract: Two basic operations performed in a computer are copying information from one register to another and comparing two registers for equality. These operations underlie the computer's ability to create and manipulate structured representations. Models of the human cognitive architecture (e.g. SOAR, ACT-R, GWT) posit that the brain must also be capable of these two operations -positing a global workspace of buffers among which copies and comparisons can be performed. Progress has been made in explaining how such buffers might be implemented in the brain. For example, the visual hierarchy ends in several cortical buffers

representing an object's shape, color, and motion as rate-coded firing patterns. However, there is little understanding of how the contents of these buffers are copied or compared. In simple stimulus-response tasks such copying and comparison may be unnecessary, but when modeling even mildly more complicated tasks such operations have proved indispensable as discussions of the "neural binding problem" make clear (Malsburg 1999). I will present a neural model, the Dynamically Partitionable AutoAssociative Network (DPAAN), for how such operations might be performed. The key to this model is the realization that the brain's coding strategy cannot be similar to that which a computer uses (i.e. a unique pattern of active bits designating each symbol in the computer's vocabulary). Such an engineered solution relies on one-to-one wiring which is not biologically plausible. Instead, the DPAAN model posits that each symbol is actually coded differently in each of the brain's buffers, but that each of these different codings is related by each being a particular piece of the same "global" attractor state. In the DPAAN model, a set of switchable synapses connect the brain's buffers and switching these on effectively merges all buffers into one global autoassociative network which can be trained to have a set of stable states -each one representing one symbol in the brain's vocabulary. Switching off these connections reduces the global network to a set of independent buffers with, crucially, each still retaining the full complement of trained stable states. Copying information from buffer A to buffer B simply entails switching on the synapses projecting from A to B. Comparing the informational contents of A and B requires determining if the firing patterns in the two are part of the same global attractor state. Simulations will be presented demonstrating how this neural coding strategy can be used to perform visual attribute binding and rule-based operations, and how a DPAAN can be used as a neural implementation of ACT-R's global workspace.

Title: Modeling hierarchical visual computation with the Matlab environment for deep architecture learning (MEDAL)

Authors: *D. E. STANSBURY[1], J. L. GALLANT[2];
[1]Univ. of California, Berkeley, Oakland, CA; [2]Univ. of California, Berkeley, Berkeley, CA

Abstract: Current computational models of neural processing account for many of the properties exhibited by neurons in peripheral sensory areas, but they have had less success in later stages of the perceptual hierarchy. The anatomical organization of the brain suggests that these later stages of processing can be modeled as a transformation of sensory inputs across a series of hierarchically-organized, nonlinear computations. A modeling approach that reflects this organization might provide a powerful tool for modeling intermediate stages of processing. Recent advances in machine learning have produced learning algorithms and model architectures that model data through multiple nonlinear layers. These methods, known as deep architecture learning (DAL), offer the neuroscience community a promising approach for improving models of neural computation. To facilitate the application of DAL methods for computational neuroscience, we have developed the Matlab® Environment for Deep Architecture Learning (MEDAL). The MEDAL software suite compiles many state-of-the-art DAL algorithms into an object-oriented framework that is easy to use. The MEDAL suite provides many routines for stimulus preprocessing, a vast array of model architectures, and a variety of model visualization tools appropriate for neuroscience applications. We demonstrate the functionality of the MEDAL software suite by modeling neurons in both the feline and primate visual systems. We find that initializing model weights using unsupervised learning greatly improves model accuracy when training data is limited. We also find that submodules available in the MEDAL suite can account for simple and complex cell behavior in V1. Finally, we find that deep model architectures provide more accurate models of intermediate stages of visual processing (V2 and V4) than can be obtained using shallow computational models commonly used in the field.

Title: A NetLogo model of the Notch regulatory network in the determination of developmental patterning

Authors: R. HIMMELWRIGHT[1], J. PFAFFMANN[2], *E. R. REYNOLDS[1];
[1]Program in Neurosci., [2]Computer Sci., Lafayette Col., Easton, PA

Abstract: The *Notch* (N) signaling pathway is involved in cell fate decision and developmental patterning in diverse organisms. We have developed an Agent-Based model of this pathway as characterized in the early *Drosophila* embryo that allows for a representation of individual molecules, their movement and their interactions within a modeling environment. We are using the model to investigate how specific molecular components that stabilize fate at the cellular level also are involved the formation of pattern in the larger group of cells. Currently our model represents many of the major molecular components of the pathway and allows us to control the levels of these components, their transition from one state to another and their movement from the nucleus to the cell membrane and back. Most steps introduce randomness into the system using probabilities of events rather sequential direct implementation.

A data logging mechanism captures an integer count of cells with a neuronal fate (as defined as a lack of *N* product) at each time step and stores them to a text file as a number sequence that preserves cell position, allowing data to be analyzed both quantitatively and spatially. Using a plot of neuron count vs. time of either single run or aggregate data, a linear regression can be applied to different regions of the graph to track data trends of the model run. Regression analysis of the peak and trough data characterizes the shape of the oscillations, while the intercept from the general regression gives a reasonable approximation of where the system is stabilizing. To quantitate pattern, we use a modification of Hamming distance that measures amount of dis-similarity between successive runs at successive spatial positions within the model.

With a wide set of initial parameters, our current model can accurately reproduce the rosette pattern of neurons and skin cells in the system through oscillations in cell fate that settle into the final fate pattern. Our first experiments define the role of specific molecular events in formation of this stable pattern. We have explored the roles of initial transcriptional rates, processing of *Dl*, processing of *N* during and after cleavage, as well *N* regulation of its own transcription and that of *Dl*. In general, results indicate that initial transcription rate can be varied and a stable pattern is still obtained. However, *Dl* processing, autoregulation of *N* transcription, and the timing of *N* cleavage with transport to the nucleus do affect the model's ability to obtain a stable and correct pattern of fate determination.

Title: Machine intelligence and learning in avionic systems

Authors: *H. C. YUAN;
Raytheon, El Segundo, CA

Abstract: Airborne avionic systems employ sensors, such as radar and infrared devices, which receive electromagnetic and optical signals. These analog signals are processed through amplification, detection, filtering and demodulation, then the signals are sampled into digital data streams and flow into a high speed digital processor. Modern airborne digital processors are programmed in high level languages with algorithms processing digital data to make real time decisions. The digital processor is the "brain" of these avionic systems, making decisions, controlling all the functions of the systems, and the algorithms implemented in the processor comprise a "machine intelligence and learning" system.
The aim of machine intelligence and learning in such systems is to supply "situational awareness" information to the avionics operator. To provide this "situational awareness", the data and information from these sensors is processed so that many decisions can be made in fractions of seconds. The operator of these systems can respond and make other decisions according to the processed information.
Research in machine intelligence, as illustrated by the research of Eliezer Yudkowsky (Cognitive Biases Potentially Affecting Judgment of Global Risk - 2008; Levels of Organization in General Intelligence - 2007), has been evolving with increasingly complex models of the world at a global level and individual or macro systems at the organizational level. In avionic systems, machine intelligence and learning models have become more sophisticated and complex with the increases in memory capacity and speed of modern digital processors, and with the application of parallel processing architectures. Airborne avionic learning systems also employ fuzzy logic intelligence models in their algorithms. The fuzzy logic models add a dimension to "situational awareness" by handling sensor data or information that is in conflict with current data, is unknown or inconsistent with current information. Fuzzy logic also adds dimension by managing sensor data according to membership functions for intentional or pertinent information vs. unintentional (random) or confusing information.
This poster presents an overview of how fuzzy logic models are applied as machine intelligence to airborne avionic systems and explores how these models can be applied to research in neuroscience.

Abstract: Maze learning has been used as a measure of spatial intelligence for decades. The Hebb-Williams maze, a type of visuo-spatial task, consist of twelve standardized problems that vary based on difficulty level, as well as the type of learning and memory needed to correctly solve the maze. These mazes have been used to examine spatial learning abilities across a wide range of species, including rats, cats, rabbits, ferrets, mice, monkeys, and even humans. Research has demonstrated that human performance on a virtual Hebb-Williams maze is statistical similar to problem solving skills employed by mice (Shore et al. 2001). More recently a study demonstrated that performance on a virtual Hebb-Williams (HW) maze by individuals affected by Fragile X Syndrome was similar to animal models of the disorder using a physical version of the HW mazes (McLeod et al. 2009). However it is unclear whether different virtual environments will affect human performance on this maze task and therefore influence the ability to translate the results generated between humans and animal models. Our work examines the performance of children (ages 8-12) and adults (ages 18-22) on a virtual Hebb-Williams maze task utilizing different virtual environments. Our study examines the influence of different graphical representations of the HW mazes on performance in a virtual environment in comparison to C57BL/6J mice completing a physical version of the HW mazes. Our data suggest that the virtual environment may influence performance efficiency on this task and therefore our ability to translate findings between species.

Title: SCRalyze - a toolbox for inferring sympathetic arousal from physiological recordings

Authors: *D. R. BACH[1,2], R. J. DOLAN[2], K. J. FRISTON[2];
[1]Zurich Univ. Hosp. For Psychiatry, Zurich, Switzerland; [2]Wellcome Trust Ctr. for Neuroimaging, Univ. Col. London, London, United Kingdom

Abstract: Observed animal or human behaviour is often used to operationalize central - psychological or neural - states. Here, we propose to formalize operational definitions as explicit causal models. These can be used to infer hidden states. When probabilistic models are used, this approach can increase precision in inferring central states, compared to operational approaches. A common human example is inference on sympathetic arousal (SA) from observed skin conductance responses (SCR). Here, we propose and validate a model-based approach to SCR by formalising a peripheral system that can be approximated as linear and time-invariant, and creating various neural models for different experimental situations. We show that for several classes of experiments, SA estimates yield a more precise prediction of the (known) central process than raw SCR values. A Matlab-based software suite - SCRalyze - implements this approach and provides for extension to other physiological, or behavioural, measures. We propose that causal models are a powerful tool to infer central processes from observed behaviour.

Title: Multi-scale community organization of the human structural connectome and its relationship with resting-state functional connectivity

Authors: *R. F. BETZEL[1,2], A. GRIFFA[3,4], A. AVENA-KOENIGSBERGER[1,2], J. GOÑI[1], J.-P. THIRAN[3,4], P. HAGMANN[3,4], O. SPORNS[1,2];

Abstract: The human connectome is defined as the human brain's full set of neural elements and their anatomical connections and it has been extensively mapped and widely studied at different spatial resolutions over the past several years, particularly in the cerebral cortex. A principal finding is that the cortical connectome can be decomposed into network communities of densely interconnected brain regions. Such structural communities, in turn, are often conceptualized as modules underlying different aspects of brain function. The process of community detection, however, may be subject to methodological limitations. For example, numerous studies attempting to infer the connectome's community structure have used a modularity measure that is prone to fail when communities range over many different sizes or when communities are forming a nested hierarchy. Also, these studies relied on the intuition that community structure is best defined in terms of a network's static topology as opposed to a definition that makes reference to dynamic processes unfolding within the structural network. In the present study we used the partition stability framework, which defines communities in terms of a Markov process (random walk), to infer the connectome's community structure at multiple dynamical scales. The connectome's multi-scale community structure was compared to observed resting-state functional connectivity, which is defined by the magnitude of statistical dependence between blood oxygen-level dependent (BOLD) signals recorded from different brain regions. Resting state functional connectivity is also believed to reflect communication and integration of information between brain regions. This comparison revealed communities across a broad range of dynamical scales that bore close resemblance to observed patterns of functional connectivity. This result suggests a relationship between communities in structural networks, models of communication processes, and brain function. It further suggests that communication in the brain is not limited to a single characteristic temporal scale, leading us to posit a heuristic for scale-selective communication in the cerebral cortex.

Title: Precision matters in gpu based eeg/meg forward solution

Authors: *N. B. BANGERA, J. D. LEWINE;
MIND Res. Network, Albuquerque, NM

Abstract: Forward solution is a critical component in source localizations methods utilized for finding epileptogenic foci. Based on the complexity of the model used, the calculation of the forward solution can get very computationally intensive. The processing power of the graphical processing units (GPU) on commercially available video cards can now be harnessed very easily using parallel programming platforms such as NVIDIA CUDA to solve such computationally intensive methods in a fraction of time required by the CPU. Our previous work translated algorithms from the CPU to the GPU domain using CUDA for computing both the Spherical and Boundary Element Model (BEM) based forward solution for EEG and MEG. The same inputs will output the same results up to a given floating point precision on the CPU and GPU. Hence differences between the CPU and GPU calculated forward solution need to be interpreted carefully. Also, older generations of GPU do not support calculations in double precision. In this study, we investigate the impact of floating point precision and verify whether single precision or double precision calculations are adequate for GPU based E/MEG forward solution for the spherical and BEM model.

For the comparison between the CPU and GPU solution, electric field and magnetic field at 64 and 306 sensors respectively was calculated on the CPU in double precision for known dipole locations in two model types (spherical and BEM) and used as the gold standard reference solution. The difference between the GPU and CPU solution was measured using L2 norm. In addition, we verified the GPU results using a beamformer based inverse solution. Firstly, we simulated EEG and MEG data for dipoles at random locations using a CPU solution in double precision. The inverse solution was then calculated using the leadfields calculated using the GPU in both single and double precision and tested against the actual dipole locations. Thus, the GPU forward solution is tested against the CPU solution using both a direct comparison as well an inverse based approach.

The single precision GPU solution for EEG was found to be accurate for both the spherical and BEM models. However, single precision GPU solution for MEG led to incorrect localization of dipole locations in both models. MEG forward solution calculated in double precision on the GPU resulted in accurate source localizations. Our results thus show that CUDA based GPU solution for MEG requires hardware with support for double precision computation whereas EEG solution can be safely computed on single precision NVIDIA GPU.

Title: What is all the noise about in interval timing?

Authors: *P. G. LYNN[1], D. NOVO[2], S. OPRISAN[2], C. BUHUSI[3];
[2]Physics and Astronomy, [1]Col. of Charleston, Charleston, SC; [3]Psychology, Utah State Univ., Logan, UT

Abstract: The perception and use of durations in the seconds-to-hours range (interval timing) is essential for survival and adaptation, and is critical for fundamental cognitive processes like decision making, rate calculation, and planning of action. The classic interval timing paradigm is the fixed-interval (FI) procedure in which a subject's behavior is reinforced for the first response (e.g., lever press) made after a pre-programmed interval has elapsed since the previous reinforcement. Subjects trained on the FI procedure typically start responding after a fixed proportion of the interval has elapsed despite the absence of any external time cues. A widely-used discrete-trial variant of FI procedure is the peak-interval (PI) procedure. In the PI procedure, a stimulus such as a tone or light is turned on to signal the beginning of the to-be-timed interval and in a proportion of trials the subject's first response after the criterion time is reinforced. In the remainder of the trials, known as probe trials, no reinforcement is given and the stimulus remains on for about three times the criterion time. The mean response rate over a very large number of trials has a Gaussian shape whose peak measures the accuracy of criterion time estimation and the spread of the timing function measures its precision.
In addition of being accurate, interval timing is scale invariant: the time-estimation errors are proportional to the estimated duration. The origin and mechanisms of this fundamental property are unknown. We discuss the computational properties of a circuit consisting of a large number

of (input) neural oscillators projecting on a small number of (output) coincidence detector neurons, which allows time to be coded by the pattern of coincidental activation of its inputs. We showed analytically and checked numerically that time-scale invariance emerges from the neural noise. In particular, we found that errors or noise during storing or retrieving information regarding the memorized criterion time produce symmetric, Gaussian-like output whose width increases linearly with the criterion time. In contrast, frequency variability produces an asymmetric, long-tailed Gaussian-like output, that also obeys scale invariant property. In this architecture, time-scale invariance depends neither on the details of the input population, nor on the distribution probability of noise.

Title: Estimating a network structure that underlies partially observed neuronal signals

Authors: *M. KOMATSU[1,3], J. NAMIKAWA[2], Z. C. CHAO[1], Y. NAGASAKA[1], N. FUJII[1], K. NAKAMURA[3], J. TANI[4];
[1]Lab. Adaptive Intelligence, [2]Lab. Behavior and Dynamic Cognition, RIKEN Brain Sci. Inst., Wako-Shi, Japan; [3]Tokyo Inst. of Technol., Yokohama, Japan; [4]KAIST, Daejeon, Korea, Republic of

Abstract: Many existing studies have proposed various methods to quantify the interaction of neuronal signals. These methods were developed to evaluate the interaction among recorded signals in an isolated network. However, in order to obtain a more complete picture of information processing in the brain, we need to incorporate the influence from unobserved dynamics. In this study, therefore, we focused on revealing these unobserved dynamics, as well as causal interactions among observed neuronal signals. At the beginning, we proposed a variant of recurrent network model that consists of observable and unobservable units. The observable units represent recorded neuronal signals and the unobservable units are introduced to represent unobserved dynamics underlying the recorded signals. Connective weights, which indicate intensities of interaction between the units, could be estimated by an iterative learning with a maximum likelihood method. Then, we applied the model to 32- and 64- channels

electrocorticograms (ECoG) recorded from cortical surface of monkeys A and K, respectively. For each monkey, estimations of connective weights were conducted with four different data sets, and five initial learning states were tested on each data set. First, we explored connective weights between observable units representing ECoG by using a cluster analysis with Ward's method. In both monkeys, we obtained the consistent results: by introducing 5 unobservable units, observable units were divided into clusters, which were corresponded to anatomical cortical regions plausibly. Second, we investigated connective weights of unobservable units. We also found that majority of networks (12/20 of monkey A, and 18/20 of K) obtained from iterative learning were consistent. That means the unobservable units involved in the networks have similar influence on observable units. The results suggest that our presented network model is capable of revealing structure underlying multi-channel signals obtained from the brain.

Title: An efficient finite difference approach to solving the time-fractional diffusion equation

Authors: *N. BHATTACHARYA, G. A. SILVA;
Dept. of Bioengineering, UCSD, La Jolla, CA

Abstract: In recent decades, fractional differential equations (FDEs) have been used to model complex transport phenomena, including instances of non-classical diffusion, which experimental evidence and computer simulations suggest may occur in many biological contexts, such as white matter fiber tracts, dendrites, cell cytoplasm, and in the neuromuscular junction. Finding tractable analytical solutions to FDEs is difficult and in many cases not possible, and therefore the development of stable and accurate numerical methods is vital. In trying to apply existing computational methods for solving the time-fractional diffusion equation, we found that there were tradeoffs between accuracy, stability, and complexity. We discuss the development of an efficient, 2nd order accurate, broadly stable numerical method for solving the two-dimensional time-fractional diffusion equation. We accomplish this by using the implicit Crank-Nicholson finite difference scheme to increase the stability regime of the method. In addition, we use an operator-splitting method and application of adaptive memory to reduce the complexity

and computational time needed to solve the time-fractional diffusion equation. Development of this numerical method now enables us to more efficiently use fractional diffusion to accurately model complex cases of diffusion in biology.

Title: The investigation of reduction processing in FSCV using PPV

Authors: *D. KIM[1], Y. OH[1], H. SHIN[1], I. KIM[1], C. KIMBLE[2], K. BENNET[3], K. LEE[4], D. JANG[1];
[1]Dept. of Biomed. Engin., Hanyang Univ., Seoul, Korea, Republic of; [2]Div. of Engin., [3]Dept. of Neurologic Surgery and Div. of Engin., [4]Dept. of Neurologic Surgery, Mayo Clin., Rochester, MN

Abstract: Background subtraction fast-scan cyclic voltammetry (FSCV) based on carbon fiber microelectrodes (CFM) has been recently utilized for the detection of neurotransmitter release in in-vivo brain due to sub-second temporal resolution. Compared to oxidation peak of dopamine (DA) in FSCV, reduction peak was few shad on the light in analytical studies although it has been used as one of representative feature of DA. The reduction peak of DA in FSCV always showed less than oxidation peak. There are several reasons for this phenomenon, but, as far as our knowledge, there are few systemic studies for the reduction processing in FSCV. Paired-Pulse Voltammetry (PPV) was suggested in order to minimize the confounding factors such as pH changes and transient effects at the CFM surface in our previous study. The waveforms are paired in doublets, two identical waveforms (“pulses”), separated in time by an arbitrary but short interval at the holding potential. When the voltammogram for one the pulses comprising a doublet is subtracted for the voltammogram for the other pulse, the effects of pH change, for example, can be eliminated. Although PPV was proposed for differentiating complex analytes, in our thought, it could be appropriately employed for the examination of reduction processing of DA in electrochemistry. In this study, the reduction processing of DA in FSCV was investigated in depth with PPV by changing gap time and with various experiment conditions such as pH changing, scan rate, and peak potential of waveform. The results of our study demonstrated that the reduction may occur between scans at a holding potential and the reduction processing may

be rate-limited by the concentration of H+ at the surface of CFM. In addition, using this reduction processing mechanism, we could improve PPV waveform and might allow for more precise determinations of kinetics of neurotransmitter in in-vivo conditions.

Title: Finite elements ear model for sound transmission simulation

Authors: *Y. PARK, D.-P. JANG, I. KIM;
Dept. of Biomed. Engin., Hanyang Univ., 222 Wangsimni-Ro, Seongdong-Gu, Seoul, Korea, Republic of

Abstract: Introduction : The sound is transmitted through the pinna, ear canal, eardrum, ossicles, and cochlea. The ear structures also transform the sound signal by acting as a filter. The power and phase of output sound signal, transmitted by the ear structures, is different with input sound signal. Because of this, the dynamic model that mimics the shape and physical characteristics of the ear is important for knowing the signal that is transmitted to auditory nerve. The purpose of this study is to make a finite element ear model and simulate the sound transmission from the ear canal to the stapes footplate.
Methods : The geometry of the ear model was based on the micro computed tomography images. The material properties of various parts of ear were obtained from the previous studies of middle ear model, and modified to calibrate the vibration modes of tympanic membrane and stapes footplate similarly with experimental data. The finite element ear model was developed using COMSOL multiphysics. We solved the acoustic-structure interaction problem using a frequency domain solver of COMSOL multiphysics.
Results : The vibration modes of tympanic membrane and stapes footplate are similar with experimental data. The displacements of tympanic membrane and stapes footplate maintain almost constant up to 1 kHz and have peak values at around 1 kHz. At the frequencies above 1

kHz, the displacement decreased with an increased in the frequency. Figure 1 shows the vibration modes of tympanic membrane and stapes footplate.

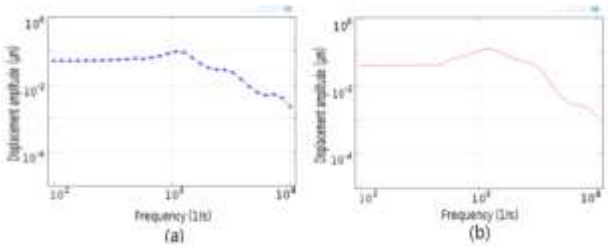

Figure 1 The vibration modes of tympanic membrane(a) and stapes footplate(b) at 80 dBSPL

Abstract: Many medical therapies revolve around the concept that an external stimulus (electrical, chemical, mechanical, etc) can bring a diseased biological system back into its normal state (e.g. cardioversion, defibrillation, deep brain stimulation). Unfortunately, many of these therapies have the potential to be just as detrimental as they are beneficial if too much of the stimulus is given. In this study, we seek to find the optimal electrical stimulation necessary to elicit a change in state within a neuronal model while minimizing the energy usage using a gradient-based algorithm.
In this paper, we show 1) the benefits of using a gradient-based algorithm to solve these optimization problems compared to more traditional techniques, 2) the phase-dependent nature of locally optimal waveforms, 3) the convergence of this algorithm in models with oscillatory states towards multiple locally optimal solutions and 4) the change in resonance properties of the

optimal waveform when presented with neurons of different latent excitability. This last finding has implications on what models are chosen when finding optimality in different neuronal systems. While an integrate-and-fire model may be suitable for finding optimality in a low-excitability neuron (e.g. motor neurons), they fail to showcase the resonance that is present in high-excitability neurons (e.g. epileptic neurons). Thus, in choosing an integrate-an-fire model, there is potential for missing out on finding more optimal resonating solutions.
We also demonstrate that with the gradient-based algorithm, one can find optimal solutions given only partially defined terminal conditions. Thus instead of specifying complete terminal conditions, we can define only the terminal conditions that are experimentally relevant, removing artificial constraints from the optimization algorithm.

Title: Detecting different states of migraineurs based on resting eeg and ssvep habituation

Authors: *L.-W. KO[1], K.-L. LAI[2], S.-B. HUANG[1], M.-H. YANG[1], C.-T. LIN[1], S.-J. WANG[2]; [1]Brain Res. Ctr., Natl. Chiao Tung Univ., Hsinchu, Taiwan; [2]Neurolog. Inst., Taipei, Taiwan

Abstract: Migraine is a neurological disorder in the world. Approximately one billion people (15% of the total population) are suffering from this disorder. Migraine characterized by episodes of severe headache, which is often pulsatile in nature and unilateral in location. Attacks are usually associated with nausea, vomiting, and sensitivity to light, sound, or movement. From clinical point of view, an altered state of brain excitability may be the fundamental pathomechanism, which render *migraine* patients more susceptible to external stimuli. The posterior mean dominant frequency was significant reduced during the attacks, with a significant

increase of interhemispheric asymmetry. These studies evidence the migraine as a neural system dysfunction. Other electrophysiological studies have addressed the issue on the brain excitability in patients with migraine, including somatosensory, visual and motor cortices by somatosensory evoked potential (SEP) and visual evoked potential (VEP). These studies show that two general phenomena exist in migraine patients: first one is central hyper excitability in SEP studies and the other is habituation defect (dis-habituation) in VEP studies, which make them more prone to headache development. This study is related to VEP and resting state of patients. The main goal of this study is to observe the habituation and resting power changes of the migraine patients and aim to find an indicator to classify the patients into three different states of migraine (i.e. inter-ictal, pre-ictal, and ictal).One hundred and ten patients in different migraine states and 9 control subjects performed the steady-state visual evoked potential experiment with EEG recordings including a series of visual stimulation at various flashing frequencies, in which 13 Hz flashing was repeated twice. The states of migraine were determined according to headache diaries. Patients who did not have migraine attack within a period of 36 hours before and after the EEG recording were classified as inter-ictal state. Those with migraine attack within 36 hours before and after the recording were classified as post-ictal and pre-ictal states. The ictal state denoted those who had migraine attack upon examination.
In this study, we applied closed-eye resting EEG and fluctuant habituation pattern to classify different migraine states. The results indicated that the resting EEG and the change of habituation can be used a reliable neurophysiological hallmark of migraine. It provides the clinicians the EEG predictors of migraine attack period. Then, this can assisted physicians to select appropriate medicine to reduce the suffering of patients.

Title: A computable database for neural model generation

Authors: *F. ROTHGANGER, D. TRUMBO, C. WARRENDER, B. AIMONE;
Sandia Natl. Labs., Albuquerque, NM

Abstract: We are developing a software package called "Neurons to Algorithms" (N2A). The scientific purpose of N2A is to facilitate biologically realistic network model development by 1) compiling (and referencing) neural data from many users and sources, 2) representing this data in a computable format, and 3) automating the process of simulation and analysis on large-scale computers.

Many have endeavored to create a definitive central repository of neural and/or biological information. All of these collections contain descriptive data, and in theory any of them could be amenable to structural analysis. However, it is rare to find a collection that can translate directly to a simulation. That is the guiding principle of this tool. It represents both structural relationships and the explicit quantitative behavior of each part. All math is in the form of simple declarative equations that describe the system dynamics.

For a given simulation, the user selects a subset of parts from the database, and specifies the quantity and spatial arrangement of each one. N2A generates the full network and sends it to a simulator such as Xyce or Neuron. It then monitors the progress of the simulation and collects the results.

The tool has been designed to keep both private models and community-shared models, and to easily move between the two. Our vision is that this community database will enable the generation and sharing of high fidelity model parts across laboratories. Where possible, N2A will interface directly with other types of repositories to avoid duplication of effort.

We will demonstrate the N2A platform using a model of the hippocampus (Aimone et al, 2009).
